Abstract

Human activities are changing ecosystems at an unprecedented rate, yet large-scale studies into how local human impacts alter natural systems and interact with other aspects of global change are still lacking. Here we provide empirical evidence that local human impacts fundamentally alter relationships between ecological communities and environmental drivers. Using tropical coral reefs as a study system, we investigated the influence of contrasting levels of local human impact using a spatially extensive dataset spanning 62 outer reefs around inhabited Pacific islands. We tested how local human impacts (low *versus* high determined using a threshold of 25 people km^{-2} reef) affected benthic community (i) structure, and (ii) relationships with environmental predictors using pre-defined models and model selection tools. Data on reef depth, benthic assemblages, and herbivorous fish communities were collected from field surveys. Additional data on thermal stress, storm exposure, and market gravity (a function of human population size and reef accessibility) were extracted from public repositories. Findings revealed that reefs subject to high local human impact were characterised by relatively more turf algae (>10% higher mean absolute coverage) and lower live coral cover (9% less mean absolute coverage) than reefs subject to low local human impact, but had similar macroalgal cover and coral morphological composition. Models based on spatio-physical predictors were significantly more accurate in explaining the variation of benthic assemblages at sites with low (mean adjusted-R^2 = 0.35) rather than high local human impact, where relationships became much weaker (mean adjusted-R^2 = 0.10). Model selection procedures also identified a distinct shift in the relative importance of different herbivorous fish functional groups in explaining benthic communities depending on the local human impact level. These results demonstrate that local human impacts alter natural systems and indicate that projecting climate change impacts may be particularly challenging at reefs close to higher human populations, where dependency and pressure on ecosystem services is highest.

1   Introduction

Humans have become a dominant force of planetary change (Steffen et al., 2007). Ecosystems worldwide are being fundamentally altered by climate change impacts against a diverse backdrop of local anthropogenic stressors. Our ability to reliably predict the future configuration of affected ecosystems requires a thorough understanding of interactions between these different stressor types (Williams et al., 2019). Increasing evidence indicates that ecosystems are being reorganised, or homogenised, into stress-tolerant or opportunistic communities, leading to novel systems that differ from their previous state in terms of their dominant constituents (Graham et al., 2014; Morse et al., 2014). Quantifying ecological reorganisation over broad scales remains challenging due to coarse taxonomic resolution inherent to large datasets that are necessary to address this topic. Nonetheless, this phenomenon may significantly alter a system's relationship with various environmental and climate change-related drivers (Côté and Darling, 2010; Williams et al., 2015a). Understanding what role local human impacts play in driving ecological reorganisation and changing a system's relationship with its biophysical environment is thus pivotal to improving predictive models and informing local management (Robinson et al., 2018; Jouffray et al., 2019; Henderson et al., 2020).

Inherent high biodiversity and the presence of multiple stressors acting at local and global scales make tropical coral reefs a unique system to examine how local human impacts drive ecological states (Hoegh-Guldberg et al., 2007; Ban et al., 2014; Norström et al., 2016; Darling et al., 2019). Locally, rapidly expanding coastal development, sewage input, and agricultural practices are reducing water quality, whilst the modernisation of fishing gear and expedited market access are facilitating overexploitation of coastal fisheries resources (Fabricius et al., 2005; Brewer et al., 2012; Hamilton et al., 2012). Globally, the intensity and frequency of thermal anomalies, unusual weather patterns, and destructive storm events are increasing (Gattuso et al., 2015; van Hooidonk et al., 2016; IPCC, 2019), and recovery windows between stress events are narrowing (Riegl et al., 2013; Hughes et al., 2018). The productivity and provision of ecosystem services (e.g. Woodhead et al., 2019) of coral reef benthic communities differ depending on their composition (Ferrario et al., 2014; Rogers et al., 2018), underlining the importance of quantifying how communities are affected by global change. The widespread negative effects of climate change-related stressors are relatively well-understood. However, despite more than half the world's coral reefs being located within 30 minutes travel time from human populations (Maire et al., 2016), the role of local stressors remains somewhat contested. These local stressors can range greatly in their intensity depending on inherent factors such as human population density and the level of exploitation, such as reliance on marine resources.

Higher human population densities have been linked to reductions in reef fish biomass and coral cover, and to increases in fleshy (turf and macro-) algal cover (Sandin et al., 2008; Williams et al., 2015b; Heenan et al., 2016; Smith et al., 2016). However, coarse taxonomic resolution (inherent to large-scale datasets) can lead to the conclusion that there is no link between local stressors and reef condition (e.g. Bruno and Valdivia, 2016). This may be a particular issue in regions such as the tropical Pacific where species diversity is exceptionally high and fleshy macroalgae,

frequently stated as principal alternative organisms on degraded reefs, do not play such a dominant role in benthic dynamics compared, for instance, to the Caribbean region (Roff and Mumby, 2012). Furthermore, reefs are increasingly existing in a partially degraded condition between distinct regimes (Mumby, 2017), likely having undergone ecological homogenisation resulting from the non-random removal of species with particular traits in response to environmental factors (McWilliam et al., 2020). In this case, coral cover can remain moderate but comprises a less diverse community of stress-tolerant and opportunistic types (Côté and Darling, 2010; van Woesik et al., 2011; Riegl et al., 2013). Ecological homogenisation is visible across reef habitat types, with inshore reefs that are naturally exposed to a more challenging environment (e.g. in terms of light, temperature, and sediment input) favouring a smaller species pool of stress-resistant corals compared to nearby outer reef habitats (Rogers, 1990; Browne et al., 2013; Williams et al., 2013; Schoepf et al., 2015; Morgan et al., 2016).

A recent study demonstrated that whilst sea surface temperature (SST), chlorophyll concentration, and wave energy have strong power in predicting benthic assemblages at remote reefs, this predictive power is lost or the relationships fundamentally altered at reefs closer to human populations (Williams et al., 2015a). Considering the dominant role of humans in shaping ecosystems, factors associated with local anthropogenic impacts may have overtaken biophysical drivers in structuring these altered reefs. It has also been postulated that reorganisation towards a stress-tolerant coral community could increase resilience to climate change, assuming co-tolerance between local and climate change-related stressors (Côté and Darling, 2010), in line with the concept of 'intrinsic resistance' (Darling and Côté, 2018). Indeed, coral richness does not translate into higher resilience to disturbances (Zhang et al., 2014). Better understanding and accounting for the role that local human impacts play in shaping benthic communities and their relationships with environmental drivers is important for developing theories, designing experiments, setting baselines, informing management, as well as optimising large-scale spatial predictive models for coral reef futures.

Here, we investigate how local human impacts affect coral reef benthic communities in the tropical Pacific. We start by classifying 62 island sites into two levels of local human impact (low *versus* high) using a set threshold of human population density informed by previous work (i.e. D'agata et al., 2014). We then ask whether the level of local human impact influences benthic community structure or the relationship between benthic community structure and spatio-physical explanatory drivers. Lastly, we examine the relative roles of ten biophysical parameters as drivers of benthic community structure under low *versus* high local human impacts. We hypothesised that spatio-physical drivers would be more related to benthic community structure on reefs exposed to low local human impacts compared to those with high local human impacts, where we expect human-associated factors to have become more dominant. This approach allowed us to develop on the findings of Williams et al. (2015a) by testing whether decoupling between reefs and biophysical drivers in the presence of humans was also detectable between different levels of local human impact.

2   Material and methods

2.1   Study area and sampling design

This study intended to build on work from Williams et al. (2015a) by assessing in more detail how local population density, rather than human presence/absence, potentially decouples the relationship between reef benthos and larger-scale environmental drivers. To do so, we utilised a large-scale dataset that is unique in having both site-level ecological (fish and benthic) and socio-economic data (in particular human density per reef area at the site level), which is missing from other datasets that rely on global socioeconomic estimates for human population density, or in some cases district-level surveys. Fish and benthic communities at 62 reefs within 17 different Pacific Island countries and territories were surveyed once between 2003–2008 (see Supplementary Figure 1 for map) as part of the Pacific Regional Oceanic and Coastal Fisheries Development Programme (PROCFish/C/CoFish) under the auspices of the Pacific Community. Importantly, all reefs were in close vicinity to, and used by, coastal human communities across a large range of intensities (e.g. relative human density ranged from 1.3–1705 humans km^{-2} reef). For site disturbance history, sampling dates and detailed sampling methodology, refer to Supplementary Table 1 and Pinca et al. (2010). Though it is important to acknowledge that the sampling program was not originally designed in a way to address macroecological questions or aggregate beyond the state/territory level, we did our best to account for the shortcomings in the design by including additional information such as observer bias (see section 2.3 for details on environmental parameters included). Furthermore, while data may not be representative of the current-day scenario, it is the trends that are important for this study. Accordingly, we are confident that despite some inevitable compromising, this gave us the best possible dataset to look at the effects of site-specific human density.

2.2   Field surveys

Underwater surveys covered outer (fore-) reefs, with on average nine (n = 3–47) joint fish-benthic 50 m transects measured at each site. Transect data were pooled within each site. Reef fish communities were measured using the variable distance-sampling underwater visual census method along transects (described in Labrosse et al., 2002). Data on abundance and size were recorded to species-level for herbivorous fish. Counts were converted to biomass (g m^{-2}) from established length-weight relationships (Kulbicki et al., 2005). Benthic cover data was obtained using the medium-scale approach described by Clua et al., (2006). This method is based on a semi-quantitative description of ten 25 m^2 (5 x 5 m) quadrats laid down on each side of the 50 m transect (i.e. 20 replicate quadrats / 500 m^2 per transect). Surveyors first recorded abiotic and live coral substrates, i.e. sand, rubble, rocky slab, boulders, and hard coral - live, bleached, and long dead, with live coral divided into broad morphologies (e.g. branching, encrusting, massive). Each component was quickly estimated using a semi-quantitative scale ranging from 0 to 100% per quadrat, in units of 5%. Secondly, benthic groups (e.g. macroalgae – inclusive of calcified and fleshy types, turf algae, crustose coralline algae [CCA], sponges, cyanobacteria) growing over abiotic substrate such as long dead coral were recorded using the same semi-quantitative scale (Table 1).

241 Fishing grounds were initially delineated from information given by local fishers and
242 quantified from satellite interpretations (similar to methods in Close and Hall, 2006;
243 Léopold et al., 2014). Total reef area (km^2) within each fishing ground was then
244 derived from reef areas quantified by the Millennium Coral Reef Mapping Project
245 from satellite images (Andréfouët et al., 2006). Socioeconomic assessments
246 determined total population within communities with access to the fishing ground,
247 allowing subsequent calculation of human population relative to reef area (referred to
248 as 'relative human density'). Finfish landings for each site, determined from
249 interviews with fishers, were extrapolated to total finfish catch per year per reef area
250 ('relative fishing pressure') (see Pinca et al., 2010).

252 **Table 1** Benthic variables included in the models and their ranges.

