Background: The analysis of lung artefacts has gained increasing importance as markers of lung pathology. B-line artefact (BLA), caused by a reverberation phenomenon, is the most important lung artefact. In this review, we discuss the current role of BLA in pneumology and explore open questions of the published consensus.

Methods: We summarized current literature about BLA. Also, we presented observations on healthy subjects and patients with interstitial syndrome (pulmonary fibrosis and edema), to investigate technical factors influencing BLA visualization.

Results: BLA imaging is influenced by more factors than recently assumed. When multiple BLA is visualized in the lung, they represent a sign of increased density due to the loss of aeration in the lung periphery. This condition may indicate different diseases including cardiogenic pulmonary edema, diffuse or focal interstitial lung diseases (ILD), infections and acute respiratory distress syndrome (ARDS). Correct interpretation of BLA in lung ultrasound is strongly influenced by associated sonographic signs and careful integration of all relevant clinical information.

Conclusions: BLA is useful to monitor clinical response, and may become crucial in directing the diagnostic process. Further research is warranted to clarify technical adjustments, different probe and machine factors that influence the visualization of BLA.

Keywords: Guidelines; pleural effusion (PE); consolidations; pneumonia; atelectasis; malignancies; pulmonary thromboembolism; interstitial syndrome

Introduction

Thorax and lung ultrasound has gained importance in daily routine (1-6) which is especially true in the setting of point of care ultrasound (POCUS) (7). To interpret ultrasound findings of the thorax and lung it is crucial to know the current symptoms, clinical condition, medical history, physical examination and imaging findings (8). In addition to conventional lung ultrasound, mainly targeted to the evaluation of real anatomic images of pleural effusion

Figure 1 Pneumonia. The value of direct sonographic signs is shown in a young boy with pneumonia. The infiltration resembles the liver (so-called hepatisation, right side of the image). Small abscesses can be identified using contrast enhanced ultrasound (CEUS) (left side, non-enhancing areas).

(PE) pleural masses and lung consolidations, the analysis of artefacts has gained growing importance as features of lung disease. Therefore, imaging of the anatomy (direct ultrasound findings) (*Figure 1* with pneumonia) and indirect signs (artefacts) (*Figure 2*) have to be differentiated. The diaphragm can be directly visualized (*Figure 3*).

In the present review, we discuss the current role of B-line artefacts (BLA) in pneumology and explore open questions of the published consensus (1). This review should serve as a discussing paper for future prospective studies.

B-line artefacts (BLA)

Many descriptions of BLA have been published and are contradictory (6,9-11). Lung ultrasound is based on direct visualization of structures such as consolidation, but also

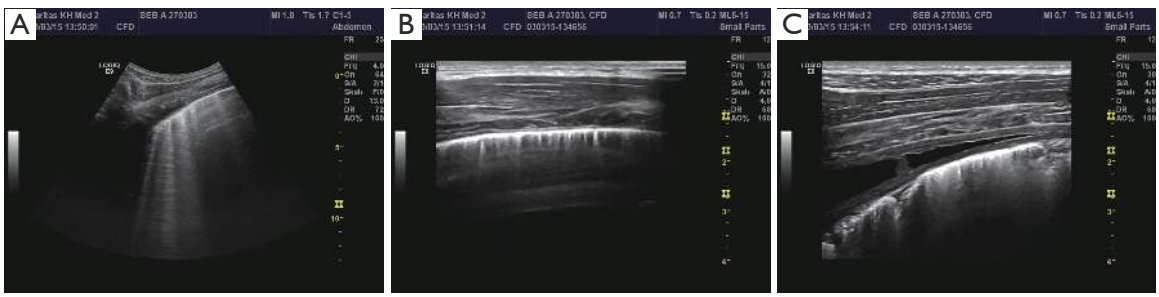

Figure 2 Pneumonia. The figure illustrates the need for a sequential approach for obtaining all the imaging information available. The value of indirect sonographic signs is shown in the same young boy with pneumonia as described in *Figure 1*. The overview with a curved array transducer shows BLA to a depth of 12 cm. A more detailed view with a high frequency transducer shows artifacts similar to BLA with much less depth penetration and additionally ALA. Examination with the same high frequency transducer then focuses on the direct ultrasound findings including pleural effusion, pleural thickening of the parietal and visceral pleura subpleural consolidations and additional the accompanying artefacts. BLA, B-line artifact; ALA, A-line artifact.

