Abstract

Magnesium ions have an important role in the structure and folding mechanism of ribonucleic systems. To properly simulate these biophysical processes, the applied molecular models should reproduce, among others, the kinetic properties of the ions in water solution. Here, we have studied the kinetics of the binding of magnesium ions with water molecules and nucleic acids systems using molecular dynamics simulation in detail. We have validated the parameters used in biomolecular force fields, such as AMBER and CHARMM, for Mg^{2+} ions, and also for the biological relevant ions, Na^+ , K^+ and Ca^{2+} together with three different water models (TIP3P, SPC/E and TIP5P). The results show that Mg^{2+} ions have a slower exchange rate than Na^+ , K^+ and Ca^{2+} in agreement with experimental trend, but the simulated value underestimates the experimentally observed Mg^{2+} -water exchange rate with several orders of magnitudes, irrespective of force field and water model. A new set of parameters for Mg^{2+} was developed to reproduce the experimental kinetic data. This set also leads to better reproduction of structural data than existing models. We have applied the new parameters set to Mg^{2+} binding with a mono-phosphate model system and with the purine riboswitch, add A-riboswitch. In line with the Mg^{2+} -water results, the newly developed parameters show a better description of the structure and kinetic of the Mg^{2+} -phosphate

binding than all other models. The characterization of the ion binding to the riboswitch system shows that the new parameter set does not affect the global structure of the ribonucleic acid system or the number of ions involved in direct or indirect binding. A slight decrease in the number of water-bridged contacts between A-riboswitch and Mg²⁺ ion is observed. The results support the ability of the newly developed parameters to improve the kinetic description of the Mg²⁺ and phosphate ions and their applicability in nucleic acid simulation.

Keywords: *ion-water exchange, Mg²⁺ ions, molecular dynamic simulations, biomolecular force field, RNA systems.*

Introduction

Metal cations play a fundamental role in folding and catalysis of ribonucleic acid (RNA) systems.¹⁻³ RNAs are biopolymers characterized by carrying high negative charge due to their phosphor-diester backbone, and by forming a wide variety of complex tertiary structures with the negative phosphate groups packed close together. The negative charges work against the formation of a compact folded structure, while the presence of positive ions facilitates folding by compensating the high negative charge densities formed when the negative groups pack closely. Metal ions can bind specific sites within a folded RNA. For example, the crystal structure of 50S ribosomal subunit shows 60 Mg^{2+} ions directly chelated by RNA, and some of them are deeply buried inside the ribosomal structure.⁴ On the other hand, spectroscopic studies and thermodynamic data show that the metal ions can interact non-specifically through water bridges with the electrostatic field generated by the RNA system.⁵ These electrostatic interactions make a large contribution to the thermodynamic stability of RNA secondary and tertiary structure, and also influence the kinetic mechanism of folding.^{6, 7} The monovalent cations, sodium (Na^+) and potassium (K^+), and the divalent cations, magnesium (Mg^{2+}) and calcium (Ca^{2+}) influence the structure and folding of RNA in different ways. Divalent ions stabilize RNA tertiary structure more effectively than monovalent ions. In an early work, Leroy et al. showed that the native structure of tRNA could not be achieved in low Na^+ concentration, but was restored after the addition of divalent ions.⁸ Recently, Draper provided a rigorous description of the stabilization of RNA structure by divalent ions.⁹ The size of the ions also matters. Small ions, such as Mg^{2+} , are more stabilizing than larger ions such as Ba^{2+} and the activation energy of folding is inversely proportional to ionic radii, meaning that the folding kinetics is slower with Mg^{2+} than with Ba^{2+} .⁷ Among the metal ions, Mg^{2+} ions have been shown to be the most relevant for RNA stability and folding.^{10, 11} Mg^{2+} ions are characterized by a high charge density due to the +2 charge and small radius ($\sim 0.65 \text{ \AA}$). This gives the ion the ability to transfer a large amount of charge into sterically confined spaces and mitigate the negative charge of RNA structures.⁴ The high charge density also results in extremely strong interactions with water molecules. Mg^{2+} forms a complex of six water molecules ($[\text{Mg}(\text{H}_2\text{O})_6]^{+2}$) packed in an octahedral arrangement and surrounded by a second solvation shell of twelve less strongly bound water molecules.^{12, 13} Mg^{2+} ion binds to RNA in two ways: directly by replacing one of the waters in the first solvation shell with an RNA atom (inner sphere contact) or indirectly with one of the first shell water molecules bridging between the ion and the RNA acceptor atom (outer sphere contact) (Figure 1).

The view that the main stabilizing contribution comes from direct binding has received less support lately and it is now believed that the outer sphere contacts are responsible for most of the stabilizing effect that Mg^{2+} ions have on RNA structures.^{14, 15} The importance of indirect interactions can be attributed to the high energies (due to the partial dehydration of the $[\text{Mg}(\text{H}_2\text{O})_6]^{+2}$ complex⁵ and RNA systems¹⁶) required for direct binding, resulting in a very slow exchange rate of waters in the first hydration shell. This makes the energy and kinetics associated with the partial dehydration of water around the ion an important factor when predicting or modeling the binding of Mg^{2+} ion to RNA.