Variable	Description	Range (%)
live hard coral	mean cover (%) of live hard coral	6.1–65.1
dead hard coral	mean cover (%) of dead hard coral; including rubble, boulders, and pavement. Dead hard coral may also include biotic groups (i.e. growing over the dead coral), which are further classified as additional categories below*	5.5–61.2
branching morphologies	proportion (%) of branching coral morphologies within live hard coral community	0.1–85.6
encrusting morphologies	proportion (%) of encrusting coral morphologies within live hard coral community	2.8–72.9
massive morphologies	proportion (%) of massive coral morphologies within live hard coral community	0.1–60.6
CCA	mean cover (%) of crustose coralline algae	0.2–43.5
macroalgae	mean cover (%) of macroalgae; inclusive of calcified and fleshy types	0.0–31.2
turf algae	mean cover (%) of turf algae	0.0–45.6

255 *not all categories are mutually exclusive – abiotic (e.g. dead coral, sand) and live
256 coral substrates were recorded up to 100%, and biotic cover (e.g. algal groups) was
257 recorded separately up to 100% (i.e. sum of substrate and biotic cover ≠100%).

2.3 Data analyses

2.3.1 Response variables

263 As response variables, we selected the main benthic groups (i.e. those with a mean
264 composition >10% of benthic community): dead coral (incorporating long dead coral,

265 rubble, boulders, and pavement), live hard coral, and algal groups (differentiating turf
266 algae, macroalgae, and CCA). We also assessed the proportional representation
267 (within the live hard coral community) of the three most commonly observed
268 morphological groups: branching, encrusting and massive morphologies. Pairwise
269 relationship tests (*corvif* function – Zuur et al., 2009) established no collinearity
270 among the response variables (correlation; $R^2 < 0.5$). Table 1 provides an overview
271 of the benthic variables and their ranges.

2.3.2 Model predictors

274 We had to make a feasible choice of how to determine low *versus* high impact sites.
275 Rather than choosing a completely arbitrary threshold, we selected one that was
276 informed by previous findings by D'agata et al., (2014) – using boosted regression
277 trees for the same dataset, the authors identified 25 people km^{-2} reef to be the
278 threshold after which taxonomic diversity of parrotfishes significantly declined. We
279 then ran a sensitivity analysis to demonstrate how robust our findings were (see
280 section 2.3.4). To compare reefs exposed to different disturbance regimes, we thus
281 categorised all sites into those subject to low (i.e. < 25 people km^{-2} reef; n = 29) and
282 high (i.e. > 25 people km^{-2} reef; n = 33) local human impact. Relative human density
283 correlates with relative exploitation – i.e. relative human density was collinear ($R^2 =$
284 0.8) with fishing pressure (tonnes fish km^{-2} reef $year^{-1}$; Table 2). This threshold was
285 also a median point and allowed similar sample sizes in each impact level (see
286 Supplementary Figure 2). Relative human density also showed weak positive
287 correlation with market gravity – an index combining the population size of nearby
288 human settlements and their accessibility to reefs (Cinner and Maire, 2018; Cinner et
289 al., 2018). However, we decided to base our study on relative human density as we
290 had unique site-level data and we see this metric to be more directly linked to
291 benthic communities in terms of human density-dependent sewage and agricultural
292 run-off in addition to subsistence and artisanal fishing.

294 The selected biophysical predictors included a variety of factors that were either
295 collected during field surveys or extracted from public data repositories (Table 2).
296 Due to inherent differences in coral reefs across latitudinal scales (e.g. Hughes et al.,
297 1999; Harriott and Banks, 2002), latitude was represented by degree distance from
298 the equator without differentiating between north and south (0–23.9°). Degree
299 heating weeks (DHW) data were extracted from the NOAA Coral Reef Thermal
300 Anomaly Database (CoRTAD version 4 - Casey et al., 2012)). Storm exposure was
301 quantified from the NOAA IBTrACS-WMO data (Knapp et al., 2010a, 2010b) within
302 ArcMAP 10.4 (ESRI, 2011), where the number of storms (categories 1–5 on the
303 Saffir-Simpson Hurricane Scale) passing within a 50 km radius of each site
304 (Behrmann projection) was extracted. Storm exposure and DHW data were confined
305 to 12 years prior to each respective site's survey date based on the premise that
306 remote reefs can recover from acute disturbances within this timeframe (Sheppard et
307 al., 2008; Gilmour et al., 2013). Reef depth, estimated during field surveys, was
308 averaged over all transects at each site. Island relief refers to each site's
309 geomorphology, and was classified into three categories: atoll, low-lying island, and
310 high island based on available information (see Supplementary Table 1 for
311 references), and authors' knowledge. Island relief was included as a predictor due to
312 its known influence on coral reef benthic and fish communities (Donaldson, 2002;
313 Houk et al., 2015). Herbivorous fish from selected families (e.g. excluding

314 herbivorous damselfish) encountered during visual surveys were classified into
315 functional groups according to Heenan et al. (2016) (see Supplementary Table 2).
316 Biomasses (g m^{-2}) of the following functional groups were then incorporated as
317 predictors: browsers, grazers, detritivores, scrapers and small excavators, and large
318 excavators and bioeroders. Market gravity (Cinner and Maire, 2018) was extracted
319 for each site in QGIS (QGIS Development Team, 2019) and was incorporated as a
320 continuous predictor.
321
322 Prior to model fitting, paired plots were assessed for collinearity between model
323 terms. Strong collinearity ($R^2 > -0.9$) between latitude and DHW precluded their joint
324 inclusion in subsequent models, and consequently latitude was selected because of
325 its complete reef-specific dataset (DHW data limited to n = 55 sites). Multi-collinearity
326 was also then tested using the generalised variance inflation factor (*GVIF*) function
327 (*car* package - Fox and Weisberg, 2019) where values >3 suggest collinearity – as a
328 result longitude was excluded from all models and the joint inclusion of browsers and
329 scrapers was prohibited (i.e. individual best-fit models were constrained to contain
330 only one or the other).
331

2.3.3 Statistical models

333 All statistical analyses were performed in R version 3.6.1 (R Development Core
334 Team, 2019). Differences in benthic community structure between reefs exposed to
335 low *versus* high local human impact level were tested using *t*-tests with appropriate
336 variance structures depending on homogeneity of variance test outcomes. Due to
337 surveyor discrepancies in recording turf algal cover, we created a random effect
338 (*bias_score*) to be incorporated within turf algae models (see Supplementary Figure
339 3 for details). No surveyor-related discrepancies were evident for other benthic
340 groups (see Supplementary Figure 3). To test how turf algal cover differed across
341 the two local human impact levels we thus used a linear mixed effects model
342 incorporating *bias_score* as a random effect. All hereon described models were run
343 separately for sites predetermined to be exposed to either low or high local human
344 impacts to explicitly test for decoupling of abiotic and biotic predictors under different
345 disturbance regimes.
346
347 To test whether the level of local human impact influences the relationship between
348 benthic community structure and spatio-physical explanatory drivers, we developed
349 a 'spatio-physical' model (i.e. focusing on spatial and physical predictors only) that
350 included storm exposure, reef depth, latitude, and island relief. To account for non-
351 linear relationships between response variables and predictors, we applied
352 generalised additive mixed effects models (GAMM) using the (Wood and Scheipl,
353 2014) and *lme4* packages. To account for possible spatial autocorrelation, ten
354 unique island clusters (*cluster*) were identified and incorporated into models as a
355 random effect (for details see Supplementary Figure 4). For turf algae models,
356 *bias_score* was additionally included as a random effect. To avoid overfitting, the
357 number of knots within models was limited to four. We retained the adjusted-R^2 (Adj-
358 R^2) values from the model output to quantify each model's explanatory power. Adj-R^2
359 values for each response variable were then compared (by paired *t*-tests) to test
360 overall differences in model performance in explaining benthic community structure
361 under the two local human impact levels.
362

8

363 **Table 2** Predictor descriptions and ranges at outer reefs. [a] predictor incorporated in
364 'spatio-physical' models; [b] predictor used in model selection procedures. For sources
365 of data, see main text.
366

Predictor	Description	Range
reef depth [a,b]	mean depth (m) of transects	3.9–10.5
degree heating weeks (DHW)	measure of cumulative thermal stress – sum of previous 12 weeks where thermal stress anomaly ≥ 1°C; value averaged over 12 years preceding survey; negatively collinear (R^2 = -0.9) with latitude; only available for n = 55 sites	0.6–3.5
latitude [a,b]	degrees (°) distance from equator (absolute value). Negatively collinear (R^2 = -0.9) with DHW	0.0–23.9
longitude	degrees (°) longitude on continuous scale (i.e. -175 counted as 185), included to account for distance from the Coral Triangle biodiversity hotspot	134.3–214.2 (i.e. -145.8)
storm exposure [a,b]	total number of storms (cat. 1 to 5 on the Saffir-Simpson Hurricane Scale) passing within 50 km of site within previous 12 years	0–14
relief [a,b]	3 classifications: 1 = atoll; 2 = low-lying island; 3 = high island	
browser biomass [b]	biomass (g m^{-2}) of browsers	0.1–58.5
detritivore biomass [b]	biomass (g m^{-2}) of detritivores	0.5–62.8
excavator biomass [b]	biomass (g m^{-2}) of large excavators and bioeroders	0.0–369.1
grazer biomass [b]	biomass (g m^{-2}) of grazers	1.1–161.0
scraper biomass [b]	biomass (g m^{-2}) of scrapers and small excavators	1.9–134.3
relative human density	number of people within communities of the primary/customary resource users (living adjacent to/accessing fishing grounds within the reef area) related to total reef area (people km^{-2} reef), positively collinear (R^2 = 0.7) with relative fishing pressure. Used to determine local human impact level	1.3–1705
relative fishing pressure	annual reef finfish catch (tonnes) km^{-2} reef year^{-1}; positively collinear (R^2 = 0.8) with relative human density	0.1–78.2

market gravity [b]	index that combines human population size and reef accessibility	0–1140

367

368 Lastly, to examine the relative roles of ten biophysical parameters as predictors of
369 benthic community structure under low versus high local human impacts, we applied
370 model selection techniques using the *MuMIn* package (Barton, 2016). From an initial
371 model containing ten biophysical predictors (i.e. those included in the 'spatio-
372 physical model' as well as biomass of herbivorous fish functional groups, and market
373 gravity – see Table 2), the dredge function was used to run all possible predictor
374 combinations and rank models from best to worst based on Akaike weight. The
375 function also returns a value between 0 and 1 for each predictor that reflects its
376 relative importance (RI), representing the total Akaike weight of all models containing
377 that predictor (i.e. higher values correspond to greater RI). Output models were
378 restricted to comprising a maximum of four predictors. One sample (Niue) was
379 removed from the model selection procedure due to a lack of data for market gravity
380 (i.e. n = 61). Model selection was run separately for sites with low and high levels of
381 local human impact, and all models incorporated the *uGamm* wrapper function to
382 allow the inclusion of random effects consistent with 'spatio-physical' model
383 constructions. To assess incongruities between benthic communities exposed to
384 different local human impact levels, we retained the 'best-fit' model structures (i.e. all
385 predictors included in models with Akaike weight >0.05) for each benthic response
386 variable, as well as the RI of individual predictors.