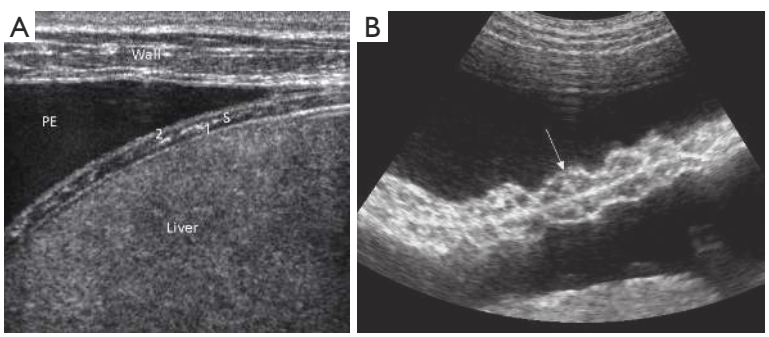

Figure 3 The anatomy of the parietal pleura and diaphragm is shown in a patient with a pleural effusion (PE). Note the thoracic wall (wall), two muscle layers of the diaphragm [1,2] next to the liver, separated by a fibrous septum (S) (A). The parts of the diaphragm are displayed using a curved array transducer (B, arrow).

Table 1 Table of possible influencing factors on BLA visualization. During a pilot study we found the following parameters influencing the detection, number, size and shape of BLA (personal observation of Christoph Dietrich and his group)

Manufacturer
Imaging techniques, e.g., tissue harmonic imaging (THI)
Compound techniques
Transducer type (e.g., cardiac, convex, linear, microconvex probes)
Transducer shape
Transducer size (image size, width)
Transducer frequency, multi-frequency
Depth penetration (transmit zone from the transducer, from the pleura)
Focus level setting, single or multiple focuses (kind of focus, e.g., electronic)
Gain, depth gain compensation (DGC)
Dynamic range
Persistence
Tissue equalization technology
Frame rate
Line density
Smoothing parameters [depending on the equipment used, e.g., "edge" (sharper or smoother border), "delta" (to control the degree of contrast resolution within an image), space time (temporal resolution, spatial resolution)]
Other preprocessing parameters
Post processing parameters
Patient's position, depth and circle of respiration
Area of examination
Focal changes of the pleura with or without pleural effusion
Examiner
Time of examination
Inter- and intra-observer variability
Pulmonary and extra-pulmonary disease

BLA, B-line artifact.

on the analysis of artefacts. B-line-like artefacts were first demonstrated by Ziskin and colleagues in 1982 in a patient with an abdominal shotgun wound, who used the term 'comet tail artefact' (12,13). The definitions of BLA and nomenclature have changed over time. Comet tails, ultrasound lung comets, and BLA is synonymously used in the literature to describe the same physical artefacts, and not exclusively in connection with lung and pleura (3). To clarify the field, a consensus document suggested that the term BLA should be used when referring to the lung (1).

According to the international consensus conference, BLA is defined as discrete laser-like vertical hyperechoic reverberation artefacts that arise from the pleural line (previously described as "comet tails"), which extend to the bottom of the screen without fading, and move synchronously with lung sliding. The artefact consists of a trail of dense echoes that resembles a distally oriented comet-tail (1,14).

The ultrasound examination of BLA has been standardized (1,2,15). Brattain *et al.* developed algorithms to evaluate the feasibility of diagnostic assistants to reliably quantify BLA in a sample set of clips from one machine (16). The normal lung is characterized by the absence, or presence of very few BLA (less than three per field of view). BLA were found in 37% of elderly subjects, but only 10% of young healthy subjects (17). In a recently performed pilot study (personal data of Christoph F Dietrich *et al.*, not published) we identified distinctive influencing factors on the detection and characterisation of BLA, which is summarized in *Table 1*. The reduction of impedance between lung parenchyma and soft tissues of the chest wall and the increased thickness of interlobular septa might explain these findings (17). Three or more BLA between two ribs in a single scan indicates a subpleural component of the interstitial syndrome (18).