Experimentally, X-ray crystallography provides structural information on the coordination of Mg^{2+} ions to RNA¹⁷⁻¹⁹ and ²⁵Mg NMR experiments^{20, 21} have been used to determine kinetic and thermodynamic parameters for the ion binding to RNA. These techniques provide mainly information on Mg^{2+} ions binding directly to RNA, but most of Mg^{2+} ions bind indirectly to RNA and are hard to observe with spectroscopic methods. New emerging techniques, like anomalous small angle X-ray scattering²² and NMR cross correlated relaxation rates,²³ show promising results studying the “diffuse” ions but still, most ion-RNA interactions remain hard to study experimentally. Computational approaches can fill in many of the voids of the experimental techniques. Poisson Boltzmann studies have predicted Mg^{2+} induced stabilization of tRNA^{Phe}²⁴ and recent, more advanced models, have predicted Mg^{2+} -RNA binding properties.²⁵ Ab initio and hybrid methods have been used to assess the structure and energy contribution of Mg^{2+} binding to guanine²⁶ and guanine-cytosine base-pair.²⁷ Classical Molecular Dynamics (MD) simulations have been widely used to provide directly atomistic detailed information on the dynamics and structural ion-binding feature of RNA systems.^{16, 28-31} For example, Auffinger and Westhof showed the sequence dependence of K^+ ion binding to nucleic acids using nanosecond atomistic simulations,¹⁶ and recently a study by Singh et. al. showed how cations are retained in major groove tunnels of an RNA molecule.³¹ The limitation of these methods lies in the accuracy of the empirical force fields and in the length of the simulation, which typically ranges up to hundreds of nanoseconds, making it impossible to directly sample the slow exchange^{32, 33} (on the order of microseconds) between Mg^{2+} and waters with standard simulations. Biomolecular force fields are usually parameterized using simple model systems and validated against experimental properties and the functional form of such force field usually do not include polarization terms. Metal ion parameters have been parameterized against available data for structural and thermodynamic properties in water solutions, such as first solvation shell structure or solvation free energy.³⁴⁻³⁶ While being an important property of ions, the calculation of

solvation free energy for metal ion in solution has been shown to be heavily dependent^{37, 38} on the system size and simulation conditions (i.e. long-range electrostatic descriptions).

Experimentally, ion solvation free energy estimation usually relies on the free energy associated with the solvation of H^+ as reference. Thus, published experimental scales for the ion solvation free energy can shift up and down (up to 40 kcal mol^{-1}), depending upon the chosen reference.

Here, we want to understand how the ion models reproduce the kinetic features of the ion-binding, such as activation energy or ion exchange rate, for which experimental data have become available since the initial force field parameterizations of Mg^{2+} . We will focus on the biomolecular force fields used in nucleic acid simulations (such as AMBER^{39, 40} and CHARMM^{41, 42}). Our final aim will be to achieve a reliable description of the kinetic properties of ion-RNA binding. The lack of polarization term in the used functional form might be a limiting factor to a very accurate description for Mg^{2+} ion interactions, but we show that there is space to improve the ion description using a simple fix charge model.

The water exchange of most biologically relevant ions is too fast to be studied experimentally, but for Mg^{2+} ions, experimental data on water exchange have been published^{32, 33} and kinetic parameters for magnesium binding to phosphate-containing systems are available from NMR experiments.^{20, 21, 43}

We begin with investigating the structural and kinetic properties of ion binding from simple (ions in water solution) to more complex systems (RNA and ions in water solutions). First, we test the existing force field parameters for Na^+ , K^+ , Mg^{2+} and Ca^{2+} ions, by comparing structural and kinetic properties of the aqueous ion obtained from MD simulations, with experimental data. Each ion has been simulated in explicit water solution using the TIP3P⁴⁴ water model. Then, we focus on Mg^{2+} ions, since this ion shows the greatest deviations from experimental data. We have investigated the effect of the different types of water model and of different sets of ion parameters. In addition to the TIP3P water model, we have tested SPC/E⁴⁵, another computationally cheap and widely used model in biomolecular simulations and the more complex and expensive five-site model, TIP5P⁴⁶. We have selected the models based on their different dielectric constants and/or diffusion coefficients. For magnesium ions, we have used the parameters developed by Åqvist³⁴ (as implemented in the AMBER99^{39, 40} force field) and implemented in CHARMM27^{41, 42} force field. Since the observed deviation from experimental data persists with all combinations of force fields and water models, we have moved on with a re-parameterization of the ion parameters. The new set of parameters

for Mg^{2+} ions is optimized to fit the experimental exchange rate of the first shell water molecules.

In the second part, we focus on the interaction of Mg^{2+} ions with an isolated phosphate group and/or with the whole RNA molecule. We have investigated the effect of water and ion models on the ion-phosphate interaction. As a model system for an RNA phosphate group, we have used dimethyl phosphate (DMP) ions (see insert in Figure 5) to mimic the RNA backbone, and for modeling a biological relevant RNA system, we have chosen the RNA purine riboswitch, *add* A-riboswitch.⁴⁷⁻⁴⁹ The adenine riboswitch is one of the smaller natural riboswitches (71 residues), whose folding is affected by the presence of Mg^{2+} ions.^{50, 51} The adenine-riboswitch is also a good example of intricate RNA globular folding (see Figure 2), and the X-ray structure⁴⁷ indicates a number of well-defined binding sites for the ions, both *via* inner and outer sphere contacts. We have analyzed how the hexa-hydrated ions bind to RNA, both from a structural and kinetic point of view and compared the results obtained with the CHARMM27d force field.

Theory and Methods

Ion-water Interactions

Non-bonded interactions between atoms in atomistic force fields are described by an electrostatic term, expressed by a Coulombic potential, and the van der Waals term, expressed by a Lennard-Jones potential:

$$V_{NONBONDED} = \sum_{\substack{\text{nonbonded} \\ \text{pairs}, ij}} \left(\frac{q_i q_j}{4\pi\epsilon_0\epsilon_1 r_{ij}} + \epsilon_{ij} \left[\left(\frac{R_{\min,ij}}{r_{ij}} \right)^{12} - 2 \left(\frac{R_{\min,ij}}{r_{ij}} \right)^6 \right] \right) \quad (1)$$

where i, j are all atom pair combinations within the cutoff distance, q_i is the charge of the atom i , ϵ_0 is the permittivity of vacuum and ϵ_1 is set to 1 for explicit solvents, respectively and r_{ij} is distance between the atoms i and j . ϵ_{ij} and $R_{\min,ij}$ are the combined atomic Lennard-Jones parameters, specifying the depth (ϵ_{ij}) and position ($R_{\min,ij}$) of energy minimum. ϵ_{ij} is obtained by the geometric mean of the two atomic parameters, $\epsilon_{ij} = \sqrt{\epsilon_i \epsilon_j}$ while $R_{\min,ij}$ is obtained by the arithmetic mean of the two atomic parameters, $R_{\min,ij} = \frac{R_{\min,i} + R_{\min,j}}{2}$. The

Lennard-Jones part of eq. 1 can be expressed in a simplified form where the parameters have been separated into one attractive and one repulsive factor:

$$V_{LJ} = \frac{C_{12}}{r^{12}} - \frac{C_6}{r^6} \quad (2)$$

where $C_{12} = \epsilon_{ij} (R_{\min,ij})^{12}$ is the repulsive factor and $C_6 = 2\epsilon_{ij} (R_{\min,ij})^6$ is the attractive factor.