387

388 **2.3.4 Assumptions and sensitivity tests**
389 All response variables were logit-transformed (appropriate for percentage data -
390 Warton and Hui, 2011) using the *car* package, following adjustment using each
391 respective variable's minimum value >0. All model predictors were standardised (z-
392 scores) to allow comparisons between predictors with largely varying effect sizes
393 and numeric values (Zuur et al., 2009). Model residuals were checked for the
394 violation of model assumptions using the *gam.check* function (see Supplementary
395 Figure 5). As part of a sensitivity analysis, 'spatio-physical' models were additionally
396 run using ± 5 and ± 10 humans km^{-2} reef as a threshold from which to categorise
397 'low' and 'high' impact sites, with consistent outcomes observed (see Supplementary
398 Table 3). Furthermore, we repeated the same for a range of thresholds based on
399 human density relative to outer reef area (as opposed to full reef area), again with
400 consistent outcomes observed (see Supplementary Table 4).

401

402

403 **3   Results**
404 **3.1   Benthic assemblages under contrasting local human impacts**
405 Benthic communities subject to high local human impact were associated with lower
406 live hard coral cover (-9.2% mean absolute coverage; t-test: p = 0.002; Figure 1A).
407 However, the relative contribution of different coral morphologies within the live hard
408 coral community did not differ significantly with local human impact level (Figure 1B).
409 The only algal group that differed significantly depending on the local impact level
410 was turf algae, which was higher under high local human impact (+10.7% mean
411 absolute coverage; linear mixed effects model: p = 0.015; Figure 1C).

412
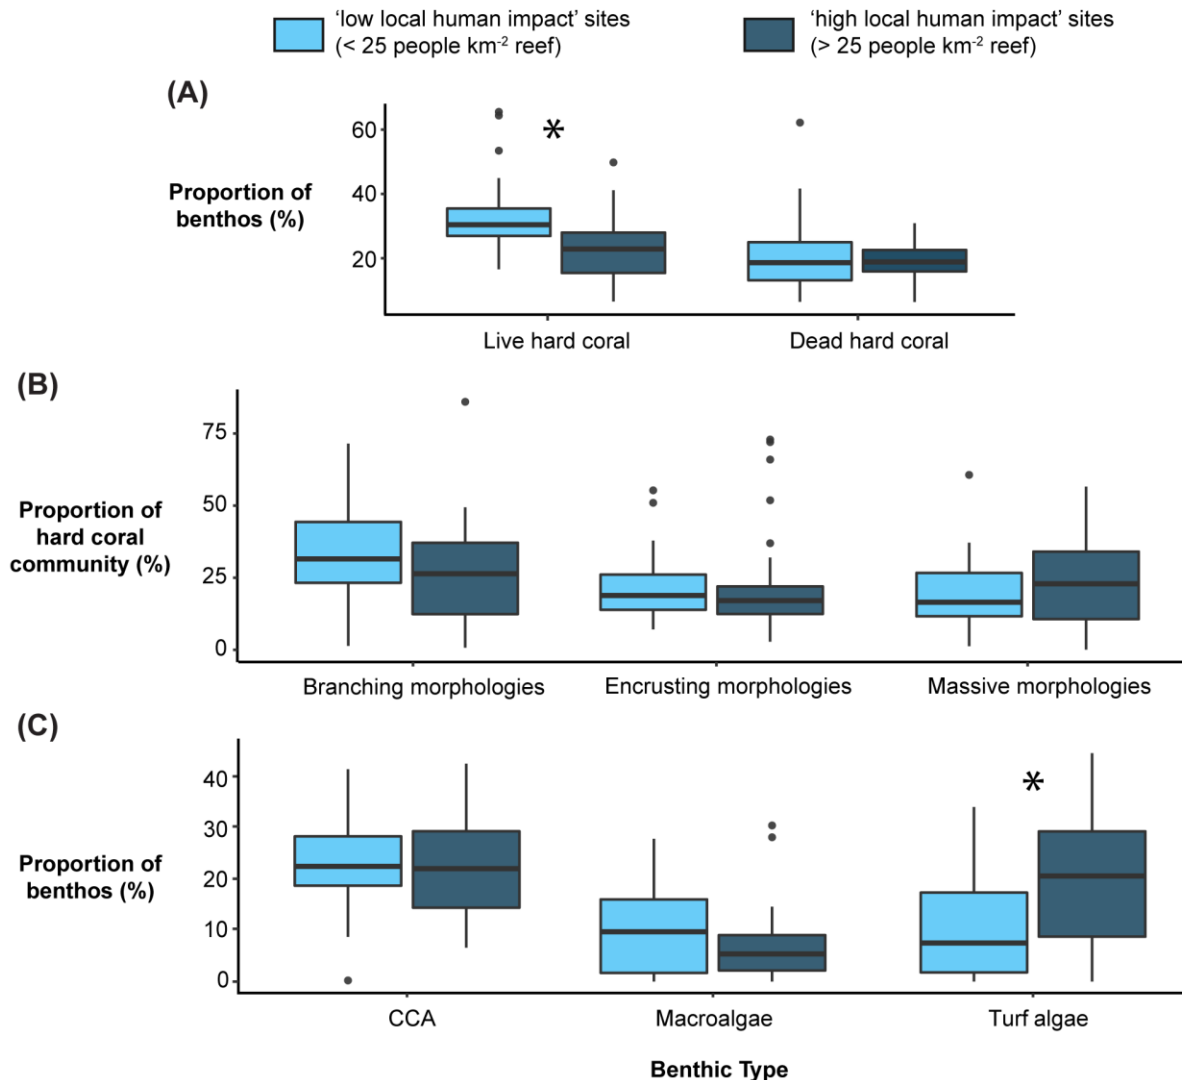

Figure 1 Boxplots detailing (**A**) benthic cover (%) of substrate types (from left to right; live hard coral, dead hard coral), (**B**) the relative proportion (%) of the three most dominant morphologies in the live hard coral community (branching, encrusting, massive), and (**C**) benthic cover (%) of different algal groups (CCA, macroalgae, turf algae), at sites determined to have low or high local impacts. Asterisk (*) indicates significant differences ($p < 0.05$) in cover of the respective benthic variable between local impact levels according to two-sample t-tests, or for turf algae according to linear mixed effect models incorporating *bias_score* as a random effect (see section 2.3.2).

3.2   Predictive strength of 'spatio-physical' model

The pre-defined 'spatio-physical' model exhibited relatively high power in explaining benthic assemblage variance at sites with low local human impacts (mean Adj-R^2 ± SE; 0.35 ± 0.09; Figure 2), but model performance was severely compromised when local human impacts were high (0.10 ± 0.04; paired t-test: $p = 0.01$). When considering only the substrate types and dominant morphological groups (i.e. without the algal groups) the mean adjusted-R^2 for sites with low local human impacts increases to 0.44 ± 0.06 but stays unchanged at sites with high local human impacts.

11

433 When local human impacts were low, 'spatio-physical' predictors explained a high
434 proportion of the variance of live hard coral (Adj-R^2 = 0.52) and macroalgae (Adj-R^2 =
435 0.59) cover, and the relative contribution of branching (Adj-R^2 = 0.64) and massive
436 (Adj-R^2 = 0.50) coral morphologies. Conversely, these variables were consistently
437 poorly explained when local human impacts were high (Adj-R^2 = 0.00, 0.26, 0.17,
438 0.10, respectively). No variance in turf algae was explained by this model for reefs at
439 either local human impact level. Significant differences in the power of the 'spatio-
440 physical' model in explaining benthic assemblage variance between 'low' and 'high'
441 impact sites held constant when the threshold was moved ± 5 and 10 humans km^{-2}
442 reef (i.e. paired t-test: p < 0.05; Supplementary Table 3).
443
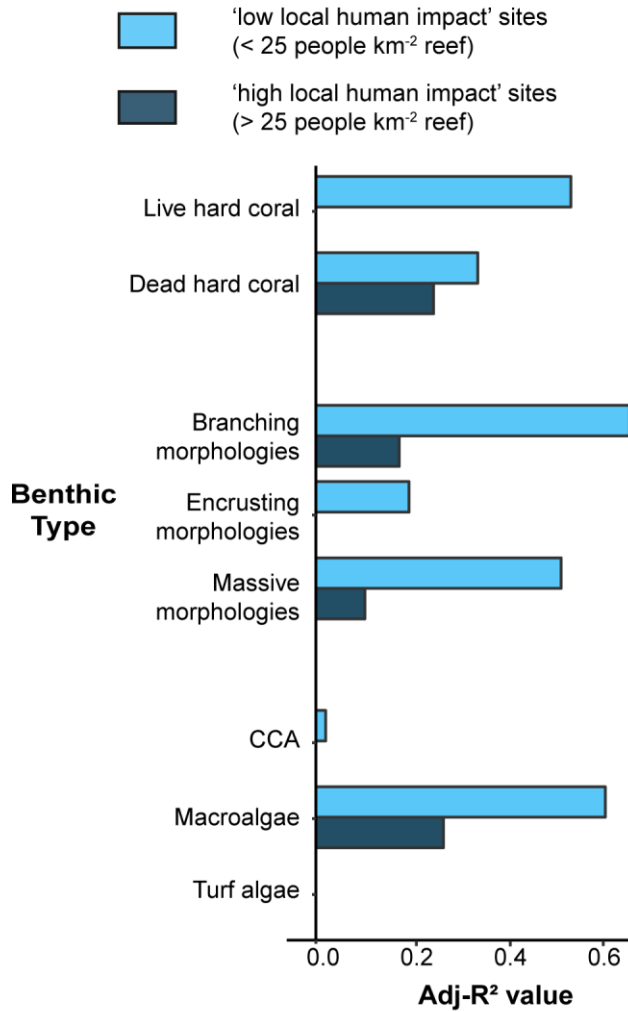

444
445 **Figure 2** Explanatory power (Adj-R^2) of the 'spatio-physical' model (including the
446 predictors storm exposure, reef depth, latitude, and island relief) in predicting
447 individual benthic responses (live hard coral, dead hard coral, the proportion of
448 branching, encrusting, and massive morphologies, and cover of algal groups CCA,
449 macroalgae, and turf algae). Bars are absent where the Adj-R^2 value = 0.
450

3.3 Relative importance of predictors

452 Best-fit' models tailored for each individual benthic variable comprised distinctly
453 different predictors depending on the level of local human impact (Figure 3A). Two of
454 the predictors where discrepancies were most apparent were storm exposure and

