Abstract

Plants are indispensable for life on earth and represent organisms of extreme biological diversity with unique molecular capabilities [1]. Here, we present a quantitative atlas of the transcriptomes, proteomes and phosphoproteomes of 30 tissues of the model plant *Arabidopsis*

36   *thaliana*. It provides initial answers to how many genes exist as proteins (>18,000), where they

37   are expressed, in which approximate quantities (>6 orders of magnitude dynamic range) and to

38   what extent they are phosphorylated (>43,000 sites). We present examples for how the data

39   may be used, for instance, to discover proteins translated from short open reading frames, to

40   uncover sequence motifs involved in protein expression regulation, to identify tissue-specific

41   protein complexes or phosphorylation-mediated signaling events to name a few. Interactive

42   access to this unique resource for the plant community is provided via ProteomicsDB and

43   ATHENA which include powerful bioinformatics tools to explore and characterize Arabidopsis

44   proteins, their modifications and interplay.

45   ***Main***

46   The plant model organism *Arabidopsis thaliana* (AT) has revolutionized our understanding of

47   plant biology and influenced many other areas of the life sciences [1]. Knowledge derived from

48   Arabidopsis has also provided mechanistic understanding of important agronomic traits in crop

49   species [2]. The Arabidopsis genome was sequenced 20 years ago and hundreds of natural

50   variants have since been analyzed at the genome and epigenome level [3,4]. In contrast, the

51   Arabidopsis proteome as the main executer of most biological processes is far less

52   comprehensively characterized. To address this gap, we used state-of-the-art mass

53   spectrometry and RNA sequencing (RNA-seq) to provide the first integrated proteomic,

54   phosphoproteomic and transcriptomic atlas of Arabidopsis. Illustrated by selected examples, we

55   show how this rich molecular resource can be used to explore the function of single proteins or

56   entire pathways across multiple omics levels.

57   ***Multi-omics atlas of Arabidopsis***

58   We generated an expression atlas covering, on average, 17,603 ± 1,317 transcripts,

59   14,430 ± 911 proteins and 14,689 ± 2,509 phosphorylation sites (p-sites) per tissue, using a

60   reproducible biochemical and analytical approach (Fig. 1a,b; Extended Data Fig. 1a-c;

61   Supplementary Data 1,2). In total, the protein expression data covers 18,210 of the 27,655

62   protein-coding genes (66%) annotated in Araport11 [5]. This is a substantial increase compared

63   to the percentage of genes with protein level evidence reported in UniProt (27%) [6] and more

64   than double the number of proteins identified in an earlier tissue proteome analysis [7] (Fig. 1c,

65   Extended Data Fig. 1d-f). In addition, we report tissue-resolved quantitative evidence for a total

66   of 43,903 p-sites making this study the most comprehensive single Arabidopsis

67   phosphoproteome published to date (Fig. 1c). 47% of the expressed proteome was found to be

68   phosphorylated in at least one instance, confirming earlier analyses of individual

69 phosphoproteomes or information assembled in the PhosPhAT database (Extended Data Fig.

70 1g,h) [8,9]. The actual figures *in plantae* are likely considerably higher as there is limited overlap

71 between these data sources. This can be readily explained by technical factors (e. g. insufficient

72 sequence coverage) and, more importantly, differences in plant genotypes or stimuli that

73 influence phosphorylation. The above figures are similar to those reported for mammalian

74 systems, underscoring the strong conservation of protein post-translational modifications as a

75 means to create functional diversity from a limited set of genes and proteins [10].

76 The atlas can be explored using the new web portal ATHENA (Arabidopsis Thaliana ExpressioN

77 Atlas; athena.proteomics.wzw.tum.de) and ProteomicsDB (www.proteomicsdb.org) [11]. Analysis

78 and visualization options include co-expression analysis, the exploration of tissue-specific

79 interaction networks and a tool for predicting tandem mass spectra of peptide sequences, which

80 can be used to validate peptide identifications reported in this study [12] (Fig. 2a,b; Supplementary

81 Table 1). ProteomicsDB further provides spectral libraries for >328,000 unmodified and >43,000

82 phosphorylated peptides. These can facilitate the development of quantitative mass

83 spectrometry-based protein assays which is particularly useful for research in Arabidopsis,

84 where comparatively few antibodies exist.

85 ***Proteomic annotation of the genome***

86 Using Araport11, the proteomic data corroborated a substantial number of annotated open

87 reading frame (ORF) borders based on the detection of 2,776 N-terminal and 2,656 C-terminal

88 peptides (Extended Data Fig. 2a). As expected, N-terminal peptides often showed cleavage of

89 the initiator methionine and N-terminal acetylation which was strongly dependent on the amino

90 acid adjacent to the initiator methionine (Extended Data Fig. 2b,c) [13]. The MS data covered, on

91 average, 44% of each protein sequence, enabling the detection of unique peptides for 14,115

92 protein isoforms. In 297 cases, the data distinguished also two or three splice variants

93 (Extended Data Fig. 2d-f; Supplementary Data 3). A selection of these isoform-specific peptides

94 was validated using synthetic peptides (confirmation rate 80%; Extended Data Fig. 2g). To

95 investigate the potential translation of predicted short open reading frames (sORF), we

96 searched the proteomic data against a published and an in-house compiled sORF collection

97 (ARA-PEP [14]; ATSO) leading to the identification of 51 distinct sORFs that were subsequently

98 confirmed using synthetic peptides (Extended Data Fig. 2g,h; Supplementary Data 3). These

99 results demonstrate the potential of the atlas to refine Arabidopsis gene models and protein

100 sequences.

101 ***Quantitative expression landscapes***

102 The dynamic range of protein and transcript expression spanned six and four orders of

103 magnitude, respectively (Extended Data Fig. 2i,j). As described before, protein evidence was

104 underrepresented for low abundant transcripts [15], indicating that proteome coverage was not yet

105 exhaustive. Low abundant transcripts were enriched for gene ontology (GO) terms such as cell

106 signaling or gene expression regulation (Supplementary Data 4). Still, the protein data cover

107 ~50% of all annotated transcription factors and ~75% of all transcriptional regulators, kinases

108 and phosphatases, many of which are themselves post-translationally regulated (Extended Data

109 Fig. 2k) [16,17]. Interestingly, protein phosphorylation was detected across the entire dynamic

110 range of protein expression, highlighting the efficiency of the employed phosphopeptide

111 enrichment (Extended Data Fig. 2j).