In the re-parameterization of Mg^{2+} ion, we start from the CHARMM27^{41, 42} parameters (labeled as $\text{MG}^{\text{CHARMM}}$) and gradually modify the repulsive term (C_{12}) to fit the experimental exchange rate. This new set of parameters is labeled as MG^{NEW} .

Simulated Systems and Force Fields

Ion-water system: Simulations have been performed of four ions, Mg^{2+} , Ca^{2+} , Na^+ and K^+ in water solution. Parameters implemented in CHARMM27 force field^{41, 42} have been used for the metal ions and the TIP3P⁴⁴, SPC/E⁴⁵ and TIP5P⁴⁶ models for water molecules. The Mg^{2+} ion has also been simulated using parameters developed by Åqvist³⁴ and Lorentz-Bertholet adapted to AMBER99 force field^{39, 40}, labeled as $\text{MG}^{\text{LB-Åqvist}}$, and using the parameters obtained in this work.

All the ions were centered in a rhombic dodecahedron box with 44 Å face-to-face dimension and solvated with 1930 water molecules.

Mg²⁺-phosphate system: Simulations were performed on a model system of Mg²⁺ bound to a “nucleic acid”-type phosphate, consisting of a dimethyl phosphate (DMP) molecule in water solution. The DMP molecule was described using the CHARMM27 all-hydrogen force field^{41, 42}. The starting structure of the Mg²⁺ bound to one of the phosphate oxygens (O_P) was taken from the adenine-riboswitch structure (see below). The solvation box was identical to the one used for the ion-water systems.

MgCl₂ system: The behavior of Mg²⁺ in solution with anions was investigated by setting up and running systems (identical to the ion-water systems in all other aspects) with a neutral MgCl₂ solution at two ion concentrations. A 0.2 M solution was achieved with 7 Mg²⁺ and a 1.0 M solution with 35 Mg²⁺ ions.

Adenine riboswitch system: The complex of the *add* A-riboswitch with the purine base, adenine, was simulated in water solution. The CHARMM27d parameters, which include an update of the 2'-hydroxyl parameters⁵² was used to describe the RNA system. As a starting structure, we used the X-ray structure of Serganov *et al.*⁴⁷ (PDB⁵³ ID 1Y26).

Hydrogen atoms were added using a standard CHARMM procedure⁵⁴. The riboswitch complex was solvated with 10471 TIP3P water molecules in a rhombic dodecahedron box with an 80 Å face-to-face dimension. The X-ray structure includes 5 Mg²⁺ ions. To obtain a zero net charge of the system, we added 30 additional Mg²⁺ ions at random positions in the bulk water.

Simulation Protocols

All MD simulations were carried out using the program CHARMM36^{55, 56} using periodic boundary conditions. The fast lookup routines for non-bonded interactions⁵⁷ was applied when possible. The SHAKE algorithm⁵⁸ was used to constrain all bonds involving hydrogens. Newton's equations of motion were integrated using the leap-frog algorithm with a 2 fs time step. The systems were solvated with a scheme where overlapping water molecules (having the water oxygen within 2.8 Å of any solute heavy atom) were removed.

A 12 Å cutoff was used for particle-particle interactions and the non-bonded list was constructed using a 16 Å cutoff and was heuristically updated every time an atom moved >2 Å since the last update. The long-range electrostatics were treated with the particle mesh Ewald method (PME)^{59, 60}, a grid of 1 Å and a kappa value of 0.34. The simulations were run

at constant pressure (1 atm) and temperature (298 K) using Berendsen barostat and thermostat⁶¹ with a coupling time of 2 ps and a compressibility of $4.63 \cdot 10^{-5} \text{ atm}^{-1}$.

An energy minimization was made on the systems in the following way: first 150 steepest descent (SD) and 150 adopted-basis Newton-Raphson (ABNR) steps with the solute atoms restrained with a force constant of $15 \text{ kcal}/(\text{mol} \cdot \text{Å}^2)$ followed by 150 SD and 150 ABNR steps with no restraints.

The ion-water systems were simulated for 10 ns each. Convergence was assessed by dividing the trajectories in two 5 ns segments and comparing the radial distribution functions (RDFs) and the residence time of water around the ion. The residence times were found to differ $<2 \%$ between the first and second half of the trajectories and the RDFs were virtually identical in terms of shape and position of maxima and minima. The Na^+ -water system was run for 40 ns for an additional verification of convergence.

To avoid structural distortions from non-optimal positions of the Mg^{2+} ions in the adenine-riboswitch complex, the system was prepared in several steps⁶². First, energy minimizations (150 SD and 150 ABNR steps) and 200 ps of MD were performed with restraints on both RNA and ions. This procedure was then repeated two times, first, with restraints removed on ions and finally, with all restraints removed. Finally 12 ns unrestrained simulation was run to equilibrate the ion positions followed by 10 ns of production time for the RNA systems.

Simulation Analyses

Radial distribution functions (RDF), $g(r)$, of water molecules around the cation were calculated from the unrestrained trajectories over 200 points with a bin size of 0.04 Å (8 Å in total). A potential of mean force (PMF) can be obtained by inverting the RDF:

$PMF = -RT \ln(g(r)) + c$. The constant c can be ignored since we are only interested in the relative change in free energy.