12

grazer biomass, which were only selected for 'best-fit' models at sites with low and
high local human impacts, respectively. Similarly, reef depth was selected as part of
'best-fit' models for more response variables (live hard coral, branching
morphologies, and macroalgae) at sites with low local human impacts. Further
discrepancies under the two levels of local human impact were revealed by
comparing the mean RI of each predictor (Figure 3B,C), as the RI trends for
predictors almost reversed between low *versus* high local human impact sites. At
sites with low local human impacts, the individual predictors with the highest RI in
explaining benthic communities were storm exposure, scraper biomass, island relief,
followed by reef depth (Figure 3B). Contrastingly, apart from island relief which was
on average the most important predictor, storm exposure, scraper biomass, and reef
depth were among the least important predictors when local human impact was high
(Figure 3C). For benthic communities exposed to high local human impact, biomass
of grazers, detritivores, and browsers, as well as market gravity, ranked as the most
important predictors of benthic community structure.
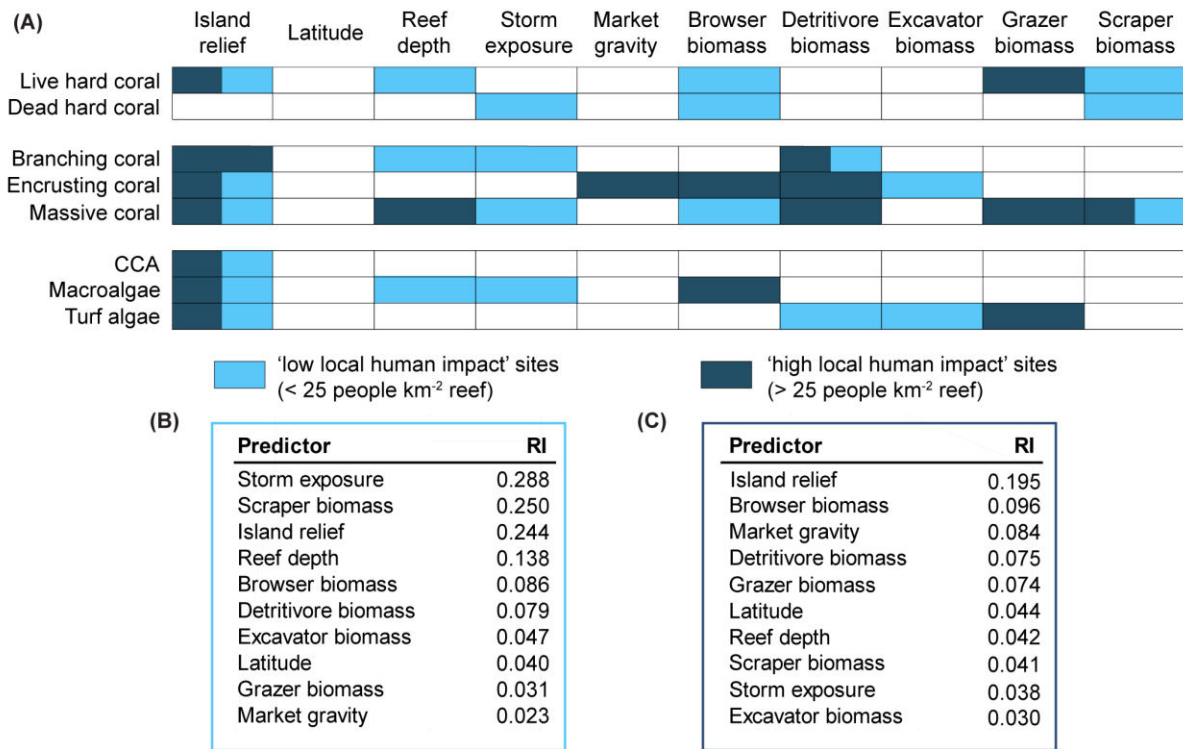

Figure 3 (**A**) Outcome of model selection procedures: coloured boxes indicate that
the predictor was selected for 'best-fit' models (i.e. those with Akaike weight > 0.05)
at sites subject to low and/or high levels of local impacts. The overall mean relative
importance of each predictor (RI - based on total Akaike weight of all models
including that predictor) in explaining the benthic response variables is shown
separately for sites subject to (**B**) low and (**C**) high local impacts. Note: though model
selection was limited to four predictors per model, all predictors included in models
with Akaike weight >0.05 are shown meaning there may be more than four predictors
shown within one impact level for a response variable. Model outputs for 'best-fit'
models are available in Supplementary Table 5.
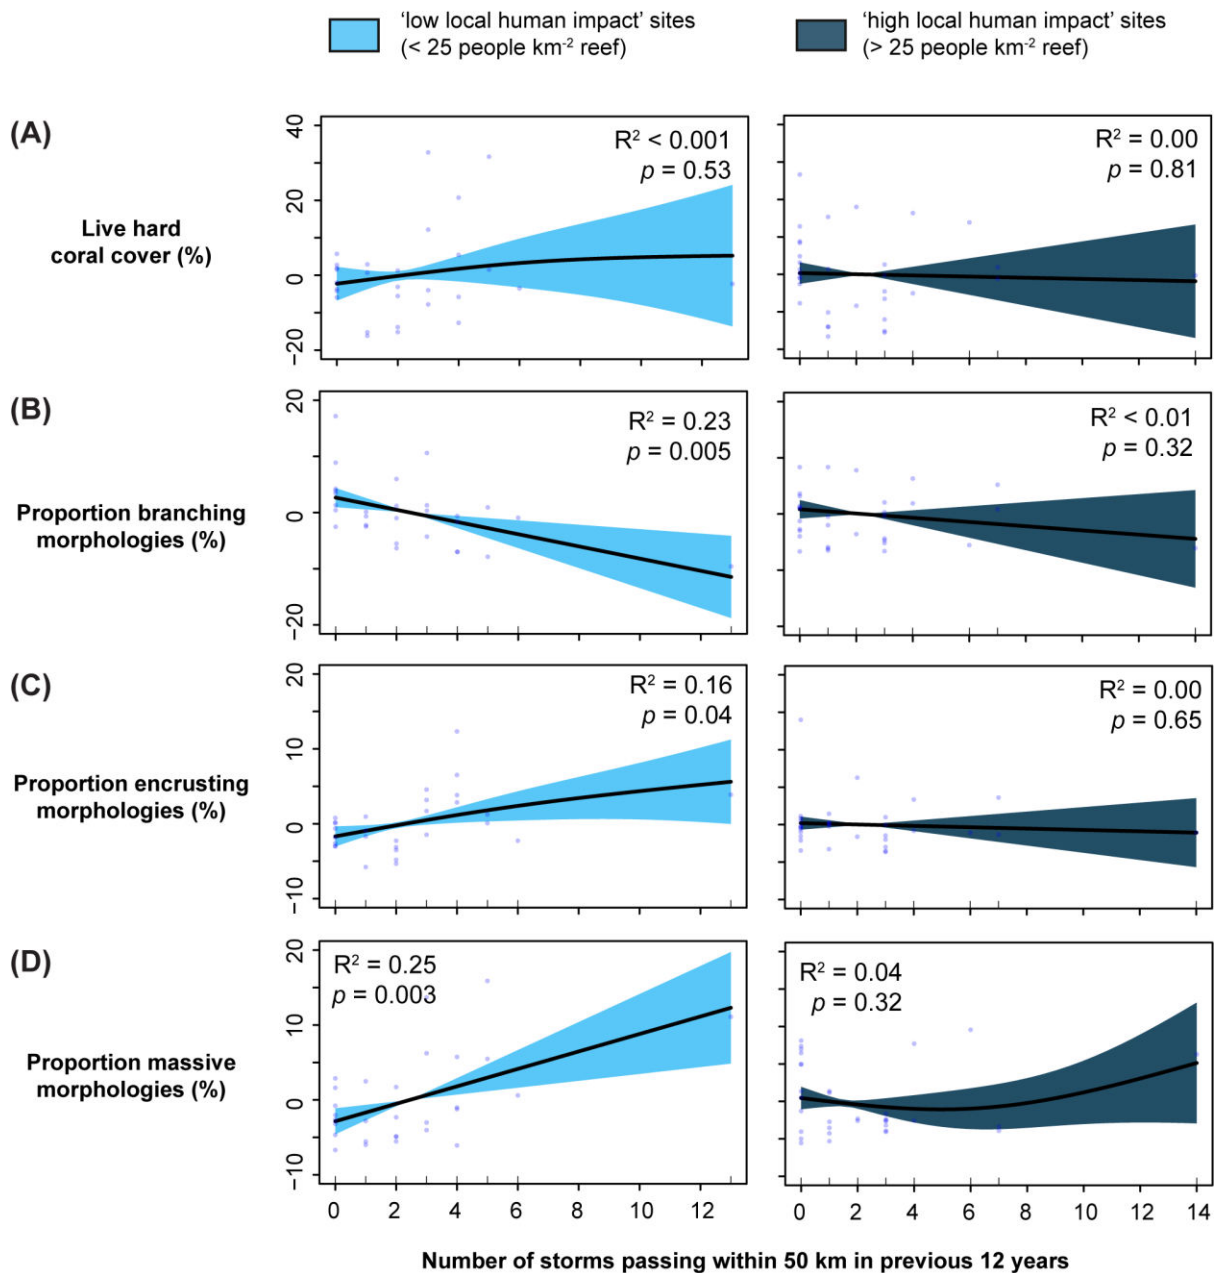

Figure 4 Smoother plots of normalised residuals from generalised additive models with 95% confidence intervals (shaded areas) to exemplify discrepancies in response-predictor relationships between local impact levels, using storm exposure as an example. The plots represent the explanatory power of storm exposure in predicting (**A**) live hard coral cover, and the proportion of (**B**) branching, (**C**) encrusting, and (**D**) massive morphologies, separated for sites with low *versus* high local impacts. Refer to Supplementary Figure 6 for all predictor-response plots from 'best-fit' models.