112 A breakdown of the molecular data for individual tissues or morphologically similar groups (e.g.

113 leaf, seed or root) showed that only few transcripts or proteins are expressed in a truly specific

114 manner (Extended Data Fig. 3a). Instead, tissue types are characterized by distinct quantitative

115 abundance patterns. For instance, the floral organs express a similar set of genes but at levels

116 that are characteristic for each flower compartment. Here, the MADS domain transcription

117 factors showed the expected differential expression, thus recapitulating established models of

118 floral organ identity [18] (Extended Data Fig. 3b,c).

119 The strong variation in quantitative gene expression between tissue groups was evident on both

120 protein and transcript level (Extended Data Fig. 3d,e). Still, we found surprisingly little overlap in

121 the rank order or even identity of the most abundant proteins and mRNAs within any given

122 tissue (Extended Data Fig. 3e,f). Extreme expression ranges were detected for e.g. seeds,

123 where the storage protein CRA1 accounted for ~10% of the total protein and the ten most

124 abundant gene products already represented more than 30% of the total amount of protein or

125 transcript, respectively (Extended Data Fig. 3e,g). Similarly, the RuBisCO complex, renowned

126 as the most abundant plant protein on earth, accounted for 4-7% of total leaf protein content [19]

127 (Extended Data Fig. 3g). We note that despite the dominance of some proteins in certain

128 tissues, we show that proteomes of plant tissues can be probed very deeply using current

129 technology, countering the long-standing notion that plant proteomics is particularly difficult [20].

130 As expected, photosynthetic activity was one of the main factors for expression pattern

131 variations between tissues, which can also be related to plastid localized proteins and their

132 abundance (Extended Data Fig. 3h,i). The most divergent expression pattern on both transcript

133 and protein level, however, was found for pollen (Extended Data Fig. 3h).

134   The comparison of expression patterns between tissues can be used to ascertain biological

135   functions of individual proteins or to disentangle closely related protein family members. A

136   closer look at the AGCVIII kinase family (23 members in Arabidopsis) [21] revealed high protein

137   expression of members of the D6PK subfamily in embryos as well as of AGC1.5 and AGC1.7

138   kinases in flowers and pollen (Fig. 2c). In line with these results, follow-up experiments showed

139   promotor activity for *AGC1.5* and *AGC1.7* but not for the closely related *AGC1.6* in pollen,

140   strongly supporting the contribution of the former two in pollen tube growth [22] (Fig. 2d,e). We

141   further uncovered an important role for the D6PKs in embryo development, where a combined

142   knockout synergistically increased the occurrence of aberrant embryo phenotypes in loss-of-

143   function mutants (Fig. 2f-i).

144   ***Regulation of protein amount in tissues***

145   The amount of protein for a given gene is determined by a regulatory system comprising

146   anabolic and catabolic transcriptional, translational and post-translational processes. This has

147   been extensively studied in unicellular organisms and, more recently, in human [23]. While this

148   broad area of research cannot be covered in detail here, consistent observations were made in

149   the current study. We found positive correlation between transcript and protein levels in most

150   tissues (Pearson's *R* 0.28-0.7, Extended Data Fig. 4a), with the majority of high or low abundant

151   transcripts resulting in high or low abundant proteins, respectively [24] (Fig. 3a). To identify further

152   molecular determinants of protein abundance, we implemented a model selection approach and

153   tested each of the selected features for the potential to explain protein level variations on a

154   tissue-specific or global level (Extended Data Fig. 4b-e; Supplementary Data 5). In addition to

155   well-known predictors like transcript levels and codon usage [25], evolutionary conservation,

156   mRNA sequence motifs and the number of protein interactions were significant predictors of

157   protein levels (Fig. 3b). However, a large proportion (48%) of protein abundance variation still

158   remains unexplained, suggesting that many additional molecular factors with great individual but

159   lower global impact may be at work which will require careful case by case experiments to

160   resolve.

161   Protein versus transcript abundance plots clearly show that similarly abundant transcripts often

162   lead to proteins with >100-fold differences in abundance. These differences in the protein-to-

163   mRNA ratio (PTR) of genes might be due to differences in translation efficiency of a given

164   transcript, transcript stability and/or the stability of the respective protein (Fig. 3c) [26]. High PTRs

165   were detected for genes involved in photosynthesis or energy metabolism (e.g. petA and rbcL)

166   (Supplementary Data 4). This implies optimized translation and stability of those proteins (and

167 transcripts) that are needed in large quantities. Conversely, genes with low PTRs were enriched

168 in processes such as hormone-mediated signaling pathways, which, in plants, often involve

169 protein degradation [27]. Members of the auxin-labile AUX/IAA protein family (e. g. IAA8, IAA13)

170 for example show low protein signal despite high transcript levels and are known to be under

171 tight control of auxin-dependent proteasomal degradation [28] (Fig. 3a).

172 We also observed inter-tissue variation of PTRs, especially for seed and pollen (Fig. 3d). Genes

173 with low PTRs in seeds mainly show differential abundance at the protein level and proteome-

174 wide time-resolved measurements in germinating seeds in response to cycloheximide

175 (translation block) or MG132 (proteasome block) treatment suggest that low PTR proteins are

176 rapidly translated from stored mRNA upon germination. High PTR proteins do not show this

177 behavior implying that they are stored in seed to be readily available for germination (Fig. 3e,f;

178 Extended Data Fig. 4f,g). This is consistent with reports that seeds and pollen accumulate

179 storage molecules including mRNAs and proteins to allow rapid development at the onset of

180 germination and likely explains the observed uncoupling of transcription and translation in these

181 durable plant tissues [29]. Fluctuating PTRs of genes between tissues indicate tissue-specific

182 regulation on either transcript or protein level. Conversely, genes with stable PTRs, are likely

183 under similar regulation in different tissues and the extensive transcriptomic resources available

184 for Arabidopsis may therefore be used to estimate relative protein abundances (Extended Data

185 Fig. 5a,b). Similarly, stable ratios between p-site abundance and the corresponding protein

186 levels, indicates that, under steady-state conditions, the majority of phosphorylation abundance

187 changes between tissues can be attributed to fluctuations of the underlying protein abundance

188 rather than phosphorylation stoichiometry (Extended Data Fig. 5c,d).