Umbrella Sampling

Potential of mean force (PMF) profiles were calculated using umbrella sampling with the harmonic bias potential $w_i(x) = k(x - x_i)^2$ along a reaction coordinate, x , defined as the distance between the Mg^{2+} ion and the water oxygen (O_w) or the distance between Mg^{2+} and the phosphate oxygen (O_p) in the DMP-system. We used a total of 53 simulation windows with the reference value for the bias potential x_i ranging from 1.6 Å to 6 Å in 0.1 Å intervals, and from 6 Å to 10 Å in 0.5 Å intervals. Initial conformations for each window were

generated by running 20 ps of MD at each point along the reaction coordinate, with $k = 500$ kcal/(mol·Å²), using the last structure in each window as the starting structure in the next window.

In the production phase each window was run for 1.0 ns (of which the first 0.2 ns was equilibration time) with a force constants of $k = 150$ kcal/(mol·Å²) for the first windows up to 6 Å and $k = 10$ kcal/(mol·Å²) for the last windows between 6 Å and 10 Å. The PMF curves were constructed from the resulting distance distributions using the Weighted Histogram Analysis Method^{63, 64} with a tolerance of 10^{-5} . All the curves have been translated to zero at a Mg²⁺-O_{W/P} distance of 8 Å for ion-O_w and 9 Å for the Mg²⁺-O_P profiles. When the distance between the two mass centers is constrained, free rotation of the solute-solute connecting vector remains possible and larger volume elements are sampled at larger distances. This leads to an entropic contribution, $S = 2RT \ln(x)$, to the average constraint force that must be subtracted out.

Error bars were obtained by dividing the trajectories of each window into three parts and calculating the standard deviation between them. For the three PMFs of Mg²⁺-O_w using the TIP3P water model, error bars were calculated using three independent replica simulations, each with 1 ns of simulation of each point along the reaction coordinate.

Calculation of Rate Constants

Transition state theory gives a relation between the rate constant (k) and the free energy of activation, ΔG^\ddagger :

$$k = A e^{-\Delta G^\ddagger / RT}, \quad (4)$$

where A is a pre-exponential factor with unit s^{-1} , T the temperature and R is the gas constant.

The pre-factor describes the frequency at which a system oscillates in its minima and the exponential factor describes the probability the oscillations have to cross the barrier of ΔG^\ddagger .

To determine the pre-exponential factor we use two approaches: 1) by directly calculating the oscillation frequency of ion-water oxygen distance in an unrestrained simulation 2) by the second derivative of the PMF as a function of the atom pair distance at the bottom of the well

according to $A = \frac{1}{2\pi} \sqrt{\frac{E''}{\mu}}$, where E'' is the second derivative of the PMF and μ is the

reduced mass of the atom pair. The second derivative was determined by fitting a second order polynomial to the bottom data points, symmetrically centered around the minima of the

energy well. The two approaches give very similar values: $6.6 \cdot 10^{12} \text{ s}^{-1}$ vs. $6.7 \cdot 10^{12} \text{ s}^{-1}$ (for $\text{Na}^+\text{-O}_w$); $5.0 \cdot 10^{12} \text{ s}^{-1}$ vs. $5.0 \cdot 10^{12} \text{ s}^{-1}$ (for $\text{K}^+\text{-O}_w$); $1.4 \cdot 10^{13} \text{ s}^{-1}$ vs. $1.3 \cdot 10^{13} \text{ s}^{-1}$ (for $\text{Mg}^{2+}\text{-O}_w$) and $9.1 \cdot 10^{12} \text{ s}^{-1}$ vs. $8.9 \cdot 10^{12} \text{ s}^{-1}$ (for $\text{Ca}^{2+}\text{-O}_w$). The calculated values show insignificant difference when determined from simulations using different ion parameter sets or water models (data not shown). In this work, we use the values obtained by approach 2.

The free energy of activation, ΔG^\ddagger , was estimated from the PMFs as the energy difference between the global minimum (binding distance) and the global maximum (peak of transition barrier).

The exchange rate of H_2O can also be calculated by directly counting the number of exchanges during the simulation. This approach is applicable only to those ions that have fast exchange (on the order of 10-100 ps) since the exchange time should be shorter than the simulation time to guarantee good sampling. To calculate the mean residence time, τ , of a water-ion contact, we have to define when the ion and water are in contact. For Na^+ ions, a contact was defined when the distance between the Na^+ ion and a water oxygen was within 3.1 Å. This corresponds to the position of the first peak in the PMF. The exchange rate, k , is then calculated as the inverse of the mean residence time.

Free Energy of Solvation

We have calculated the relative solvation free energy, ΔG_{SOLV}^{REL} , between a Mg^{2+} ion represented by two parameter sets, $\text{MG}^{\text{CHARMM}}$ (state A) and MG^{NEW} (state B).

The free energy difference between the two states was calculated using the coupling parameter approach together with the thermodynamic integration:

$$\Delta G_{AB} = \int_{\lambda_A}^{\lambda_B} \left\langle \frac{\delta H(\lambda)}{\delta \lambda} \right\rangle_{\lambda_i} d\lambda_i \quad (3)$$

where the Hamiltonian (H) is a function of the coupling parameter λ ,

$H(\lambda) = \lambda H_B + (1 - \lambda) H_A$. The coupling parameter λ defines the progress of the system along the path between the initial and final state by ranging from 0 (state A, ion-water interactions with $\text{MG}^{\text{CHARMM}}$) to 1 (state B, ion-water interactions with MG^{NEW}). One approach to evaluate the integral in eq. 3 is to calculate the average at a number of discrete λ -steps (denoted by λ_i in eq. 3) between 0 and 1 by performing separate simulations for each of the chosen λ -steps. The integral can then be determined numerically.

To calculate the free energy, we have used a dual-topology approach as implemented in the *thermodynamic simulation methods* (TSM) module of the CHARMM package.^{65,66} Separate simulations were performed for 11 λ -values, linearly spaced between 0 and 1. At each λ -point, the system was first equilibrated for 50 ps and then data was collected for a further 100 ps. Three independent sets of simulations have been used to calculate ΔG_{SOLV}^{REL} and the error was determined by calculating the standard deviation between the obtained values.