Individual relationships of 'best-fit' predictors for each response variable further emphasised discrepancies between benthic communities and environmental predictors driven by local human impacts (for all plots see Supplementary Figure 6). A clear example of this discrepancy can be seen in coral compositional changes with

14

499 increasing storm exposure. Whilst live hard coral cover remained unrelated to storm
500 exposure under both local human impact levels (Figure 4A), the morphological
501 composition was closely correlated with storm exposure at sites where local human
502 impacts were low (Figure 4B–D). Specifically, with increasing storm exposure, the
503 relative proportion of branching morphologies decreased significantly (Figure 4B),
504 whereas encrusting (Figure 4C) and massive (Figure 4D) morphologies increased.
505 No morphological changes with storm exposure were observed at sites with high
506 local human impacts. Though these relationships appear primarily driven by few
507 points at the higher end of storm exposure, they remained consistent when all reefs
508 exposed to >10 storms were removed from the analysis – i.e. significant at 'low'
509 impact sites (branching coral p = 0.02; encrusting coral p = 0.02; massive coral p =
510 0.03), insignificant at 'high' impact sites (all morphological growth forms p > 0.05),
511 and no relationship for either impact for total live hard coral cover (p > 0.05).
512
513

514 **4   Discussion**
515
516 Under increasing climate change-associated stressors and local anthropogenic
517 influence (Burke et al., 2011; Gattuso et al., 2015; IPCC, 2019), it is particularly
518 important for researchers and planners to maximise the ability of models to predict
519 ecosystem futures to allow appropriate mitigation strategies to be implemented. This
520 study indicates that the role of local human impacts in changing coral reef ecological
521 communities and their responses to environmental drivers should be accounted for.
522 The results revealed that local human impacts influenced both benthic community
523 structure and relationships with biophysical predictors. Specifically, models based on
524 spatio-physical predictors (i.e. reef depth, latitude, storm exposure, and relief)
525 exhibited high power at explaining benthic assemblages under low local human
526 impacts but were strongly compromised where local human impacts were high.
527 Importantly, these outcomes remained similar when our threshold for human
528 impacts, informed by previous work, was reduced or increased in the frame of a
529 sensitivity analysis. Increasing sewage input, agricultural run-off, and sedimentation
530 are potential changes associated with increasing human densities that reduce water
531 quality and affect benthic communities (Fabricius, 2005; Fabricius et al., 2005; Ford
532 et al., 2017). Furthermore, as fishing removes biomass of functionally important fish
533 species, important top-down control of some benthic organisms is lost (Bellwood et
534 al., 2004). These localised human impacts may homogenise benthic communities by
535 driving ecological reorganisation that favours tolerant taxa (Darling et al., 2019). Our
536 results indicate that this homogenisation may be occurring at Pacific Island reefs that
537 are exposed to local human impacts, leading to novel systems that react
538 fundamentally differently and unpredictably to environmental predictors compared to
539 reefs less influenced by humans (Williams et al., 2015a). In turn, we expect that local
540 human impacts will influence responses of coral reefs to climate change-related
541 stressors, and that reefs close to human populations will require context-specific
542 management approaches to maximise their future sustainability and associated
543 critical ecosystem services (Moberg and Folke, 1999).
544
545 The results emphasise the variation in benthic assemblages that exists among
546 Pacific Island reefs exposed to different levels of local human impact. Benthic
547 communities were not restricted to distinct regimes dominated by either hard corals

548 or macroalgae, supporting previous studies from the Pacific (Bruno et al., 2009;
549 Albert et al., 2012; Jouffray et al., 2015, 2019; Smith et al., 2016). In fact,
550 macroalgae was the least common of all the algal groups, with turf algae and CCA
551 more prominent on these outer reefs. Reefs at sites with higher local human impacts
552 comprised significantly more turf algae and less live hard coral. Abundant and
553 diverse outer reef coral communities (e.g. Ellis et al., 2017) have likely retained
554 sensitive species, facilitating measurable differences (i.e. reductions in live hard
555 coral cover) under higher local human impacts. Higher turf algae coverage at sites
556 with more local human impacts provides further evidence that turf algae may
557 become the dominant benthic group on degraded Pacific Island reefs (Jouffray et al.,
558 2015; Smith et al., 2016; Tebbett and Bellwood, 2019). This may contrast with coral
559 reef systems in the Caribbean, where macroalgae naturally play a more dominant
560 role (Roff and Mumby, 2012). Furthermore, a signal of local human impact may have
561 been detected if the data had distinguished macroalgae into fleshy/frondose and
562 calcified types (e.g. Smith et al., 2016; Cannon et al., 2019). A similar link between
563 human population size, hard coral cover, and turf algae has also recently been
564 reported from sites in the Indian Ocean (Brown et al., 2017).
565
566 The 'spatio-physical' models were weak in explaining the variance of benthic
567 communities exposed to relatively more local human impacts. At these sites, model
568 selection identified mostly local biotic controls or ecological features such as fish
569 biomass and market gravity to be of highest relative importance. These results
570 suggest that reefs altered by chronic local human impacts become decoupled from
571 spatio-physical factors (Williams et al., 2015a) and become more related to factors
572 associated with human activities (e.g. market gravity) or local ecological features
573 (e.g. biomass of functional groups of fish). Interestingly, this outcome contrasts to
574 recent findings by Robinson et al. (2018) who did not detect decoupling at inhabited
575 *versus* uninhabited reefs. Our different outcomes for decoupling could in part be
576 explained by Robinson et al. (2018) combining (i) hard corals and CCA, and (ii)
577 fleshy macroalgae and turf algae, each of which we found to exhibit different
578 responses to local impacts (i.e. with higher local impacts hard coral cover reduced
579 whereas CCA remained unchanged, turf algae increased whereas macroalgae
580 remained unchanged). Model selection indicated that the specific spatio-physical
581 predictors whose influence were most disrupted by local human impacts were storm
582 exposure and reef depth. Storms can have mixed effects, benefitting reefs by
583 alleviating thermal stress during warmer summer months but also causing physical
584 destruction, particularly to delicate branching coral morphologies, leading to a higher
585 proportion of more robust massive morphologies (Heron et al., 2005; Manzello et al.,
586 2007). Accordingly, when local human impacts were low, coral communities
587 comprised relatively less branching and more encrusting and massive morphologies
588 at sites subject to more frequent storms. However, relationships between storm
589 exposure and benthic assemblages were only observed at sites classified as having
590 low local human impacts. Returning to the concept that local human impacts drive
591 ecological reorganisation, we would expect reefs with less local human impacts to
592 harbour a great diversity of species and morphologies, thus allowing for greater
593 levels of ecological reorganisation in response to a stormier environment (i.e.
594 favouring more robust morphologies). We anticipate that Pacific reefs would more
595 likely display this phenomenon than Caribbean reefs due to a significantly larger
596 initial species pool, with greater response diversity and functional redundancy

affording a higher level of ecological insurance (Elmqvist et al., 2003; Bellwood et al., 2004; Nyström, 2006), and a loss of structurally-complex coral species throughout most of the Caribbean over past decades (Alvarez-Filip et al., 2009). It would be interesting to test whether storm exposure results in more conspicuous negative impacts on coral cover (e.g. Gardner et al., 2005) in less diverse regions due to the limited capacity for ecological reorganisation to a tolerant community, even in sites with minimal local human impact. In terms of reef depth, benthic communities at sites with low local human impacts also exhibited a higher level of depth-structuring (particularly in terms of coral cover and composition, consistent with Huston, 1985) compared to those with high local human impacts. Island relief was also identified as being a strong predictor of benthic community structure (despite being found to be a weak predictor on central-western Pacific reefs - Robinson et al., 2018), and interestingly this role was maintained regardless of local human impact level. Importantly, when considering latitude – collinear with DHW/cumulative thermal stress – as an individual predictor, our results neither contradict nor confirm previous observations that local impacts exacerbate the sensitivity of coral communities to thermal stress (Wiedenmann et al., 2013; Ellis et al., 2019), instead highlighting a large variance among sites.

Thermal stress and the intensity of storms are projected to increase under future climate change scenarios (IPCC, 2019), with profound implications for coral reefs and adjacent ecosystems. Our findings suggest that while the effects of factors associated with climate change (e.g. storm exposure) on Pacific reef benthic assemblages may be reasonably well-predicted where local impacts are low, system responses become less predictable as local human impacts increase. In both marine and terrestrial systems, structural changes caused by local impacts have profoundly changed how ecosystems respond to natural stressors: for example, local stressors have affected how parts of Australia's Great Barrier Reef have recovered from recent climate change impacts (MacNeil et al., 2019; Mellin et al., 2019) and habitat fragmentation and modification have exacerbated recent impacts of tropical and temperate forest fires (Brando et al., 2014; Alencar et al., 2015; Taylor et al., 2016). Because the effects of storms are strongly dependent not only on their intensity, but also the extent of the fetch, their frequency, and intrinsic reef properties such as topography (Lugo et al., 2000; Heron et al., 2005), this study incorporated all recorded storms (category 1–5 on the Saffir-Simpson Hurricane Scale) passing within 50 km of each site. We thus cannot deduce benthic community responses to increasing storm *intensity*, which is projected to occur (IPCC, 2019).

Functional groups of herbivorous fishes also emerged to be of contrasting relative importance depending on the level of local human impact, shifting from scrapers and small excavators at less impacted reefs to grazers at more impacted reefs. Browsers were of similar importance at reefs exposed to both local human impact levels, perhaps linked to the fact that their food source (macroalgae) remained constant regardless of local human impact level. Additional reasons for this could be that browsers have remained more resilient to fishing pressure than other herbivores, or that visual survey data does not accurately represent browser populations (for example some browser species are known to be particularly wary of divers – Kulbicki, 1998). Fish that act on turf algae and/or on surfaces available for coral settlement seem to be more sensitive to local human impacts, likely in response to

646 benthic community shifts. Scrapers and small excavators clear substrate for
647 calcifiers, justifying their higher relative importance in models focused on less locally
648 impacted reefs where live hard coral cover was higher and conditions for settlement
649 and growth of juvenile corals were likely better (e.g. less nutrients, lower
650 sedimentation). Contrastingly, grazers crop and maintain algal turfs, explaining their
651 importance under higher local human impacts where turf algae were more dominant.
652 These results align with findings in the Hawaiian Archipelago, where biomass of
653 grazers and scrapers were the most important predictors of turf/macroalgal, and
654 calcified regimes, respectively (Jouffray et al., 2015; see also Robinson et al., 2018).
655 Though collinearity tests ruled out significant, potentially confounding relationships
656 between biomass of different functional groups with individual abiotic predictors, it is
657 important to acknowledge that fish communities themselves can be affected by
658 various physical predictors (Williams et al., 2015b; Samoilys et al., 2019), which
659 could in turn influence benthic structure.
660
661 Other factors not included in these analyses are known to structure benthic
662 assemblages, including chlorophyll, SSTs, and wave exposure (Gove et al., 2013,
663 2015; Williams et al., 2013; Robinson et al., 2018; Darling et al., 2019). Remotely
664 sensed chlorophyll data captures offshore productivity, but we expected land-based
665 input to dominate many of these reefs which are close to land, while the survey
666 design (sometimes around the periphery of small islands/atolls) made wave
667 exposure challenging to quantify. Additionally, wave exposure, mean SSTs, and
668 climatological ranges can be relatively well-captured by latitude in the Pacific (Gove
669 et al., 2013). Also, although this study goes into more detail than many similar large-
670 scale analyses by evaluating coral growth forms, it is still limited in its ability to
671 quantify ecological reorganisation, which would require higher resolution data (at
672 least family or genus). This limitation can be overcome by broad-scale surveys
673 refining the level at which hard coral communities are recorded, which will become
674 easier with improvements in automated software tools. These results do however
675 emphasise that even broad morphological groupings (i.e. branching, massive,
676 encrusting morphologies) provide pertinent information on ecological changes and
677 can improve model performance compared to when overall hard coral cover is
678 considered (Gove et al., 2015).
679
680 Importantly, the threshold used in this study for determining low and high impact,
681 while informed by a previous study, was set *a priori* and thus does not allow defining
682 a 'carrying capacity' of human density – this would require a different survey design
683 and analytical approach, and should be pursued in future studies. We would
684 however suggest that although this metric is most applicable to areas where
685 customary resource use is common practice, we anticipate that this threshold (25
686 humans km^{-2} reef) is highly relevant across the Pacific region (i.e. given that it is a
687 median point in this dataset for which sites were selected due to being regionally
688 representative of fished areas). Furthermore, the study design was not originally
689 meant to address macroecological questions but was nonetheless the best available
690 to study the questions we were interested in (with incorporation of appropriate
691 secondary data on local environmental context). Again, future studies should
692 address this by appropriate designs that allow for large-scale comparability and
693 collect both ecological and socio-economic local data. Our findings indicate that
694 island relief is a factor that should be considered in designing regional sampling

18

programs with comparable sites. Finally, we should aim to obtain context-specific information on factors associated with human population density (e.g. sewage treatment presence, farming and associated fertiliser-usage) that strengthens our ability to predict benthic communities under various levels of human population density and improve its use as a proxy of local human impact.