189 ***Co-expression of paralogs and complexes***

190 Based on the 'guilt by association' idea, gene co-expression analysis is widely used to ascribe

191 common functionality between genes and can be performed on transcript or protein level. We

192 observed that co-expressed gene pairs also have high STRING [30] scores, indicative of physical

193 or functional interactions (Extended Data Fig. 6a). To illustrate this point, we focused on co-

194 expression analyses of gene paralogs and interacting proteins. Arabidopsis, like most plants,

195 has undergone genome duplications and retains a considerable number of highly conserved

196 paralogs in the genome [31]. Compared to randomly selected gene pairs, duplicated genes show

197 a clear shift towards positive expression correlations (both transcript and protein). This indicator

198 for redundant gene function is supported by the finding that knock-out mutants of the more

199 abundant paralog are more likely to display a measureable plant phenotype [32] (Extended Data

200 Fig. 6b-d; Supplementary Data 6). Such comparative expression analyses can be useful to
201 prioritize knock-out combinations for phenotype analyses of functionally redundant genes.

202 Analyzing proteins that engage in physical interactions recorded in AtPIN [33] for co-expression
203 across tissues suggests that ~26% of AtPIN pairs may be stable rather than transient complex
204 partners (online methods; Extended Data Fig. 6e,f). As expected, protein-based correlations
205 were consistently higher than transcript correlations. Because co-expression analyses tend to
206 generate a large number of interaction candidates, we sought to prioritize these using data from
207 size-exclusion chromatography-mass spectrometry experiments (SEC-MS) as an independent
208 experimental approach [34] (Extended Data Fig. 7a-c; Supplementary Data 7,8). Indeed, we found
209 that co-detection in SEC-MS, in addition to co-expression in the tissue atlas, substantially
210 reduced the list of candidates, illustrated here by the detection of the coatomer complex in the
211 intersection of the SEC-MS and tissue atlas data (Fig. 4a,b). The identification of known protein
212 complexes was consistently improved by using this approach, which combines information from
213 SEC and the tissue atlas datasets (Extended Data Fig. 7d, Supplementary Data 9, see online
214 methods).

215 Interestingly, in seed tissues, the ζ-subunit of the coatomer complex was almost exclusively
216 provided by the ζ-1 paralog, while this was almost absent in all other tissues (Extended Data
217 Fig. 7e). Subunit abundance comparisons also provided information about complex
218 stoichiometry and similar results were obtained for stable complexes when using the SEC-MS
219 or tissue atlas dataset (Fig. 4c, Extended Data Fig. 7f,g). We, therefore, propose that our tissue
220 atlas resource can provide an initial approximation of the relative subunit frequency of known
221 complexes with unresolved stoichiometry. This could be particularly useful for membrane- or cell
222 wall-associated complexes, which are difficult to study biochemically.

The Arabidopsis phosphoproteome

224 The number of kinases (642 ± 55) and phosphatases (119 ± 6) as well as the ratios of individual
225 families were comparable across most tissues. Pollen and egg cell-like callus, however, stood
226 out implying extensive signaling activity in these tissues (Extended Data Figure 8a-c). In
227 contrast to the wealth of available phosphoproteomic data to date, information on kinase-
228 substrate relationships, critical for understanding signaling cascades or pathway activities, is still
229 sparse. Because these relationships are difficult to discover experimentally, scientists often
230 initially take a computational approach. We used the motif-X algorithm [35] to identify 266
231 phosphorylation motifs that grouped into 'proline-directed', 'acidic', 'basic' or 'other' motif classes
232 [36] (Extended Data Figure 8d-f; Supplementary Table 2, Supplementary Data 10). Together with

233 information about the co-occurrence of kinases and p-sites in tissues, as well as external
234 information like co-localization or interaction, we anticipate that this dataset can help untangle
235 kinase-substrate and kinase-p-site relationships in the future.

236 Overall, the number of p-sites per protein showed vast variations. For example, members of the
237 LEA protein family [37] are phosphorylated at almost every serine, threonine or tyrosine residue in
238 their sequences (Fig. 5a; Extended Data Fig. 8g,h). Phosphorylation of these unstructured
239 proteins involved in seed maturation and desiccation may be a mechanism to regulate their
240 conformational state or phase transitions [38]. Conversely, other proteins showed p-site clusters in
241 regulatory domains, including the juxtamembrane domain of receptor-like kinases [39] (Extended
242 Data Figure 8i), implying a role in recruiting interaction partners akin to human receptor tyrosine
243 kinases.

244 While the mere detection of a phosphorylation event does not directly imply a functional
245 consequence, it provides important starting points [40]. For example, the abscisic acid (ABA)
246 receptor RCAR10, involved in the ABA signaling cascade, was found to be phosphorylated at
247 four sites. We generated phosphomimic mutants (S113D, S32D) that displayed reduced ABA
248 response compared to the wild type receptor (Fig. 5b). While this might be linked to an effect on
249 ABA binding or PP2C interaction for pS113 which is part of the interaction surface for protein
250 phosphatase 2 (PP2Cs) co-receptors, it is more likely due to altered interactions with other
251 regulatory proteins for pS32, which is localized at the receptor periphery [41] (Extended Data Fig.
252 9a,b). Interestingly, both RCAR10 phosphomimic variants altered the ABA response of
253 RCAR10-PP2C co-receptor combinations, suggesting changes in the interaction profile and
254 phosphorylation-based fine-tuning of ABA signaling during development and stress response
255 (Extended Data Fig. 9c,d).

256 As a second example for functional consequences of protein phosphorylation, we studied QKY,
257 a protein localized to plasmodesmata and involved in floral and silique morphogenesis [42]. Since
258 one of its p-sites (S262) was detected in all assayed tissues and further p-sites were found
259 between the first and second C2 domains in other MCTP family members, we speculated about
260 a possible effect of pS262 on QKY function (Extended Data Fig. 9e,f). To test this hypothesis,
261 we generated plant lines expressing phosphomimic and phosphomutant *QKY* transgenes in the
262 strong *qky-9* mutant background [43]. The data show that phosphomimic but not phosphomutant
263 protein constructs rescued both flower and silique mutant phenotypes, suggesting that
264 phosphorylation of S262 is required for normal QKY function (Fig. 5c-f, Extended Data Fig. 9g-
265 j).