Case series

We present here the personal observations (Christoph F. Dietrich) on healthy subjects and patients with interstitial syndrome (pulmonary fibrosis and edema), to investigate technical factors influencing BLA visualization. Analysis was based on lung ultrasound studies performed on the same subject utilizing different equipment (Siemens Acuson Sequoia, Hitachi Ascendus, Hitachi 8500, GE Logiq E9, Siemens S2000, Siemens Acuson 300, Supersonic Aixplorer, Mindray M9, Mindray Resona, VScan Dual probe, Toshiba Aplio). A variety of possible influencing factors on BLA were investigated (*Table 1*). Some of the influencing factors summarized in *Table 1* are illustrated in the *Figures 4* and *5*.

Review of the literature

Since BLA are artefacts caused by physiologic changes in the lung parenchyma, they are potentially influenced by machine settings and signal processing. Sophisticated pre- and post-processing should be turned off if possible or

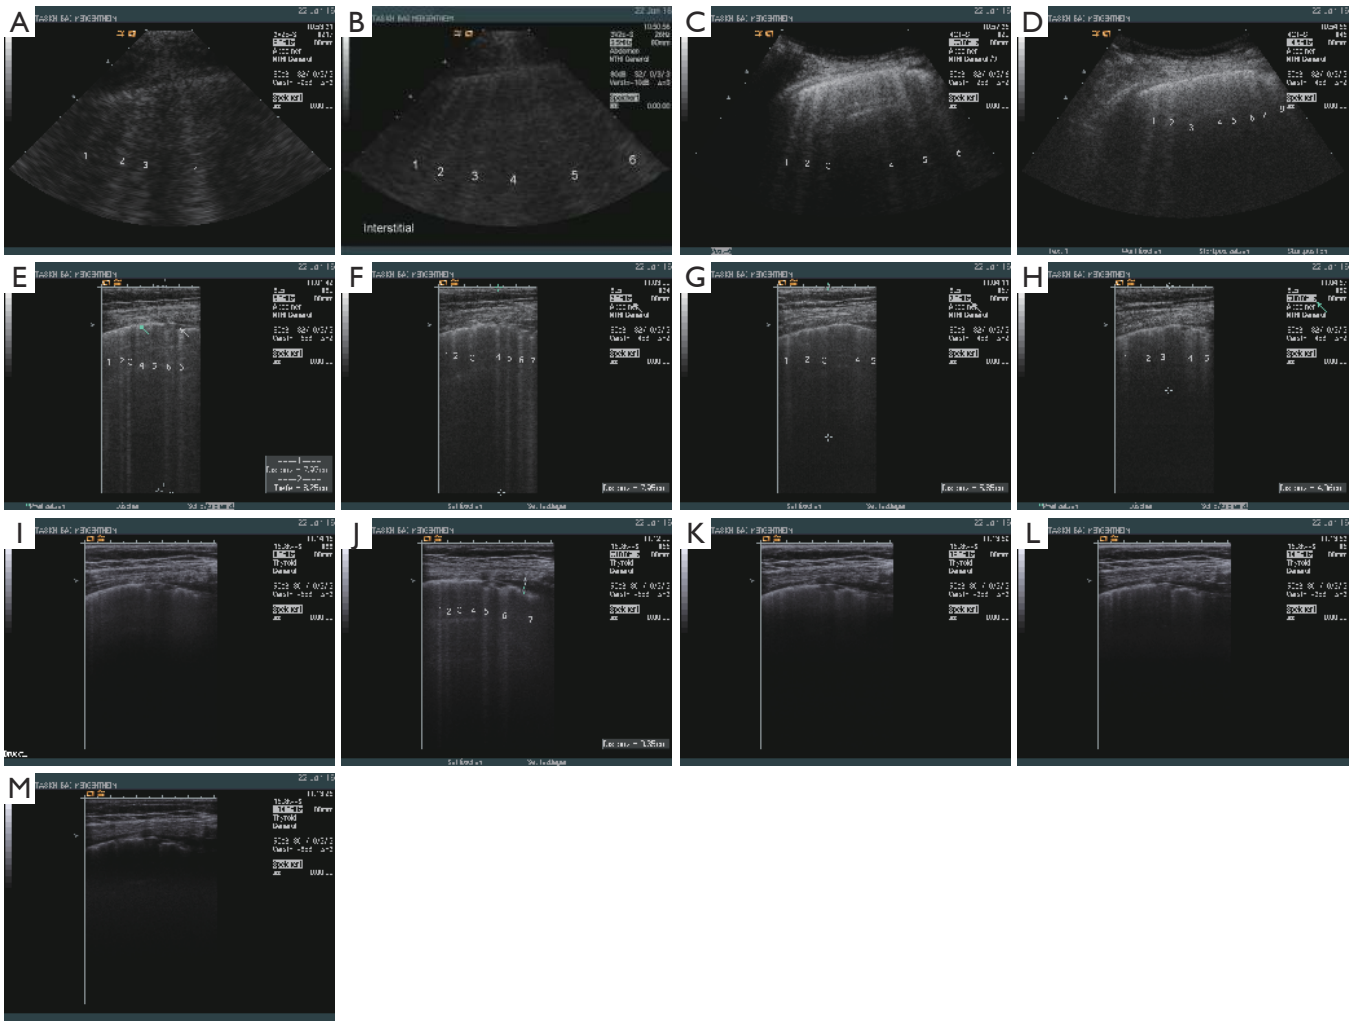

Figure 4 The influence of ultrasound transducers and transducer frequency on BLA was examined in a patient with rheumatoid arthritis and lung fibrosis being treated with methotrexate. The examinations were performed using Acuson Sequoia with different multifrequency transducers, 3V2c-S (cardiac), 4C1-S (curved array abdominal), 8L5 (linear), 15L8w-S (linear), using tissue equalisation modus (TEQ) for all sequences. The sequences allow comparison of findings using these different techniques. The fibrotic changes of the pleura could be delineated only using high frequency transducers. Influencing factors examined were the transducer itself, the frequency used, harmonic imaging (HI), depth penetration, focus zone, location, and others (not shown). Both, 3V2c-S [2 MHz (A) and 3.5 MHz (B)] and 4C1-S [3 MHz (C) and 4.5 MHz (D)] showed multiple BLA indicating typical signs of lung fibrosis. The size, shape, depth penetration and other features were somewhat comparable similar to the findings with the 8L5 transducer examined with 5 (E), 6 (F), 7 (G), and 8 MHz (H). The higher the frequency, the lower the penetration. The 15L8w-S transducer with 8, 10, 12 and 14.0 MHz without and with HI revealed significant lower depth penetration and different amounts of BLA (I-M). Less BLA was observed in the higher frequencies. The figures illustrate that high frequency transducer information on direct pleura findings is important for correct interpretation since pleural irregularities, subpleural consolidation and the very small amount of pleural effusion could only be seen using high frequency transducers. BLA, B-line artifact.