Our findings contribute to a better understanding of the role of local human impacts on diverse ecosystems such as tropical coral reefs. The results provide empirical evidence that local human impacts drive conspicuous changes in benthic community relationships with environmental predictors, with indications of ecological reorganisation. Even if decisive steps are taken to reduce fossil fuel emissions, most reefs will suffer long-term degradation from the effects of climate change by 2050, and >75% of reefs will experience annual severe bleaching (Frieler et al., 2013; van Hooidonk et al., 2016). Our results show that local human impacts can lead to increasingly unpredictable relationships between benthic communities and their physical environment, and that overlooking their role could pave way to significant errors in future projections, potentially compromising mitigation efforts.

5 Conflict of Interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

6 Author Contributions

AF developed the study idea with close support from JBJ, AN, BM and SF. AF led the statistical analyses together with input from JBJ, GW and SF. BM and FM provided expertise on the original data. All authors provided support throughout the interpretation of the results and development of the manuscript. All authors approve this final version.

Supplementary Figure 1 - Map of the 62 sites surveyed across 17 different Pacific Island countries and territories, coloured by local impact level.
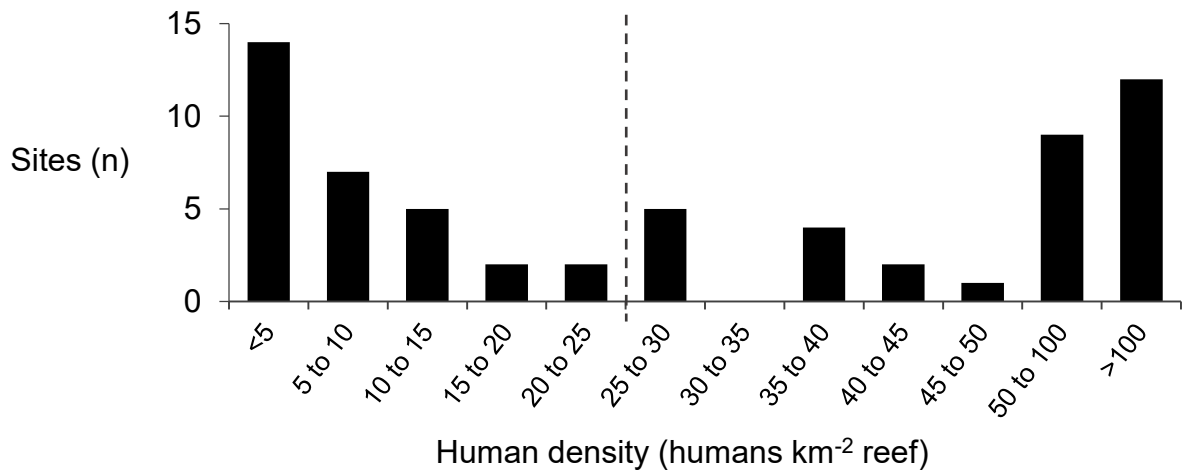

Supplementary Figure 2 - Number of sites by human density (humans km^{-2} reef). Dashed line indicates threshold separating low impact from high impact sites.

(A)

(B)
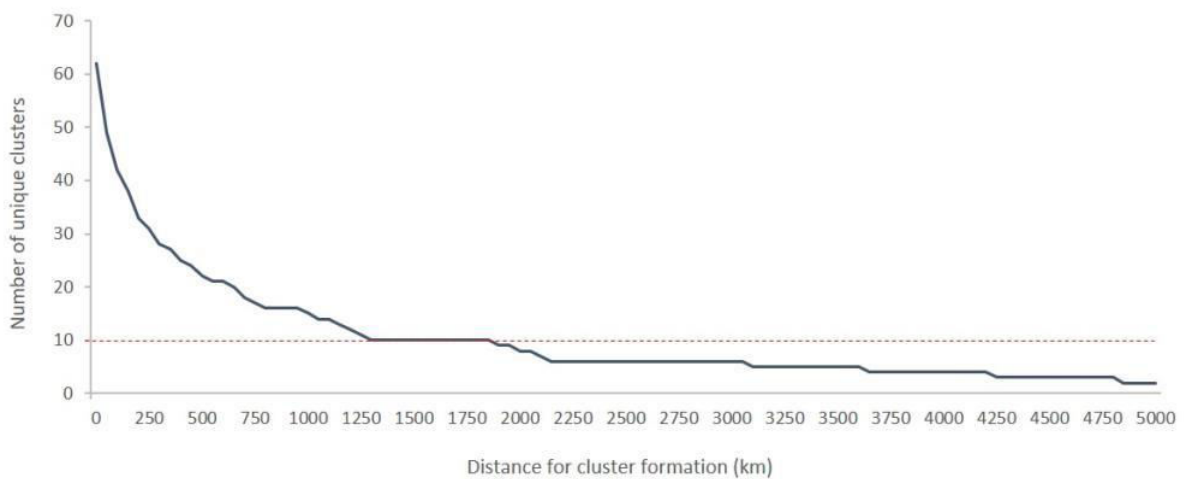

Supplementary Figure 3 - To account for possible spatial autocorrelation among sites, we included island cluster as a random effect within models (based on methodology of Williams et al. 2015*). Island clusters were identified using (A) hierarchical clustering based on pairwise Euclidean distances between each of the 62 sites, by finding (B) an inflection point in the number of unique clusters and cluster distance which we identified to be at ~1300 km, resulting in ten unique island clusters.

*Williams GJ, Gove JM, Eynaud Y, Zgliczynski BJ, Sandin SA. (2015) Local human impacts decouple natural biophysical relationships on Pacific coral reefs. *Ecography*, **38**, 751–761.
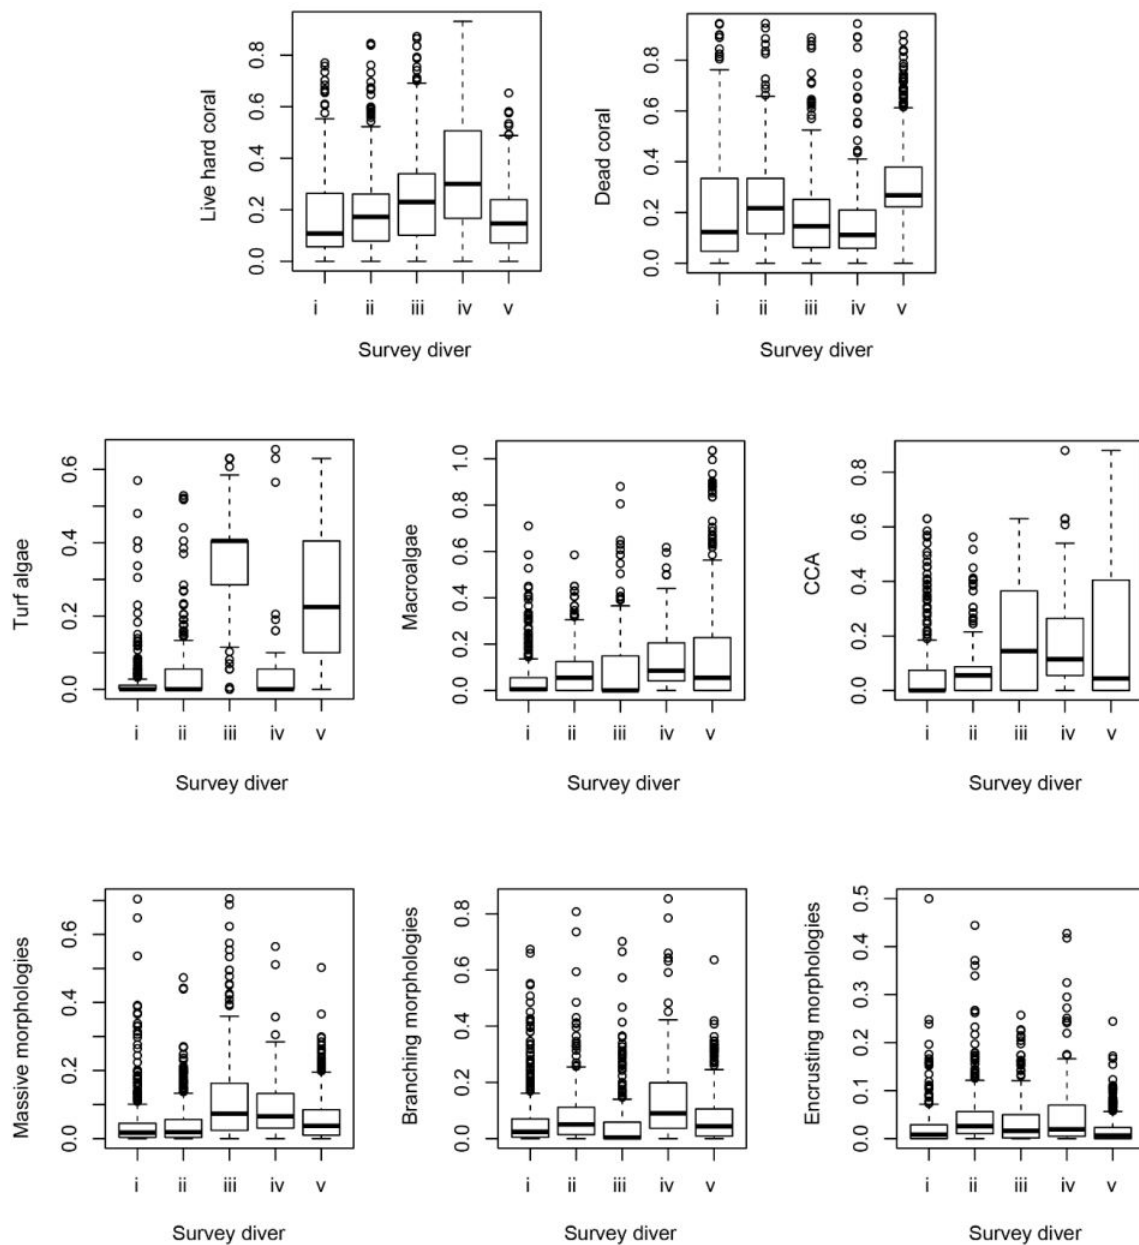

Supplementary Figure 4 - Boxplots representing ranges of response variables recorded by the core survey diver team - the core survey team consisted of five divers, who recorded 94% of all transects. Additional surveyors were included in the remaining 6%. As surveyor bias is inherent to such datasets, we tested for surveyor effects on our response variables. These tests indicated that significantly higher turf algae coverage was reported by two of the core survey team (survey divers iii and v). It became apparent that even within one reef, there were discrepancies in the reported turf algae cover between these survey divers and survey divers i, ii, and iv. This was not an issue with other benthic groups nor morphological classifications of hard corals (i.e. massive, branching, and encrusting). To account for the differences in turf algae reporting, we scored the contribution of survey divers iii and v to total surveys at each reef on a continuous scale from 0 to 1 (i.e. 0 meaning survey divers iii and v were not present on any transects at the reef, and 1 meaning all transects at a reef were conducted by survey diver iii and/or v). This score (referred to as *bias_score*) was included as a random effect in subsequent turf algae-focused models.