Results and Discussion

Ions in water solution

MD simulations for Na^+ , K^+ , Mg^{2+} and Ca^{2+} ions have been performed in water solutions for 10 ns, using TIP3P model for water molecules and CHARMM27 parameters for the ions. Table 1 reports the main structural parameters obtained from our simulations together with experimental values when available. The reported structural properties of ions are acquired from X-ray and neutron diffraction experiments (see review by Ohtaki and Radnai⁶⁷ for a detailed description).

We define the distances between the ion and the water molecules in the first and second coordination shell (r_1 and r_2 in Table 1) as the position of the first and second peak in the RDF, respectively. The r_1 values lie within the range of experimental values for Na^+ and K^+ , or very close (a deviation from experiment values of <4%) to the experimental values for Ca^{2+} , while for Mg^{2+} , the deviation is larger (~6%). The r_2 value has a value of 4.6-5.1 Å for monovalent ions, while for the divalent ions it is 4.1-4.6 Å. The second solvation shell is not well defined for the monovalent ions and therefore, no experimental data is available. In case of the divalent ions, Mg^{2+} (4.1 Å) and Ca^{2+} (4.6 Å), the CHARMM parameters and TIP3P water model, reproduce the experimental distances (4.1-4.2 Å for Mg^{2+} and 4.5-4.6 Å for Ca^{2+}) accurately. The water coordination number for the first and second solvation shell (CN_1 and CN_2) of Mg^{2+} agrees well with experimental data. As with r_2 , CN_2 is not well defined for the monovalent ions Na^+ and K^+ and no experimental data are available for Ca^{2+} ions as far as we know.

Before calculating the kinetic properties of the ion-water system, we check that a simulation time of 10 ns was enough to guarantee the convergence of the water residence time around the ions. That is not the case for Mg^{2+} . For this ion no ion-water exchanges were observed during the simulations. To obtain the kinetic parameters for the Mg^{2+} , umbrella sampling was used to generate the PMF profile between the ion and water molecules, from which the heights of activation barriers of ion-water binding were obtained. In all umbrella sampling windows, the Mg^{2+} ion is coordinated by six molecules, except in those windows corresponding to the maximum in the energy profile where the ion is coordinated by five water molecules plus two water molecules at slightly larger distance, one is the pulled water molecules and the other is a water molecule about to replace the pulled one.

Figure 3 shows the potential of mean force profile between ion and oxygen of a water molecule for all the four ions. In the case of Na^+ , K^+ and Ca^{2+} , the PMF is obtained by

inverting the RDF calculated between ion and water oxygen. The values of the activation free energy, ΔG^\ddagger , are reported in Table 1. Applying eq. 4, we have calculated the exchange rate for the ion-water binding (k_l in Table 1) from ΔG^\ddagger using the following pre-factor values: (1) (1) $\text{Na}^+\text{-O}_w$: $6.7 \cdot 10^{12} \text{ s}^{-1}$, (2) $\text{K}^+\text{-O}_w$: $5.0 \cdot 10^{12} \text{ s}^{-1}$, (3) $\text{Mg}^{2+}\text{-O}_w$: $1.3 \cdot 10^{13} \text{ s}^{-1}$ and (4) $\text{Ca}^{2+}\text{-O}_w$: $8.9 \cdot 10^{12} \text{ s}^{-1}$.

We compared the kinetic constant, k , for $\text{Na}^+\text{-H}_2\text{O}$ exchange calculated from ΔG^\ddagger (using eq. 4) with the rate obtained from analysis of the mean residence time of O_w in the first solvation shell of Na^+ . Both exchange rate constants, $5.0 \cdot 10^{10} \text{ s}^{-1}$ using eq. 4 and $2.52 \cdot 10^{10} \text{ s}^{-1}$ from direct counting, are in agreement with the available experimental information ($> 10^{10} \text{ s}^{-1}$). In the following, the kinetic constants, k , are calculated from ΔG^\ddagger .

To compare the results with available experimental data, we have to take some considerations into account. Experimental data describing the kinetics of water exchange around ions are best acquired from ^{17}O NMR experiments^{32, 33}, but the limit in time resolution of these techniques lies at about 10^{-10} s, which is not enough to accurately measure the exchange rate (k) of water around Na^+ , K^+ and Ca^{2+} . With this in mind, we can see that the rate constants, calculated from the free energy of activation for Na^+ ($5.0 \cdot 10^{10} \text{ s}^{-1}$), K^+ ($3.3 \cdot 10^{11} \text{ s}^{-1}$) and Ca^{2+} ($2.4 \cdot 10^{10} \text{ s}^{-1}$) lie within an order of magnitude from the experimental values ($> 10^{10} \text{ s}^{-1}$). We can also see that the relative values of exchange rate for these three ions, $\text{K}^+ > \text{Na}^+ > \text{Ca}^{2+}$, agree with the experimental data reported in a review by Helm and Merbach⁶⁸. Another aspect to consider is that experimental studies^{32, 33} have approximated the pre-factor A used in eq. 4 (relating ΔG^\ddagger with k) with $A = \frac{k_B T}{h} = 6.2 * 10^{12} \text{ s}^{-1}$, while we have determined A directly from the simulation data.

The agreement between the experimental and simulated data observed for Na^+ , K^+ and Ca^{2+} ions gives strength to the view that the CHARMM27 parameters and TIP3P water model describe the structural and kinetic aspect of the binding of these ions with water molecules accurately. Mg^{2+} ions have a considerably slower exchange rate than the other three ions, both in experiment and in simulations, but the calculated exchange rate of $6.4 \cdot 10^3 \text{ s}^{-1}$ is two order of magnitudes slower than the experimental rate³³ of $6.7 \cdot 10^5 \text{ s}^{-1}$. This prompts us to find a better representation of Mg^{2+} in water solution.