266   Taken together, we have generated the most comprehensive, albeit still incomplete, draft of the
267   Arabidopsis (phospho)proteome to date and highlighted some of the many uses that can be
268   envisioned for this resource. Yet, much remains to be accomplished including a more
269   systematic coverage of protein sequence variants or post-translational modifications. The tens
270   of thousands of newly discovered phosphorylation sites that await functional characterization
271   present a particular future challenge. The examples we provide demonstrate that investigating
272   different levels of omics data can lead to new insights into biological processes. We therefore
273   anticipate that this resource along with the provided online computational tools will enable the
274   Arabidopsis research community to perform many further types of systems-level analyses not
275   covered here. We also expect that the study will more broadly impact plant research as the work
276   demonstrates that mass spectrometry-based quantitative protein assays are a veritable way to
277   overcome the disabling lack of antibodies for plant research.

374 **Figure legends**

375 **Figure 1 | Tissue map and multi-omics dataset.** a, Schematic representation of tissue
376 samples analysed in this study and coloured according to morphology group: Flower (light grey),
377 seed (dark brown), pollen (yellow), stem (dark green), leaf (light green), root (dark grey), fruit
378 (light brown), callus (magenta), cell culture (blue). b, Number of identifications at the protein,
379 transcript and phosphorylation site (p-site) level for all tissues (n = 1 measurements per tissue).
380 A dashed line indicates the number of core proteins, transcripts or p-sites detected in all tissues.
381 Tissue-enhanced proteins or transcripts are marked in darker colour. P-sites with high
382 confidence amino acid localization (class I,>0.75 localization probability) are shown in pink,
383 ambiguous site localizations in purple. The number of p-sites exclusively detected in one tissue
384 is shown as circles. c, Total number and overlap of identified gene loci in the transcriptome,
385 proteome and phosphoproteome datasets compared to Araport11 (left panel) and total number
386 of identified p-sites and proportion of class I sites (right panel).

387 **Figure 2 | Data exploration in ATHENA and ProteomicsDB.** a, Schematic representation of
388 data analysis options in the web tool ATHENA (Arabidopsis THaliana ExpressioN Atlas) and
389 ProteomicsDB. b, Mirror plot showing near identical observed and predicted tandem mass
390 spectra (n = 1 acquired spectra) for a peptide from the 'uncertain' protein AT4G13955, thus
391 validating its existence as a protein. SA denotes the normalized spectral contrast angle, a
392 measure for spectrum similarity. c, Upper panel: summed absolute protein expression of AGC1
393 and AGC3 subfamilies of AGCVIII kinases. Lower panel: relative protein expression profiles of
394 D6PK family members and the closely related kinases AGC1.5, AGC1.6 and AGC1.7. Arrow
395 heads indicate embryo and pollen tissue with high expression of D6PKL3 or AGC1.5 and
396 AGC1.7, respectively. d-e, Representative images of GUS-stained flowers expressing *AGC1.6*
397 (n = 20 independent transgenic lines) and *AGC1.7* (n = 12 independent transgenic lines)
398 promotor-GUS fusions. Arrow-heads indicate anthers containing pollen grains. Scale bars 1
399 mm. f-i, Representative images of embryo phenotypes (at heart stage or age matched
400 equivalent) and their respective frequency for wild type (WT), *d6pkl3* single, *d6pk012* triple
401 (*d6pk d6pkl1 d6pkl2*) and *d6pk0123* (*d6pk d6pkl1 d6pkl2 d6pkl3*) quadruple knock-out mutants.
402 Scale bars 20 µm.

403 **Figure 3 | Protein and mRNA expression.** a, Scatter plot of protein versus transcript
404 abundance (median across 30 tissues). Arrows mark examples for genes with high protein to
405 transcript ratio (PTR, rbcL, petA) or low PTR (IAA8, IAA13). Pearson correlation (*R*). b, Relative
406 contribution of molecular features (averaged across tissues) able to predict protein abundance.
407 UTR, untranslated region, Dn/Ds, ratio of non-synonymous to synonymous nucleotide
408 substitutions. c, Schematic representation of the steps where modulation of PTRs may occur.
409 For example, the higher the transcription rate the lower the PTR. d, PTR distribution of genes
410 for selected tissues. Genes with high and low PTRs are defined as being outside two standard
411 deviations of the median PTR distribution. e, Analysis of the proportion of genes with high or low

412   PTRs that are at least 4-fold differently abundant on transcript and/or protein level in seed
413   compared to all other tissues (depicted as arrows). The percentage of genes below the 4-fold
414   criterion are placed at the origin of the plot. n denotes the number of genes with high or low
415   PTRs in seed as defined in panel d. f, Relative protein expression changes of proteins with high
416   or low PTRs (from panel e) in seeds incubated for 8h, 16h and 24h with 100 µM cycloheximide
417   (translation block), MG132 (proteasome block) or DMSO (control).

418   **Figure 4 | Protein complex characterization by protein co-expression and SEC-MS.** a,
419   Upper panel: 221 proteins that form a module in the tissue atlas based on their co-expression
420   across all tissues. Lower panel: co-elution of 57 proteins in a size-exclusion chromatography
421   (SEC)-mass spectrometry experiment using flower tissue. b, Overlap of proteins (n=14)
422   between the groups of co-expressed and co-eluting proteins in a. Ten of the proteins in the
423   intersection are subunits of the coatomer complex. c, Tissue-resolved absolute abundance (top
424   panel) and relative proportions of coatomer complex subunits based on the tissue atlas protein
425   expression data (lower panel) showing heterogeneous expression but a fairly homogeneous
426   composition of the complex across tissues. Paralogs of the α, β, β', ε and ζ coatomer subunits
427   were combined for the analysis. Tissue groups are coloured as in Figure 1.

428   **Figure 5 | Ascribing function to protein phosphorylation.** a, Scatter plot of the proportion of
429   potential phosphorylation acceptor sites in a protein sequence (limited to S, T and Y) versus the
430   proportion of STY residues found to be phosphorylated in this study. While most proteins
431   including RCAR10 and QKY show only a small proportion of phosphorylated residues, the LEA
432   proteins are phosphorylated at almost every possible residue. b, Abscisic acid (ABA) response
433   (average ± SD; n = 3) of ABA treated protoplast cells transformed with wild type or
434   phosphomimic variants of RCAR10 (S32D and S113D) suggesting that S32 and S113
435   phosphorylation are functionally involved in RCAR10 activity. c-f, Representative images of
436   flowers and siliques of wild type (WT), *qky-9* mutant and *qky-9* expressing phospho-dead
437   QKY$_{S262A}$ or phosphomimic QKY$_{S262E}$ constructs showing that QKY$_{S262E}$ but not QKY$_{S262A}$
438   rescues the *qky-9* phenotype. Scale bars: flower 1 mm, silique 0.5 cm.