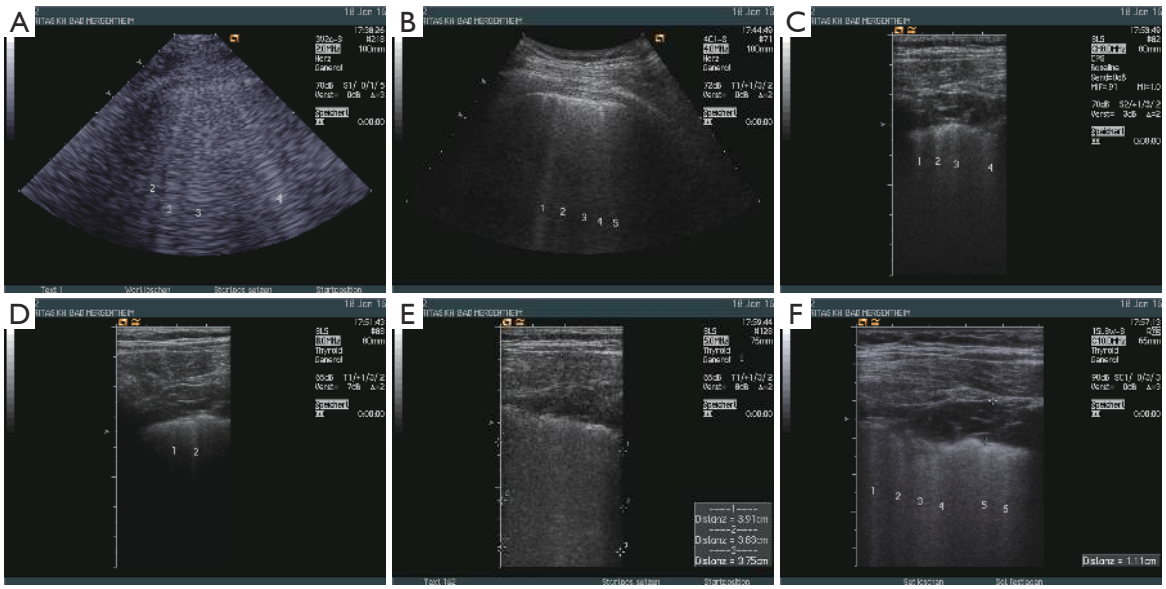

Figure 5 The influence of ultrasound transducers and transducer frequency on BLA visualization was examined in a patient with mixed lung fibrosis and edema and focal pleural irregularities. The examinations were performed using Acuson Sequoia with different multifrequency transducers, 3V2c-S (cardiac), 4C1-S (curved array abdominal), 8L5 (linear), 15L8w-S (linear). The images demonstrate that the focal pleural irregularity was only detected using the high frequency probes, which might influence the imaging characteristics and accompanying signs in BLA patterns. The sequence demonstrates that not all transducers show the same findings. Influencing factors were the transducer itself, frequency used, harmonic imaging (HI), depth penetration, focus zone. The 3V2c-S (2 MHz) (A) and 4C1-S (4 MHz) (B) transducers showed multiple BLA indicating both fibrosis and edema. The amount of BLA and the surrounding artefacts were different. Multiple BLA were detected using 8.0 MHz with harmonic imaging (C) and less without harmonic (D). The "sound of lung water" (pulmonary edema) is best shown by 8L5 using 5.0 MHz (E). The 15L8w-S transducer revealed multiple BLA with 10.0 MHz (F). BLA, B-line artifact.

limited to a minimum to allow comparability. Sperandeo *et al.* compared the BLA examinations done with a low-medium frequency (3.5–5.0 MHz) convex probe and a high-frequency (8–12.5 MHz) linear probe. Counts of BLA were higher when convex probes were used (14). However, other more accepted studies performed with convex probe (15), linear probe (19), cardiac probe (20) and microconvex probe (21) showed similar findings on the visualization of BLA in a variety of settings and patients and by using different machines. Microconvex 2–5 MHz transducer was recommended by Lichtenstein *et al.* because this transducer provides an extended view of the pleural surface and penetrated deeply enough to verify the characteristic of vertical artefacts. The abdominal probe at 3–5 MHz has the advantage of coupling a wider field of view of the pleura and detection of deep structures (15). The additional use of high frequency transducers to identify pleural and subpleural changes was generally neglected. The higher the frequency the lower the penetration but other factors also influence the depth of penetration, e.g., harmonic imaging.

We conclude that BLA looks different at different levels, depending on the frequency and transducer shape used. The depth of penetration should be standardised to 4–8 cm starting from the pleural line (depending on the frequency used). The focus of the image should be set at the level of the pleural line, focusing the most energy for reflection and reverberating. Tissue harmonic imaging, compound imaging, different pre- and post-processing techniques, filters and interpolation algorithms can alter the appearance of BLA.