Water models. To study the effect of the water models on the structure and kinetics of $\text{Mg}^{2+}\text{-H}_2\text{O}$ complexes, we calculated PMF-profiles of Mg^{2+} solvated with SPC/E and TIP5P water molecules in addition to TIP3P (Figure 4, Table 1). The SPC/E water model reproduces the

experimental distance to the first hydration shell (r_1) slightly better (2.00 Å) than TIP3P model but still underestimates the distance with almost 5%. The result does not improve with TIP5P water model with an r_1 distance of only 1.90 Å, around 10% below the experimental value. The reproduction of the second hydration shell is better, with the SPC/E model producing the experimental 4.1 Å and the TIP5P model slightly below, at 4.0 Å. The coordination numbers for the two solvation shells are correctly reproduced for all three water models.

The free energy of activation, ΔG^\ddagger , calculated with different water models lies within the error margin (see Table 1). All the barrier values give exchange rates off by more than two orders of magnitude from the experimental value. This points out that the difference in models does not affect the kinetic description of Mg^{2+} - H_2O interactions.

Mg²⁺ parameter sets. Another factor involved in the Mg^{2+} - H_2O interactions are the Lennard-Jones parameters of the metal ion. We have compared $\text{MG}^{\text{CHARMM}}$ and $\text{MG}^{\text{LB-Åqvist}}$ with a new set of parameters, MG^{NEW} (Table 2), which has been optimized to reproduce the experimental exchange rate of water in the first solvation shell. The new Mg^{2+} Lennard-Jones potential has a significantly lower well depth (ϵ) than $\text{MG}^{\text{CHARMM}}$ and $\text{MG}^{\text{LB-Åqvist}}$. However, the effect of this has little influence on the first solvation shell since the strong attractive electrostatic interactions pull the interacting atoms (Mg^{2+} - O_w , Mg^{2+} - O_p etc.) at a distance far up on the “repulsive wall” of the Mg^{2+} -O Lennard-Jones potential, far way from the minimum. The structural properties (Table 1) of $\text{MG}^{\text{LB-Åqvist}}$ ($r_1 = 1.98$ Å and $r_2 = 4.2$ Å) are very similar to the results using $\text{MG}^{\text{CHARMM}}$. With MG^{NEW} , the distance to the first solvation shell ($r_1 = 2.04$ Å) is improved considerably compared to all previous results while r_2 (4.2 Å) is kept at the correct experimental value.

The comparison of PMF profiles for the three Mg^{2+} parameters (Figure 4, Table 1) show that the $\text{MG}^{\text{LB-Åqvist}}$ parameters do not exhibit better kinetic properties than $\text{MG}^{\text{CHARMM}}$, the barrier ($\Delta G^\ddagger = 13.2 \pm 0.2$ kcal/mol) gives an exchange rate nearly three order of magnitudes slower than the experimental. The MG^{NEW} parameters ($\Delta G^\ddagger = 9.9 \pm 0.1$ kcal/mol) reproduce the experimental exchange rate (to which it has been optimized) within the error margin of the ^{17}O NMR experiment (keeping in mind that a 0.1 kcal/mol error in ΔG^\ddagger translates into an error of around $1.5 \cdot 10^5 \text{ s}^{-1}$ in k).

The exchange rates of water from the second solvation shell, k_2 , obtained from the second minima and barrier of the PMFs, reveal only small variations between the different water

models and ion parameters, all within the error margin. The pre-factor for these interactions was determined from the second energy well and is $2.14 \cdot 10^{12} \text{ s}^{-1}$. The calculated exchange rates, k_2 , are in the range $4.3 \cdot 10^{11} \text{ s}^{-1}$ - $7.3 \cdot 10^{11} \text{ s}^{-1}$. No experimental data exist for these exchange rates as far as we are aware.

The re-parameterization of the Mg^{2+} was performed by solely modifying the repulsive term Lennard-Jones term, C_{12} , to avoid altering the solvation properties of the ions too much. To check the effect of the new parameters on the solvation free energy value, we have calculated the relative solvation free energy between $\text{MG}^{\text{CHARMM}}$ and MG^{NEW} . Changing the ion parameter from $\text{MG}^{\text{CHARMM}}$ to MG^{NEW} corresponds to a change of 24.4 kcal/mol in the solvation free energy which is less than 6% of the reference values for $\text{MG}^{\text{CHARMM}}$ (441.65 kcal/mol⁶⁹) and around 6% of the experimental values (between -435.4 and -437.4 kcal/mol)^{70, 71}. Note that $\text{MG}^{\text{CHARMM}}$ was originally parameterized to reproduce solvation free energy.

We have also checked that the MG^{NEW} parameters do not affect the description of an ion solution compared to the original force field. We have done this by performing 10 ns MD simulation of MgCl_2 at a concentration of 0.2 M and 1 M in water solution using $\text{MG}^{\text{CHARMM}}$ and MG^{NEW} for Mg^{2+} and compared the Mg^{2+} - Cl^- radial distribution function. Both force fields show a first peak at around 4.2 with similar height according the concentration conditions. The change in Mg^{2+} parameters do not affect the ion distribution in solution in a relevant way and the results are in line with experimental evidence that Cl^- tends to be surrounded by its own hydration shell.¹²

Mg^{2+} -Phosphate Interactions

To model the binding between Mg^{2+} ions and nucleic acid phosphates, a system consisting of a Mg^{2+} ion and a dimethyl phosphate (DMP) in water solution has been used. The potential of mean force between the phosphate oxygen (O_P) of DMP and the Mg^{2+} ion has been calculated using different water models and magnesium parameters (Figure 5). The Mg^{2+} - O_P minimum distance (Table 3) is shorter than the Mg^{2+} - O_W distance, due to the negatively charged phosphate group. Only small differences for the Mg^{2+} -P distance (Table 3) are seen between the different water models and Mg^{2+} parameters, but MG^{NEW} parameters reproduce the Mg^{2+} -P distance (calculated value of 3.41 Å vs. experimental value of 3.6 Å⁷²) better than the other models (3.30-3.38 Å). For the second shell interactions the TIP5P water model stands out with an r_2 (O_P) distance considerably shorter (3.6 Å) than the other models (4.0-4.1 Å). No data on the distance between Mg^{2+} and O_P atoms bridged by a water molecule are reported in

the X-ray diffraction work on a magnesium-phosphate solution. Caminiti⁷² in his analysis showed an average number of one phosphate bound to Mg^{2+} , indicating that the cation is always directly bound to the phosphate in his experiment.