439

Methods

Sample preparation

Inflorescence and seed samples: *Arabidopsis thaliana* wild type Columbia-0 (Col-0) plants were grown under continuous white light conditions at 22°C. Samples for flower parts and siliques were harvested from mature plants. Stage 15 flowers [46] were dissected into petal, sepal, stamen and carpel. Fully grown green siliques were separated into septum, valves and green seeds (stage 10). Surface-sterilized mature dry seeds were stored for two days at 4°C and subsequently imbibed for 24 h or kept dry. For pollen collection, plants were grown on soil under a long photoperiod (16 h of light, 21°C, 65% humidity). Mature pollen was bulk-harvested from open flowers at developmental stage 13 [46]. A vacuum cleaner was modified with three subsequent nylon meshes (80 micron, 35 micron, 10 micron mesh) for large scale pollen isolation as described [47]. Pollen was collected in a 1.5 ml reaction tube, snap-frozen in liquid nitrogen and stored at -80°C until further use.

Cell culture and callus samples: Cell culture samples (root cells, Col-0) were grown in medium composed of 4.3 g/l Murashige and Skoog basal medium (MS), 30 g/l sucrose and 0.33 mg/ml KH_2PO_4, supplemented with 2.4-D (final concentration 1 mg/l; pH adjusted to 5.8 with KOH) at 22°C under continuous light and harvested either three or ten days after sub-culturing. To generate callus inducing medium (CIM) callus, root explants were harvested from two weeks-old seedlings (Col-0) grown in sterile culture on MS plates. 5 to 10 mm long root segments were cultured on CIM medium composed of 1x Gamborg's B-5 salts, 20 g/l glucose, 0.5 g/l MES, 1x Gamborg's vitamin solution and 1% Phytoagar supplemented with 2,4-D (500 µg/l) and kinetin (50 µg/l). CIM calli appeared after 7 to 10 days and were propagated in two weeks-subculture intervals on CIM medium. To generate the callus line with an egg cell-like expression profile, the coding sequence of RKD2 (AT1G74480) was amplified from pistil cDNA using the primer pair RKD2fw and RKD2rev (Supplementary Data 11). Pistils from flowers at developmental stage 12 [47] were harvested to purify mRNA and generate cDNA as described [48]. The PCR fragment was cloned into pENTR/D-TOPO (Invitrogen, Carlsbad, USA) and subsequently transferred into the GATEWAY-compatible destination vector pH7FWG2.0 [49] with LR clonase. The resulting expression vector 35Sp:RKD2-GFP was used for floral dip transformation of Arabidopsis [50]. Seeds of transformed plants were surface-sterilized and grown on ½ MS medium with 2% (w/v) sucrose, 1% Phytoagar, and Hygromycin (30 µg/ml). RKD2-induced calli had formed after 20 to 30 days and were propagated in two weeks-subculture

472   intervals on ½ MS, 2% (w/v) sucrose, 1% Phytoagar, Hygromycin (30 µg/ml). Calli were

473   collected with a sterile scalpel blade and immediately frozen in liquid nitrogen.

474   ***Leaf and root samples:*** Arabidopsis plants (Col-0) were grown under continuous light

475   conditions at 22°C. Senescent rosette leaves were collected from 35 days-old plants. Samples

476   for stem, first node, second internode and first cauline leaf were collected from 30 days-old

477   plants. Rosette leaf sections (Leaf7: distal; proximal; petiole) were harvested from 22 days-old

478   plants before bolting. Seedlings were grown on ½ MS plates under continuous light for

479   seven days and separated into cotyledons, hypocotyl, root tip, root maturation zone or seed

480   apical meristem including cotyledons and first leaves. Whole roots were harvested from 22

481   days-old plants grown under continuous light on ½ MS plates.

482   Classification of growth stage and plant section was done as described [44,51-53]. Harvested

483   material from at least three individual plants was combined for each sample, frozen in liquid

484   nitrogen and stored at -80°C until further use.

485   **Protein lysis and digest**

486   Frozen plant material was homogenized with a tissue lyzer (Qiagen, Hilden, Germany) or with

487   mortar and pestle in liquid nitrogen. Proteins were precipitated over night with 10%

488   tricholoroacetic acid in acetone at -20° C and subsequently washed two times with ice-cold

489   acetone. Dry samples were incubated with urea digestion buffer (8 M urea, 50 mM Tris-HCl pH

490   7.5, 1 mM DTT, cOmplete™ EDTA-free protease inhibitor cocktail (PIC) [Roche, Basel,

491   Switzerland], Phosphatase inhibitor [PI-III; in-house, composition resembling Phosphatase

492   inhibitor cocktail 1,2 and 3 from Sigma-Aldrich, St. Louis, USA]) for 1 h. Protein concentration

493   was determined with a Bradford assay [54]. 1 mg of protein was reduced (10 mM DTT, 1h, room

494   temperature), alkylated (55 mM chloroacetamide, 30min, room temperature) and subsequently

495   diluted 1:8 with digestion buffer (50 mM Tris-HCl pH 8.0, 1 mM $CaCl_2$). In-solution pre-digestion

496   with trypsin (Roche, Basel, Switzerland) was performed for 4 hours at 37°C (1:100

497   protease:protein ratio), followed by overnight digestion with trypsin (1:100 protease:protein

498   ratio). Samples were acidified to pH 3 using trifluoroacetic acid (TFA) and centrifuged at

499   14,000 *g* for 15 min at 4°C. The supernatant was desalted on 50 mg SepPAC SPE catridges

500   (Waters, Milford, USA). Peptides were eluted with 0.1 % TFA in 50% acetonitrile (ACN) and

501   vacuum-dried in a Thermo Savant SPD SpeedVac (Thermo Fisher Scientific, Waltham, USA).

502   **Peptide enrichment and off-line fractionation**

503 Fe^{3+}-IMAC was performed as described previously with some adjustments [55]. Briefly, desalted

504 peptide samples were re-suspended in ice-cold IMAC loading buffer (0.1% TFA, 40% ACN). For

505 quality control, 1.5 nmol of a synthetic library of phosphopeptides and their corresponding non-

506 phosphorylated counterpart sequence (B2 and F1) [56] were spiked into each sample prior to

507 loading onto a Fe^{3+}-IMAC column (Propac IMAC-10 4x50 mm, Thermo Fisher Scientific,

508 Waltham, USA). The enrichment was performed with Buffer A (0.07% TFA, 30% ACN) as wash

509 buffer and Buffer B (0.315% NH_4OH) as elution buffer. Collected full proteome and

510 phosphopeptide fractions were vacuum-dried and stored at -80°C until further use.