Comments

Indeed, there is the possibility that visualization of BLA may vary by changing technical adjustments, machines and probes. However, there are two points to consider regarding this hypothesis. The first is that the normal adjustment of the lung image should be optimized simply by regulating the gain and all the other basic settings. In the aerated lung, the pleural line should be well visualized. The focus should be set at the level of the pleural line and the subpleural zone

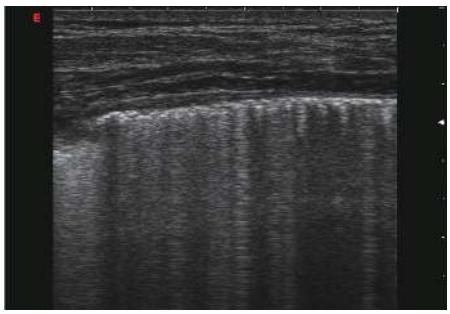

Figure 6 Sarcoidosis. A 26-year-old man got a cold by biking. Dry cough, left sided pleuritic pain and dry rales on auscultation was observed. Ultrasound shows an interrupted visceral pleura reflex with small subpleural consolidations and multiple irregular BLA. Extrapulmonary manifestations of sarcoidosis are often observed. BLA, B-line artifact.

adjusted for optimal imaging showing the typical granular echoic aspect, regardless of the probe and frequency used. The second consideration is that a slight variability in the number of visible BLA may have no influence on the final diagnostic adjudication (6). However, new studies are needed to verify the exact influence of diverse adjustments, machines, probes and frequencies on the image generation of BLA, focalized on whether these changes may effectively bias the diagnostic criteria in lung ultrasound. In the specific pneumology setting, such as the high resolution imaging study of pulmonary fibrosis, these influencing factors may be of more importance than in the emergency setting.

Are BLA reproducible?

BLA is reproducible and identifying them is easy to learn by operators with different skill and expertise (15,20,22-28). In a recently published large multicenter study, Pivetta *et al.* obtained a Kappa statistic for agreement of 0.94 on 1,200 scans performed by several operators, reviewed by an expert and two residents with limited training. In the same study, intraobserver agreement was 0.97 for the expert operator and 0.92 for the physicians with limited training (29).

The use of BLA in clinical practice

It is crucial to incorporate the current complaints, clinical condition, medical history, physical examination and imaging results to interpret ultrasound findings of the thorax and lung. One should always ask first, does the severity of the patient's clinical condition correlate with the extension and diffuse pattern of BLA? Only then should bedside decisions be made on lung ultrasound BLA findings (30) as the meaning of BLA, by definition a low specificity sign, can dramatically change.

Which diseases can be differentiated using BLA?

BLA diagnoses a loss of peripheral lung aeration due to interstitial disease involvement, but considering only BLA it is not possible to differentiate the cause. BLA appears with pulmonary edema (diffusely and homogeneously distributed) and congestive heart failure (31-36) lung contusions, pneumonia and acute respiratory distress syndrome (ARDS) most commonly (typically focally or inhomogeneously distributed). If ARDS is diffuse, it can appear like pulmonary edema and potentially bilateral lung contusions. While they have been reported in pulmonary edema, pulmonary fibrosis, pneumonia, or ARDS, single focal BLA can also be observed in healthy individuals (31). However when integrated with clinical decision making, one can differentiate pulmonary edema or ARDS from interstitial pneumonia, pulmonary fibrosis, lung contusions and other conditions.

The presence of multiple diffuse bilateral BLA indicates the interstitial syndrome and the number of lines increases with decreasing air content and increasing lung density. Causes of the interstitial syndrome include the following conditions (1):

- Pulmonary edema of various causes (including cardiogenic pulmonary edema and ARDS);
- Interstitial pneumonia or pneumonitis;
- Diffuse parenchymal lung disease (pulmonary fibrosis).

Some studies indicate good correlation between the number of BLA and the grade of pulmonary edema (15,37,38). Increased extravascular lung water (EVLW) is the main determinant of multiple and diffuse BLA on chest ultrasonography (39,40). BLA resolution appears to occur in real time as fluid is removed from the body. Together these data support thoracic ultrasound as a useful and potentially superior method for evaluating physiologic response to the removal of fluid (20,23,41).