The kinetic constants (k_1 and k_2) were calculated both for the direct (k_1) and indirect (k_2) binding of Mg^{2+} to the phosphate group (Table 3), using a pre-factor calculated to be $1.1 \cdot 10^{13} \text{ s}^{-1}$ for the Mg^{2+} -phosphate system and $2.7 \cdot 10^{12}$ for the second solvation shell. The TIP5P model gives considerably faster rate ($4.1 \cdot 10^{-1} \text{ s}^{-1}$) than TIP3P and SPC/E models ($2.6 \cdot 10^{-3} \text{ s}^{-1}$ and $1.7 \cdot 10^{-2} \text{ s}^{-1}$).

Comparison of the three Mg^{2+} parameters (Figure 4 and Table 3) shows that $\text{MG}^{\text{LB-Åqvist}}$ ($1.3 \cdot 10^{-3} \text{ s}^{-1}$) performs similarly as $\text{MG}^{\text{CHARMM}}$, while the MG^{NEW} parameters give a rate (10.3 s^{-1}) that is several orders of magnitude faster. This exchange rate is far too slow to be possible to sample with any reasonable simulation times without artificial constraints. As far as we know, no experimental data are available for the phosphate- Mg^{2+} exchange in monophosphate system like DMP. ²⁵Mg NMR studies are available for Mg^{2+} -nucleic acid systems. A value of $0.5 \cdot 10^3 \text{ s}^{-1}$ was reported for magnesium binding to DNA²¹, $1.5 \cdot 10^3 \text{ s}^{-1}$ for 5S rRNA²⁰ and $2.5 \cdot 10^3 \text{ s}^{-1}$ for tRNA^{Phe}²⁰. The values obtained with MG^{NEW} parameters exhibit the best agreement with these experimental rates compared to the other two sets of parameters. In this comparison, we have to take into account that the experimental exchange rates may be affected by interactions between the ions and other atoms in the nucleic acid systems that are not present in our model systems.

The exchange rates of the second shell binding show smaller differences than the first shell exchange and lie between $2.0\text{-}4.7 \cdot 10^{11} \text{ s}^{-1}$ for all systems. The rates mean that these interactions are very short lived with residence times measured in a few ps, the same order of magnitude shown by water with K^+ ions. It is noteworthy that the TIP5P water model gives a fast first shell exchange but has the slowest exchange rate from second shell binding.

Mg^{2+} -RNA Interactions

To test the performance of the MG^{NEW} parameters in a nucleic acids context, *add* A-riboswitch was simulated in explicit water/ Mg^{2+} ions solution, using the $\text{MG}^{\text{CHARMM}}$ and MG^{NEW} parameters for the ion and TIP3P model for water molecules. We used the CHARMM27d force field to describe RNA, since the MG^{NEW} was developed starting from the ion parameters implemented in CHARMM force field. The X-ray structure⁴⁷ of the A-riboswitch includes five Mg^{2+} ions, of which two are directly bound to an RNA phosphate. 30

additional Mg^{2+} ions had to be added to neutralize the system. First, we have checked that the use of different Mg^{2+} did not affect the tertiary structure of the RNA. Both MD simulations yielded structures similar to the experimental structure with an overall RMSD of 3.21 Å with $\text{MG}^{\text{CHARMM}}$ and 3.01 Å for MG^{NEW} , in agreement with a previously performed simulation.⁷³ All the secondary and tertiary structure elements are conserved during the 10 ns simulation. Although 10 ns simulations are too short to assess the RNA force field performance, the results suggest that the ion parameters do not lead to any gross structural distortions on this time scale. Then the behavior of the two parameter sets has been compared by calculating the direct and indirect contacts made by Mg^{2+} ions to RNA system. Both simulations show two ions bound via inner sphere contacts to the RNA system in agreement with the crystallographic structure. Among the other ions, on average 24.4 ($\text{MG}^{\text{CHARMM}}$) or 22.2 (MG^{NEW}) ions are bound to the riboswitch via outer sphere contacts. Each outer-sphere contact has an average lifetime of 52 ± 2.7 ps with $\text{MG}^{\text{CHARMM}}$ and 57 ± 5.3 ps with MG^{NEW} (average values and standard deviations obtained from five segments of 2 ns each) before breaking.

The two Mg^{2+} ions that were directly bound to RNA in the X-ray structure remain bound during the simulation time for both parameter sets as expected by the high activation barrier between Mg^{2+} and phosphate ion (Table 3). The ions bind directly to OP1/OP2 atoms of residues 23 and 24 with an average distance of 1.89 Å with $\text{MG}^{\text{CHARMM}}$ and 1.95 Å with MG^{NEW} in agreement with the values seen in the PMFs of the model systems. The distances in the X-ray structure are 2.1-2.4 Å. In addition, these ions have indirect contacts to adjacent atoms, as observed in the X-ray structure. But the MG^{NEW} parameters, on average, have slightly fewer water-bridged contacts per Mg^{2+} (2.4) than $\text{MG}^{\text{CHARMM}}$ (2.9), in line with the Mg^{2+} -water results (Table 4).

Table 4 shows the time-average number of ions that have at least one water-bridged contact (distances less than 2.4 Å for Mg-O_W and $\text{H}_W\text{-O/N}_{\text{RNA}}$) with any nitrogen or oxygen atom of the *add* A-riboswitch. Table 4 also reports the average number of water bridged contacts that each $[\text{Mg}(\text{H}_2\text{O})_6]^{+2}$ complex has with any acceptor atoms. The contacts have been categorized according to which RNA part they are in contact with. Figure 2 shows a selection of indirect Mg^{2+} binding to the *add* A-riboswitch together with free and direct bound ions, as observed in the simulations.