Live hard coral
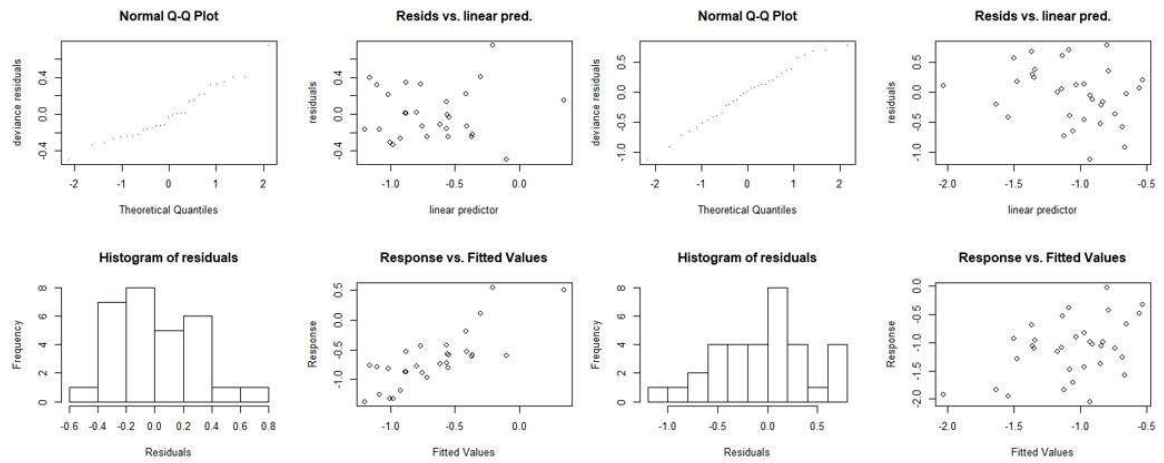

Dead hard coral
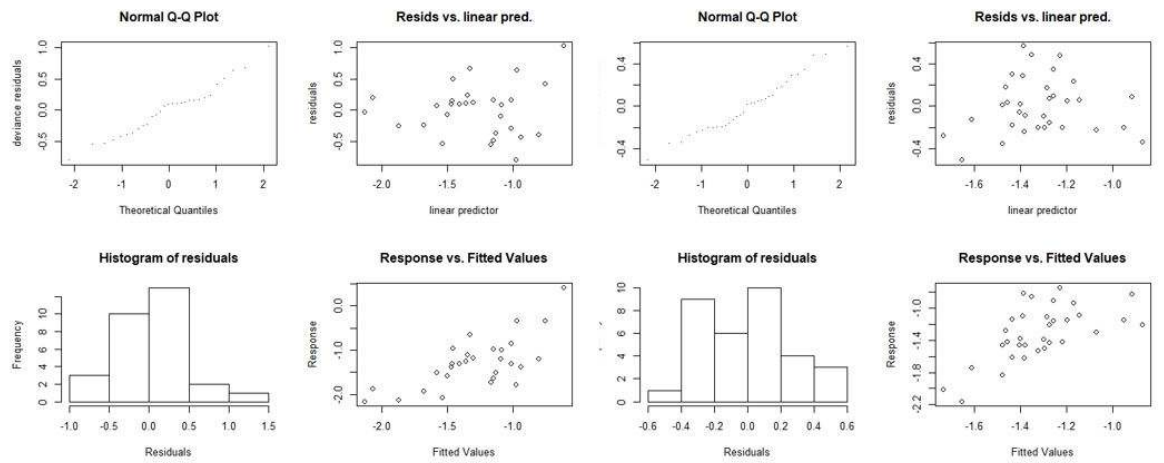

Branching morphologies
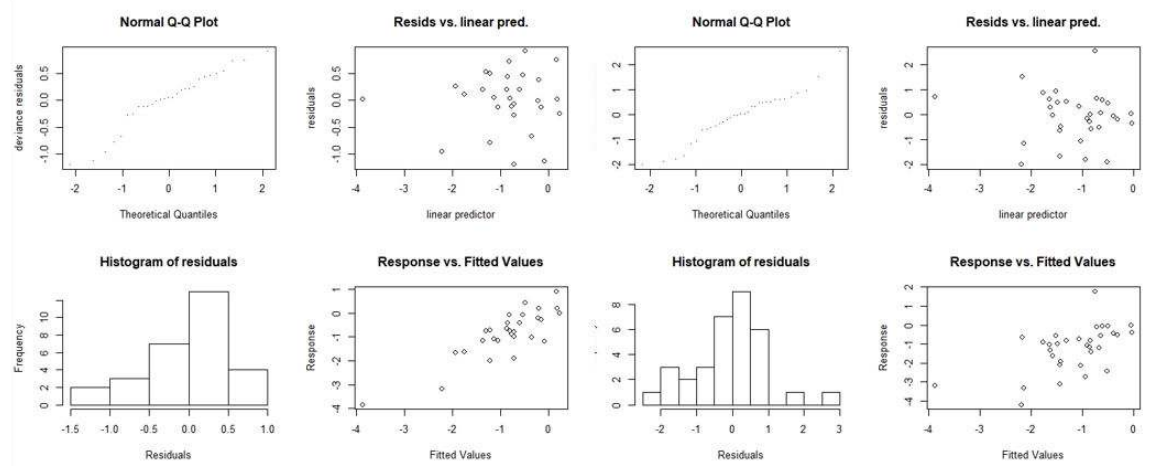

Encrusting morphologies
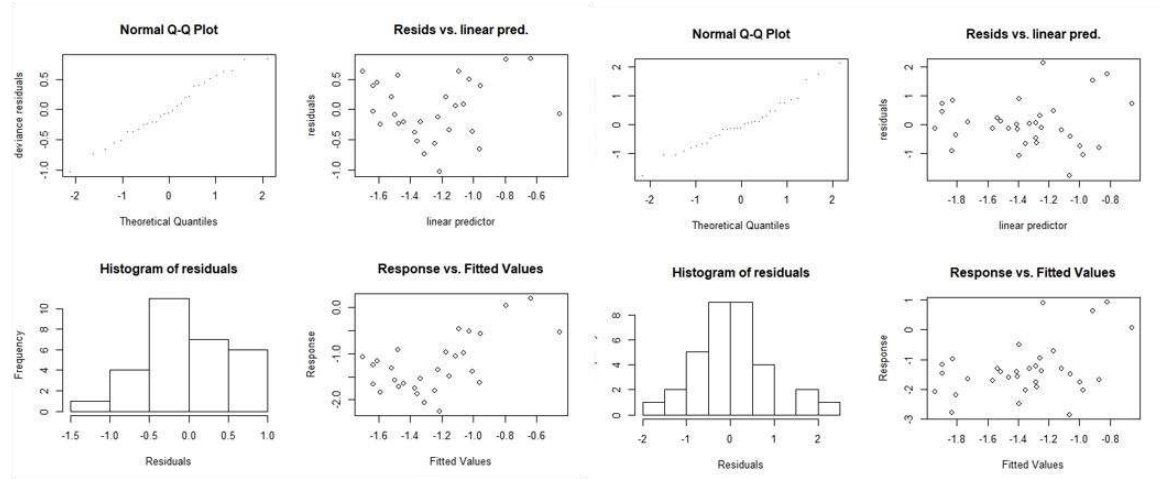

Massive morphologies
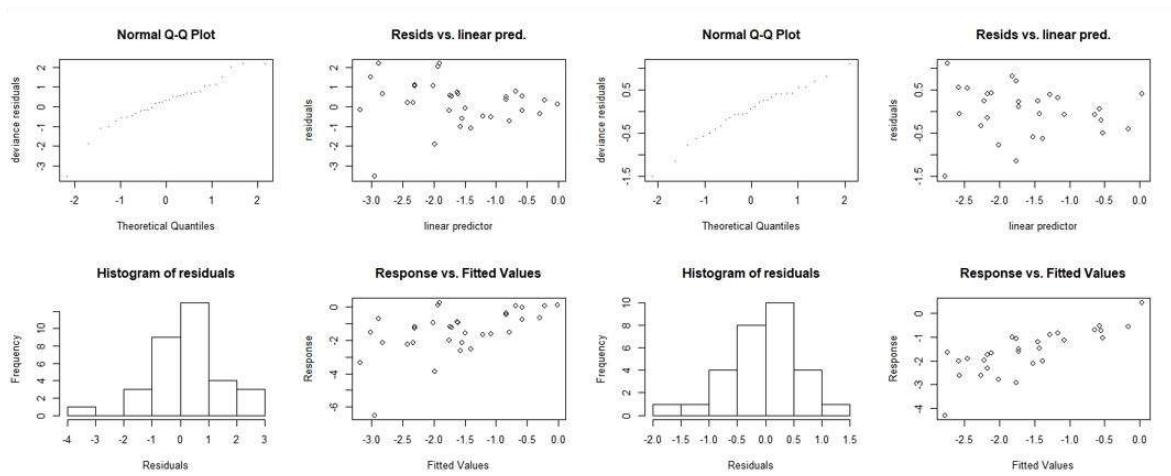

CCA
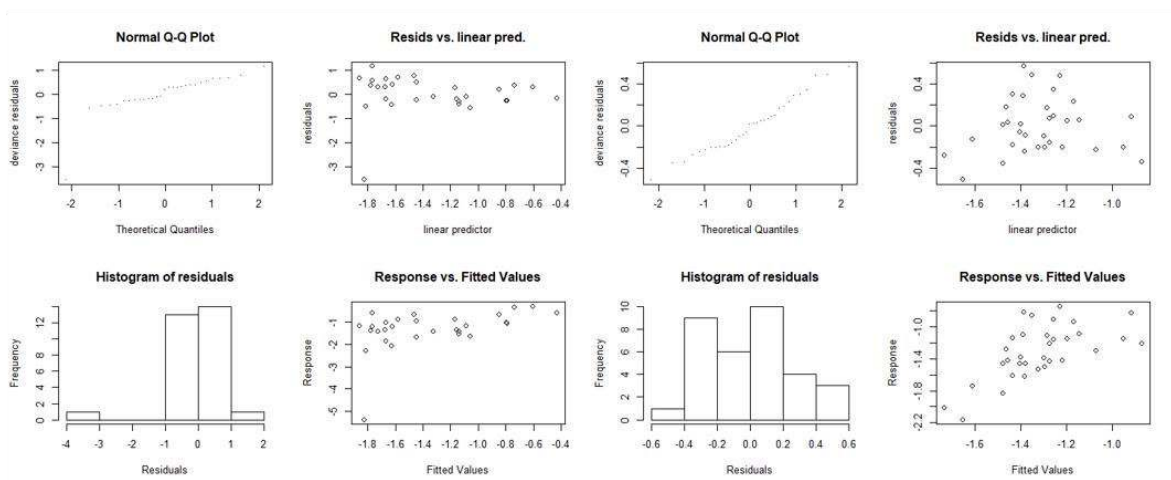

Fleshy algae
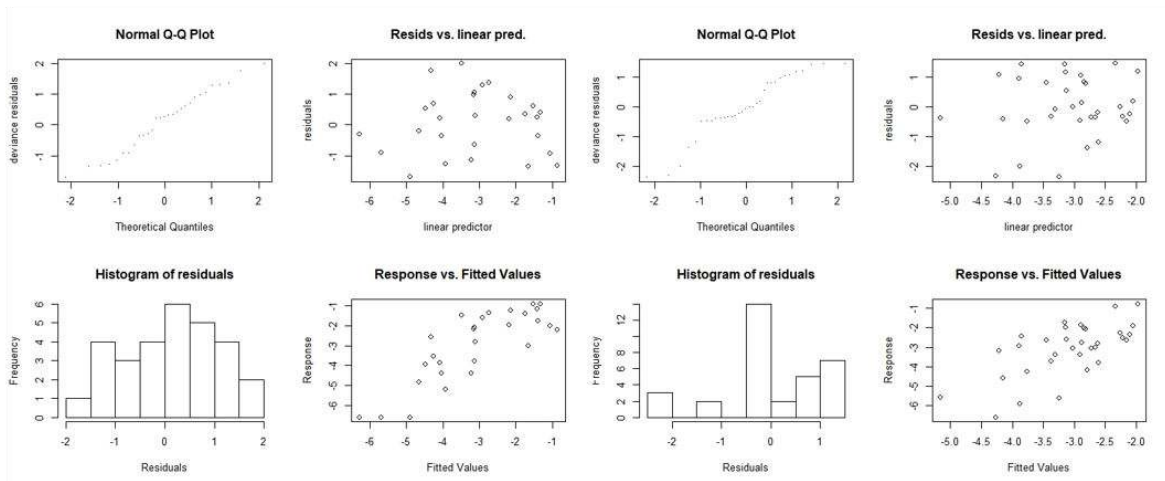

Turf algae
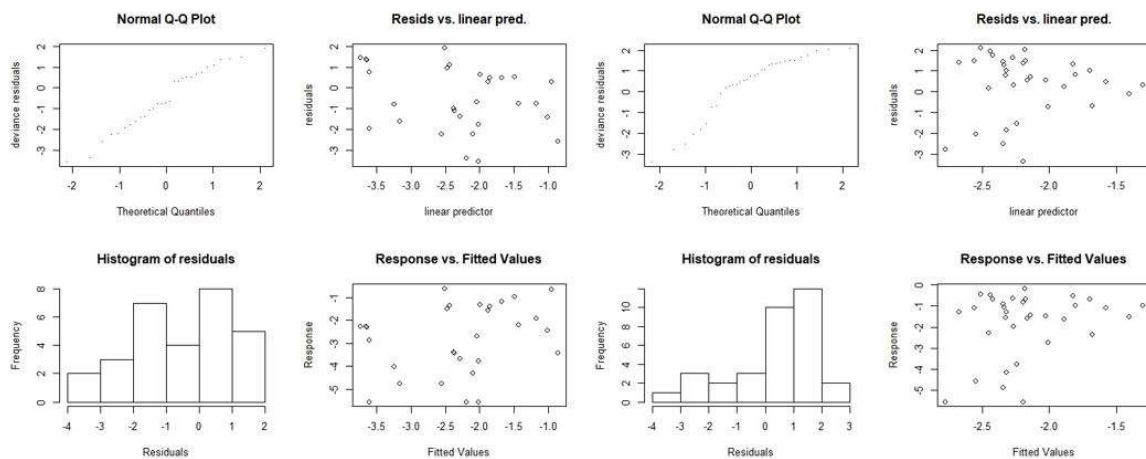

Supplementary Figure 5 - Residuals ($gam.check) of 'spatio-physical' models (for each response variable (in order from top to bottom: live hard coral, dead hard coral, branching morphologies, encrusting morphologies, massive morphologies, CCA, macroalgae, turf algae). Left set of graphs = models based on low local impact sites (< 25 humans km^{-2} reef); right set of graphs = models based on high local impact reefs (> 25 humans km^{-2} reef):

(A)

Grazer biomass | Reef depth | Scraper biomass | Storm exposure

Live hard coral (% cover)
- p = 0.53, R² = 0.002
- p = 0.02, R² = 0.19
- p = 0.013, R² = 0.30
- p = 0.42, R² = 0.02
- p = 0.076, R² = 0.153
- p = 0.544, R² = 0.00

Dead hard coral (% cover)
- p = 0.0003, R² = 0.44
- p = 0.158, R² = 0.033
- p = 0.03, R² = 0.23
- p = 0.77, R² = 0.00

Branching coral (% of live hard coral)
- p = 0.31, R² = 0.07
- p = 0.89, R² = 0.00
- p = 0.003, R² = 0.37
- p = 0.21, R² = 0.00

Encrusting coral (% of live hard coral)

Massive coral (% of live hard coral)
- p = 0.42, R² = 0.00
- p = 0.03, R² = 0.07
- p = 0.07, R² = 0.17
- p = 0.18, R² = 0.00
- p = 0.298, R² = 0.03
- p = 0.14, R² = 0.00
- p < 0.0001, R² = 0.411
- p = 0.60, R² = 0.02

CCA (% cover)

Macroalgae (% cover)
- p = 0.04, R² = 0.11
- p = 0.999, R² = 0.00

Turf algae (% cover)
- p = 0.03, R² = 0.14
- p = 0.0001, R² = 0.42

Grazer biomass (g m⁻²)   Reef depth (m)   Scraper biomass (g m⁻²)   Market gravity index

(B)

Supplementary Figure 6 – Individual relationships between selected predictors for each respective response variables as per 'best-fit' model outcomes. (A) Smoother plots of normalised residuals from generalised additive mixed effect models (*gamm4* package) with 95% confidence intervals (shaded areas). Plots are based on the $gam output from these models. These graphs provide relationships between individual response variables and predictors that were selected for 'best-fit' models (those with Akaike weight > 0.05; see Figure 4; Supplementary Table 4) at outer reef sites with low and/or high local human impacts. Plots are provided in terms of reefs exposed to low (light grey/left panel) *versus* high (dark grey/right panel) local impact as determined using a threshold of 25 humans km^{-2} reef. Large crosses (X) mean that the predictor was not selected for 'best-fit' models for reefs exposed to either impact level. (B) Boxplots conveying relationships between the predictor island relief and benthic response variables for which it was selected for 'best-fit' models (i.e. those with Akaike weight > 0.05; see Figure 4; Supplementary Table 4).

Supplementary Table 1 - Table containing survey dates and timelines of disturbances (up to 12 years before surveys) with associated references provided.