511 For the full proteome fraction, hydrophilic strong anion exchange chromatography (hSAX)

512 peptide separation was performed as described previously [15]. Briefly, an equivalent of 300 µg

513 protein digest was reconstituted in hSAX solvent A (5 mM Tris-HCl, pH 8.5) and separated

514 using a Dionex Ultimate 3000 HPLC system (Dionex Cor., Idstein, Germany) equipped with an

515 IonPac AG24 guard column (2x50 mm) and an IonPac AS24 stong anion exchange column (2x

516 250 mm, Thermo Fisher Scientific, Waltham, USA). Fractions were collected in 96 well format

517 and subsequently pooled to 24. Individual fractions were acidified with formic acid (FA),

518 desalted on self-packed StageTips (five disks, Ø 1.5 mm C18 material, 3M Empore™, elution

519 solvent 0.1% FA in 50% ACN) and dried down prior to LC-MS/MS analysis. Phosphopeptide

520 fractions were separated into four fractions using a StageTip (five disks, Ø 1.5 mm C18

521 material, 3M Empore™) based high pH reversed phase protocol as described previously [57].

522 Phophosphopeptides were eluted with 2.5%, 7.5%, 12.5% and 50% ACN in 25 mM NH_4FA pH

523 10. The flow through and 50% ACN fraction were combined and all fractions were dried down

524 prior to LC-MS/MS analysis.

525 For the cycloheximide and MG132 chase experiments, 300 µg peptides for each sample were

526 reconstituted in high pH reversed phase loading buffer (2.5 mM NH_4HCO_3, pH 8) and

527 fractionated using a Dionex Ultimate 3000 HPLC system (Dionex Corp., Idstein, Germany) and

528 a Waters XBridge column (BEH130 C18, 3.5 um, 2.1x150mm; Waters, Milford, USA). Peptides

529 were separated by a linear gradient from 4% Buffer D to 32% D in 45 min, followed by a linear

530 gradient from 32% D to 80% D in 6 min. The proportion of Buffer A was kept at 10% during

531 fractionation (Buffer A: 25 mM NH_4HCO_3, pH 8; Buffer C: 100% ACN; Buffer D: 100% ultrapure

532 water). Fractions were collected in 96 well format, subsequently pooled to 48, acidified and

533 dried in a SpeedVac.

534 ***Seed treatment with cycloheximide and MG132***

535 Aliquots of surface-sterilized mature dry seeds ((10 mg, Col-0) were stored for two days at 4°C

536 in the dark and subsequently imbibed with 2 ml liquid ½ MS at 22°C under constant light. After 4

537 h incubation, cycloheximide (CHX) or MG132 (*N*-(benzyloxycarbonyl)-Leu-Leu-Leu-al) was

538 added to a concentration of 100 µM. Since both CHX and MG132 were dissolved at the same

539 stock concentration in 100% dimethylsufloxide (DMSO), the respective volume of 100% DMSO

540 was added to the control samples. As a baseline sample, one seed aliquot was dried and

541 immediately frozen in liquid nitrogen after the 4 h incubation in ½ MS medium. Seeds for CHX,

542 MG132 and DMSO control were removed after 8 h, 16 h and 24 h treatment, dried and frozen in

543 liquid nitrogen. Germination of treated seeds was visually checked after 4 days of incubation.

544 Both compounds CHX and MG132 were active and led to complete or partial inhibition of seed

545 germination as compared to a DMSO treated control sample (Extended Data Fig. 4i).

546 Protein extraction and digest was performed as described above. Peptide quantification prior to

547 high pH reversed phase fractionation was done using the Pierce™ BCA protein assay kit

548 (Thermo Fisher Scientific, Waltham, USA) [58].

549 ***Size exclusion chromatography (SEC)***

550 Homogenized flower (stage 15), leaf (rosette leaf 7) and root (whole root) samples were lysed in

551 ice-cold 50 mM Tris-HCl pH 7.4, 100 mM NaCl, 10% glycerin, PIC, PI-III and 0.1% Triton-X100.

552 After filtering (Ø 0.2µm), 0.25 ml lysate containing 1 mg of protein was injected on a Superose 6

553 10/30 GL column (GE Healthcare, Chicago, USA) and separated at a flow rate of 250 µl/min on

554 an Äkta pure 25 (GE Healthcare, Chicago, USA). Molecular weight calibration of the column

555 was performed with the high molecular weight gel filtration calibration kit (GE Healthcare,

556 Chicago, USA). After the void volume, 80 fractions of 125 µl each were collected, vacuum dried

557 and re-solubilized in urea digestion buffer. In-solution digestion with trypsin and sample

558 desalting on self-packed StageTips was performed as described above. For quality control,

559 PROCAL peptide standard [59] was spiked into each SEC fraction prior to LC-MS/MS analysis.

560 ***LC-MS/MS analysis***

561 Nanoflow LC-MS/MS was performed by coupling a Dionex 3000 (Thermo Fisher Scientific,

562 Waltham, USA) to a QExactive Orbitrap HF (Thermo Fisher Scientific, Waltham, USA). Samples

563 for the proteome and phosphoproteome analysis were re-suspended in loading buffer

564 containing 0.1% formic acid (FA) or 50 mM citrate and 1% FA, respectively. Peptide loading and

565 washing were done on a trap column (100 µm i.d. x 2 cm, packed in-house with Reprosil-Pur

566 C18-GOLD, 5 µm resin, Dr. Maisch, Ammerbuch, Germany) at a flow rate of 5 µl/min in 100%

loading buffer (0.1% FA) for 10 min. Peptide separation was performed on an analytical column (75 μm i.d. x 40 cm packed in-house with Reprosil-Pur C18, 3 μm resin, Dr. Maisch, Ammerbuch, Germany) at a flow rate of 300 nl/min using a 110 min gradient from 4% to 32% solvent B (solvent A: 0.1% FA, 5% DMSO in HPLC grade water; solvent B: 0.1% FA, 5% DMSO in acetonitrile) for the tissue map full proteome analysis and a two-step 110 min gradient from 2% to 27% solvent B for the phosphoproteome analysis [60]. Peptides were ionized using a spray voltage of 2.2 kV and a capillary temperature of 275°C. The instrument was operated in data-dependent mode, automatically switching between MS and MS2 scans. For the full proteome samples of the tissue atlas experiment, full scan MS spectra (m/z 360 – 1300) were acquired with a maximum injection time of 10 ms at 60,000 resolution and an automatic gain control (AGC) target value of 3e6 charges. For the top 12 precursor ions, high resolution MS2 spectra were acquired in the orbitrap with a maximum injection time of 50 ms at 15,000 resolution (isolation window 1.7 m/z), an AGC target value of 2e5 and normalized collision energy of 25%. The underfill ratio was set to 1% with a dynamic exclusion of 30 s. Only precursors with charge states between 2 and 6 were selected for fragmentation. For the phosphoproteome analysis, the MS2 spectra were acquired with a resolution of 30,000 (isolation window 1.7 m/z) and a maximum injection time of 120 ms. Dynamic exclusion was set to 35 s.