Interstitial lung diseases (ILD) (diffuse, focal)

The ultrasound assessment of ILD is determined by the presence and semi-quantification of BLA (*Figure 6*). The distance between each of the two adjacent BLA correlates

with the severity of disease (42,43). A BLA cut-off value of BLA ≥4 was suggested as the criteria for pulmonary fibrosis in transthoracic lung ultrasound (44). A focal sonographic pattern of the interstitial syndrome may be seen in pleurisy (45) and at the margin of pneumonia, contusion, in pulmonary infarction, atelectasis and neoplasia (46-48). Therefore, it is necessary to consider the focal interstitial syndrome within the context of the history and clinical findings. Lung ultrasound might prove a suitable method for screening patients with systemic sclerosis for incipient pulmonary structural changes (49,50).

Pneumonia

Meta-analyses confirm that pneumonia can be diagnosed using lung ultrasound (2,11). BLA is often seen in the areas adjacent to the consolidation, likely as an expression of inflammatory perilesional edema. Pleural line abnormalities and PEs were consistently associated with areas of confluent BLA and/or lung consolidation (51).

Chronic obstructive pulmonary disease (COPD)

Lung ultrasound appears to be particularly useful in differentiating exacerbations of COPD, a condition that does not show BLA, from decompensated heart failure (52).

Acute respiratory failure

The primary diagnosis of pulmonary interstitial fluid in the emergency setting is crucial for the differentiating between cardiogenic and non-cardiogenic factors determining acute respiratory failure (53). BLA has been demonstrated as a useful primary diagnostic test in this context. In patients with acute lung injury (ALI)/ARDS, a given degree of lung aeration (referring to well defined CT scan entities) corresponds to a specific ultrasound pattern (7,21,54,55). Lung ultrasound is also a useful, non-invasive tool in predicting hydration status in mechanically ventilated patients (56).

Monitoring fluid overload

Monitoring of different states, e.g., fluid overload in hemodialysis, semi-quantification of EVLW and pulmonary aeration has been studied as well. The change in BLA is rapid and BLA responds quickly to changes in lung water content. Thus, as a fluid overloaded patient is dialyzed, it is possible to track BLA resolution in real time as fluid, and therefore EVLW, is removed from the body (25,41,57-59). In patients with cardiogenic pulmonary edema, evaluation of BLA and a change (decrease) in their number enables noninvasive monitoring of response to therapy (15).

Pulmonary embolism

Severe pulmonary embolism with acute respiratory failure shows the A profile (regular sliding with absence of BLA) with a 95 % sensitivity (60). The best diagnostic strategy to confirm or exclude suspected pulmonary embolism is the combination of clinical assessment, plasma D-dimer measurement and computed tomographic pulmonary angiography (CTPA). Lung US looking for lung consolidation cannot be considered as the first imaging test but a possible alternative to CTPA when the latter is contraindicated or not available (61). In the emergency department and intensive care setting, a combined strategy based on a multiorgan ultrasound (veins, heart, lung) was shown to improve diagnostic accuracy compared to lung ultrasound alone (60,62).

Open questions

Future research protocols on lung artefacts should focus on:

(I) The role of different transducers in the evaluation of BLA;

(II) The possible influencing factors (*Table 1*) in the visualization of BLA and whether these may be of any practical importance in changing the diagnostic criteria for the first diagnosis of interstitial syndromes and in monitoring techniques of pulmonary congestion and aeration;

(III) The clinical significance of subtle pleural fluid, pleural irregularities, pleural nodules and small subpleural consolidations, studied by higher resolution ultrasound imaging;

(IV) The role of endoscopic ultrasound in evaluating BLA has not been examined so far (63-66).

Conclusions

BLA has been incorporated into the diagnosis of lung diseases and gained importance. BLA are reverberation artefacts, displayed on the screen as vertical echogenic lines, which are easily identified. BLA are signs of diffuse or focal interstitial lung involvement and in general is considered as a sign of partial loss of aeration and increased

density of peripheral lung parenchyma. In conjunction with comprehensive review of other clinical information including the clinical setting and patient's condition, BLA assessment may become crucial in directing the diagnostic process. BLA is useful to monitor clinical response, in critically ill ICU patients and outpatients in rheumatology, pulmonology, cardiology and nephrology settings. Further research is warranted to clarify technical adjustments, different probe and machine factors that influence the visualization of these artefacts in the normal lung and in diseases, and in definitions to increase the specificity of BLA in the myriad of different settings it can be applied to.