Additional survey information: Criteria for site selection: (i) having active reef fisheries, (ii) being representative of the country, (iii) being relatively closed systems, (iv) being appropriate in size, (v) possessing diverse habitats, (vi) presenting no major logistical problems, (vii) having been previously investigated and (viii) presenting particular interest for the respective Fisheries Agency. For full details see Pinca et al. (2010). Originals surveys grouped reefs into four geomorphological structures, but this study focused only on outer (fore-) reefs (primarily due to replication). Though 63 individual outer reefs were surveyed, one reef had less than three replicate transects and thus was removed, leaving 62 replicate reefs.*

Supplementary Table 3 - As part of a sensitivity analysis, 'spatio-physical' models were additionally run using ± 5 and ± 10 humans km^{-2} reef as a threshold from which to categorise 'low' and 'high' impact sites. Notably, site allocations were the same for 30 and 35 humans km^{-2} reef (i.e. no sites had values between 30 and 35 humans km^{-2} reef). Values in tables represent adjusted-R^2 values from GAMM models with structure as described in the manuscript. All outcomes were consistent with those found for the 25 humans km^{-2} reef threshold, indicating the findings are robust.

	Threshold = 15 humans km^{-2} reef		Threshold = 20 humans km^{-2} reef

Supplementary Table 4 - As an additional analysis, 'spatio-physical' models were run for human density as calculated per *outer reef area* only (i.e. human density per outer reef) using 60, 80 and 100 humans km^{-2} outer reef as thresholds from which to categorise 'low' and 'high' impact sites (note: the thresholds are higher as the area of reef relative to humans is smaller when considering only outer reef). Values in tables represent adjusted-R^2 values from GAMM models with structure as described in the manuscript. All outcomes were consistent with those found for the 25 humans km^{-2} reef threshold, indicating the findings are robust. While certain target fish species only occur on the outer reefs, some of the fishing and gleaning activity to meet protein demands would be focused on areas other than outer reefs. Furthermore, additional impacts by local human populations (in particular nutrient input) would be diluted in cases where large areas of backreef occur. Thus, even though there are trade-offs involved with either calculation of human density, we feel that human density per total reef area is the most appropriate proxy of local human impact, and thus present those values in the main manuscript.

Supplementary Table 5 - Best-fit model outcomes based on GAMM models (with island cluster as a random effect for all response variables, and surveyor bias as an additional random effect for turf algae). A '+' indicates that the predictor was selected by model selection procedures for the respective row's model. RI values in grey boxes under model selection output (boldface if predictor was selected by model selection procedures for models with Akaike weight >0.05). (A) outcomes for low local impact sites (< 25 humans km^{-2} reef), (B) outcomes for high local impact sites (> 25 humans km^{-2} reef).