SEC samples were measured using a 60 min 4% to 32% gradient. MS2 spectra were generated for the top 20 precursors, with a maximum injection time of 50 ms at 30,000 resolution (isolation window 1.7 m/z), a normalized collision energy of 25% and a dynamic exclusion of 20 s.

The samples for cycloheximide and MG132 treated seed samples were analyzed by a micro-flow LC system coupled online to an Orbitrap Fusion Lumos mass spectrometer (Thermo Fisher Scientific, Waltham, USA)) as described previously [61]. The micro LC system was built by combining a modified Vanquish pump with the auto-sampler of the Dionex UltiMate 3000 RSLCnano System. The sample was directly loaded onto a Thermo Fisher Scientific Acclaim PepMap 100 C18 LC column (2 μm particle size, 1 mm ID x 150 mm), the flow rate was 50 μl/min and column temperature was maintained at 55 °C. A 15 min linear gradient of 7%-32% solvent B (solvent A: 0.1% FA, 3% DMSO in HPLC grade water; solvent B: 0.1% FA, 3% DMSO in acetonitrile) was used to separate all the samples, followed by 1 min 95% solvent B washing and 1 min 0.5% solvent B equilibrium time at a flow rate of 100 μl/min. The Orbitrap Fusion Lumos mass spectrometer was operated with the Ion Max API Source installed with a HESI-II probe (50 μm ID). The detailed acquisition parameters are: Positive polarity; spray voltage 3.5 kV, funnel RF lens value at 40, capillary temperature of 325 °C, auxiliary gas heater

19

600   temperature of 300 °C. The flow rates for sheath gas, aux gas and sweep gas were set to 32, 5,

601   and 0, respectively. Full scan MS spectra (m/z 360 – 1300) were acquired in the orbitrap with a

602   maximum injection time of 10 ms at 120,000 and an AGC target of 4E5. MS2 spectra were

603   acquired in the linear ion trap (rapid scan mode) after collision-induced dissociation (CID)

604   fragmentation with collision energy set at 35%, an AGC target of 1E4 and maximum IT of

605   10 ms. The isolation window was set to 0.4 m/z and scans were recorded with a maximum duty

606   cycle of 0.6 s and the option 'inject ions for all parallelizable time' enabled. Only precursors with

607   charge states between 2 and 6 were selected for fragmentation and the lowest scan range of

608   MS2 was fixed at 100 m/z. The intensity threshold was set to 5E3 and the dynamic exclusion to

609   12 s.

610   ***Peptide and protein identification and quantification***

611   Raw data files were searched with MaxQuant software (v. 1.5.8.3) using standard settings

612   unless otherwise described [62]. MS/MS spectra were searched against Araport11 [5] protein

613   coding genes (Araport11_genes.201606.pep.fasta; download 06/2016), with trypsin as protease

614   and up to two allowed missed cleavages. Carbamidomethylation of cysteines was set as fixed

615   modification and oxidation of methionines and N-terminal acetylation as variable modifications.

616   The 'match-between-runs' function was enabled for corresponding fractions within one

617   parameter set, where applicable.

618   For the tissue map analysis, full proteome and phosphoproteome samples were processed

619   together as two separate parameter groups, with phosphorylation of serine, threonine or

620   tyrosine defined as variable modification only for the phosphoproteome group. Here we also

621   added the spike-in phosphopeptide library sequences [56] to the database search space.

622   For sORF identification two sORF databases (ATSO and ARA-PEP) were added to the search

623   space in addition to Araport11. ARA-PEP is a previously described repository of putative sORF-

624   encoded peptides in Arabidopsis [14]. ATSO (*Arabidopsis thaliana* sORFs) was generated by

625   using sORFfinder [63] and our RNA-seq analysis data to identify putative new sORFs in non-

626   coding intergenic regions (ATSO.non_coding.pep.nr.cd-hit_aS1_aL0.3_c1.out.nr.fasta). Three

627   targets were used as input for sORFfinder. Sequences of intergenic and non-coding regions

628   relative to the Araport11 annotation and sequences resulting from a Trinity [64] *de novo*

629   transcriptome assembly which are non-overlapping with the Araport11 annotations. Afterwards,

630   the sORF nucleotide sequences were translated to amino acid sequences. CD-HIT [65] was used

631   with the parameters –aS 1 –aL 0.3 –c 1 to reduce sequence redundancy. .

632 SEC experiment raw files for flower, leaf and root were all searched together, with each SEC
633 fraction designated as individual experiment and the 'match-between-runs' function enabled.

634 The seed experiment raw files were searched using standard settings as described above.

635 Peak list files generated by Baerenfaller et al. (2008) [7] were downloaded from Pride
636 (PRD000044) and searched with the Mascot [66] search engine (version 2.4.1, Matrix science)
637 against the Araport11 database. The target-decoy option of Mascot was enabled and search
638 parameters included a precursor tolerance of 1.3 Da and a fragment ion tolerance 0.45 Da.
639 Enzyme specificity was set to trypsin and up to two missed cleavages were allowed. The
640 Mascot ^{13}C option, which accounts for the misassignment of the monoisotopic precursor peak,
641 was set to 1 and oxidation of methionine and carbamidomethylation of cysteines were included
642 as variable and fixed modification, respectively. The isobarQuant workflow was used to
643 generate protein identification files [67].