It is evident that the total average number of interacting ions is slightly larger for $\text{MG}^{\text{CHARMM}}$ (24.4) than for MG^{NEW} (22.2) and that almost half of these ions only interact with the O1P and/or O2P of the phosphate (O3' and O5' does not have any contacts at all with Mg^{2+}). For

both parameter sets, interactions of Mg^{2+} ions only with the sugar units or the bases are not frequent (~4% and 8% of total interactions). This may be due to the confined space around these parts. Simultaneous interactions with phosphates and base or sugar units are common (Figure 2) and, together, involve almost half of the interacting ions for both the parameter sets. While simultaneous interactions with a sugar and base are very rare, there is on average one Mg^{2+} ion interacting with all three RNA parts simultaneously. The ions that interact with multiple parts of the RNA residues are often deeply buried in the RNA (Figure 2) and each $[\text{Mg}(\text{H}_2\text{O})_6]^{+2}$ complex is seen having on average 3-4 (and up to as much as 7-8 on some occasions) contacts with oxygens and nitrogens with both the compared parameter sets. The $[\text{Mg}(\text{H}_2\text{O})_6]^{+2}$ complexes that interact exclusively with the phosphate groups, also form multiple contacts, which is a result of the $[\text{Mg}(\text{H}_2\text{O})_6]^{+2}$ complex water bridging to O_P :s of two adjacent residues (Figure 2).

The average lifetime of the indirect contacts is approximately 65 ps for O_P contacts and 36 ps for sugar and base contacts with only minor differences (<1ps) between the $\text{MG}^{\text{CHARMM}}$ and MG^{NEW} parameters. This is considerably longer than predicted from the second shell exchange rates of the model systems (2-5 ps) presented above, which can be explained by the cooperative effect of multiple, simultaneous contacts and the confined space around the ion-water complexes.

Conclusions

We have evaluated the performance of two Mg^{2+} ion models, implemented in the biomolecular force fields, AMBER99 and CHARMM27, to reproduce the kinetic properties of the binding of Mg^{2+} ions with water and phosphate ion. Molecular dynamics simulations together with umbrella sampling have been performed to calculate the activation barrier between the cation and water and between the cation and phosphate ion. We then examined the effect of different sets of parameters for Mg^{2+} and three models for the water molecules (TIP3P, SPC/E and TIP5P). The water exchange rate was calculated from the free energy barrier of water removal, which gave comparable results as the directly counted water exchange rate for the case of Na^+ .

For the most biologically abundant cations, such as Na^+ , K^+ and Ca^{2+} , the exchange rates are found around 10^{10} - 10^{11} s^{-1} (using $\text{MG}^{\text{CHARMM}}/\text{TIP3P}$), while Mg^{2+} ions exchange in the order of 10^3 s^{-1} . In particular, the $\text{MG}^{\text{LB-Åqvist}}/\text{TIP3P}$ combination gives the slower exchange rate while $\text{MG}^{\text{CHARMM}}/\text{TIP5P}$ the faster. The trend in exchange rate values for ions is found to be: $\text{K}^+ > \text{Na}^+ > \text{Ca}^{2+} > \text{Mg}^{2+}$, which agrees with the experimental data by Helm and Merbach.⁶⁸ The calculated values lie within an order of magnitude from the experimental values, except for Mg^{2+} ions, where the difference with experimental values ($k = 6.7 \cdot 10^5 \text{ s}^{-1}$) is huge. For this ion, the difference between parameter sets or water models is insignificant when compared to the deviations from experimental values.

Based on these results, a new set of Mg^{2+} parameters (MG^{NEW}) was developed by fitting to the activation free energy in the Mg^{2+} -water system. The new set reproduces, not only the experimental exchange rate, but also structural data of the binding of Mg^{2+} ions to water molecule better than other models.

To model interactions between Mg^{2+} and an RNA backbone phosphate group we used a system with a Mg^{2+} cation and a monophosphate anion (dimethylphosphate) in explicit solvent. The results show that exchange between metal ion and phosphate ion is faster with $\text{MG}^{\text{NEW}}/\text{TIP3P}$ (10.3 s^{-1}) than with $\text{MG}^{\text{CHARMM}}$ ($4.1 \cdot 10^{-1}$ and $2.6 \cdot 10^{-3} \text{ s}^{-1}$ for TIP5P and TIP3P respectively) or with $\text{MG}^{\text{LB-Åqvist}}/\text{TIP3P}$ ($1.3 \cdot 10^{-3} \text{ s}^{-1}$). No experimental data are available for the ion exchange for this specific system, but NMR data for nucleic acid systems indicate an exchange rate of 0.50 - $3.0 \cdot 10^3 \text{ s}^{-1}$, close to $\text{MG}^{\text{NEW}}/\text{TIP3P}$. From a structural point of view, the results from $\text{MG}^{\text{NEW}}/\text{TIP3P}$ have a better agreement with X-ray diffraction data of Caminiti⁷² than the other models.

Finally, the $MG^{NEW}/TIP3P$ model was applied in a biological context (with the *add A*-riboswitch) and compared with $MG^{CHARMM}/TIP3P$. The Mg^{2+} ions parameters do not affect the main structure feature of the RNA system. Both parameter sets reproduce the ion direct binding to RNA in agreement with the X-ray structure.⁴⁷ Concerning the indirect binding, an average number of 22-24 Mg^{2+} ions interact with the RNA (one Mg^{2+} ion each three residues) with an average residence time of 51-53 ps. No differences were observed between the parameter sets concerning the type of RNA atoms that are water bridged with the magnesium ions. A 9% decrease in the average number of the indirect Mg^{2+} -RNA contacts are observed with $MG^{NEW}/TIP3P$ model.

Together, these results provide support for the ability of the newly developed parameters to improve the kinetic description of Mg^{2+} in water solution and to be used in nucleic acid simulation in combination with CHARMM force field. With simulations now being performed on the millisecond scale^{74, 75}, the correct representation of slow processes is becoming more important. A good description of the kinetic properties of the magnesium ion-water is the first step towards an atomistic force field able to simulate the kinetic step of RNA systems accurately. The following natural step will be to evaluate/improve the kinetic description of Mg^{2+} phosphate interactions, but first more system-specific experimental data are necessary.