644 ***Spectra validation***

645 sORF peptides identified by database searching that could not be mapped to an existing
646 Araport11 gene model were synthethized at JPT Peptide Technologies (Berlin, Germany) using
647 Fmoc-based SPOT synthesis on membranes [59] and measured on the same mass spectrometer
648 that was used for data acquisition (Tissue atlas full proteome method; see above for method
649 description). Experimental and synthetic peptide spectra were extracted from the raw files and
650 used for similarity calculation without prior processing. Normalized spectral contrast angle (SA)
651 comparison between spectra of the tissue sample and synthetic peptides was performed using
652 in-house R scripts [68] factoring in peaks which are either shared between spectra or exclusive to
653 the synthetic peptide spectra. Peaks exclusive to experimental spectra were ignored.
654 Candidates were selected with SA angle cutoff larger than 0.7 and BLASTed against the
655 UniProt database for further validation (Supplementary Data 3).

656 Protein identifications for the 'uncertain' evidence category of UniProt were validated by
657 comparing the experimental spectra to in-silico predicted fragment spectra (Supplementary
658 Table 1) [12]. For this, a spectral library was obtained from Prosit
659 (https://www.proteomicsDB.org/prosit) [12] by uploading all sequence-charge combinations of
660 peptides that were identified for 'uncertain' proteins. To obtain the best matching spectra, the
661 collision energy of Prosit was calibrated using a standard quality control run from the same
662 mass spectrometer that was used for data acquisition. The resulting predicted spectral library

663 was visualized and compared to the experimentally acquired data analog to the sORF candidate

664 peptides. SA values larger than 0.7 were used as cutoff.

665 *RNA sequencing*

666 Total RNA was isolated with the NucleoSpin RNA Plant kit (Macherey-Nagel, Düren, Germany)

667 according to the manufacturer's instructions. DNA was removed by on-column treatment with

668 rDNAse (Macherey-Nagel, Düren, Germany). For recalcitrant samples (seed, silique, pollen), a

669 LiCl-based protocol was adopted with minor modifications [69]. After LiCl precipitation, the RNA

670 pellet was dissolved in rDNAse buffer and treated with rDNAse (Macherey-Nagel, Düren,

671 Germany) at 37°C for 10 min. The final pellet was re-suspended in 35 µl DEPC-treated water.

672 RNA was quantified (Nanodrop™, Thermo Fisher Scientific, Waltham, USA) and quality

673 checked with a Bioanalyzer 2100 (Agilent Technologies, Santa Clara, USA). RNA integrity

674 number (RIN) values between 6.4 and 10 were accepted for further analysis. cDNA libraries

675 were prepared using the TruSeq Stranded mRNA Sample Preparation kit (Illumina, San Diego,

676 USA) according to the instructions. Clusters were generated in two batches and sequenced on

677 a High throughput flow cell with the HiSeq 2500 platform (Illumina, San Diego, USA) to a depth

678 of 36 million reads per sample. Quality assessment of raw and trimmed 75 bp paired RNA-seq

679 reads was performed with FastQC. Raw RNA-seq reads were trimmed to remove adapter

680 contamination and poor quality base calls using Trimmomatic version 0.35 with parameters

681 (ILLUMINACLIP: Illumina-PE.fasta:2:30:10; LEADING:3; TRAILING:3; SLIDINGWINDOW:4:20;

682 MINLEN:36) [70]. Trimmed RNA-seq reads were mapped to the Araport11 [4] transcriptome with

683 Kallisto version 0.43.1 (default parameters) [71].

684 *Data processing*

685 MaxQuant output tables were filtered for non-plant contaminants, reversed sequences and

686 proteins which were only identified based on modified peptides. Protein abundance estimation

687 was based on either intensity-based absolute quantification (iBAQ) [26], or top3 quantification [72],

688 depending on the analysis. MaxQuant ProteinGroups containing several gene loci were filtered

689 out in order to retain only unambiguously identified gene loci for further analyses. In case

690 multiple protein isoforms were identification in distinct ProteinGroups, only the isoform with the

691 higher number of razor+unique peptides was retained.

692 mRNA quantities are displayed as transcripts-per-kilobase-million (TPM) and a cutoff of 1 TPM

693 was used as lower limit of detection across all samples. Gene ontology [73] (GO)-term analysis for

694 the transcript abundance range was performed using the 1D enrichment function from Perseus

695 [74,75] with Benjamini-Hochberg FDR threshold set to 0.01. In this function, a two-sided Wilcoxon-

696 Mann-Whitney test is employed to test for systematically larger or smaller transcript abundance

697 within a GO category as compared to the global distribution of all values (Supplementary Data

698 4).

699 For further qualitative and quantitative analyses, all transcript or protein isoform information was

700 collapsed onto gene level. Unless otherwise stated, displayed abundances for protein, transcript

701 and phosphorylation sites (p-site) were $\log_2$ transformed. Protein, peptide and transcript

702 datasets for the tissue map and seed treatment experiments were median centered to the

703 overall median of the respective dataset. No normalization was performed for the p-site dataset,

704 since total p-site intensity variations between tissues are also due to biological sample

705 differences. Instead, the spike-in phosphopeptide library was used, to assess reproducible

706 enrichment efficiency and MS measurement quality of phosphoproteome samples [56].

707 Phosphorylation sites (p-sites) which were reported in the MaxQuant output table

708 (Phospho(STY)sites.txt file) with a 'localization probability' larger than 0.75 were designated as

709 'high confidence localizations' or class I sites [76]. P-sites were considered exclusive if they were

710 only detected in a single tissue. The number and identity of p-sites and phosphoproteins

711 detected in this study were compared to datasets available through PhosPhAT4.0 and a

712 published meta-analysis [8,9] (Extended Data Fig. 1h).

713 *Data analysis*

714 *Genome annotations:* Chromosome information contained in the Arabidopsis locus identifiers

715 (AGI codes: AT [Arabidopsis thaliana]; 1, 2, 3, 4, 5, M, C [chromosome number, M for

716 mitochondrial, C for chloroplast]; G [gene]; 12300 [five-digit code for position on chromosome]),

717 was used to assign genes to their respective chromosomes (Extended Data Fig.1c). Araport11

718 gene identifiers (Arabidopsis gene identifiers [AGI]) were mapped to the UniProt *Arabidopsis*

719 *thaliana* reference proteome (taxon identifier 3702; UP000006548; download 11/2018) based on

720 protein sequence. Swiss-Prot, TremBL as well as protein existence criteria annotations (level1:

721 evidence on protein level; level2: evidence on transcript level; level 3: inferred from homology,

722 level 4: predicted, level 5: uncertain) were subsequently obtained from UniProt (Extended Data

723 Fig.1d).

724 N- and C-terminal peptide sequences were extracted from the MaxQuant peptides.txt file and

725 filtered for zero missed cleavages (n = 2,776) (Extended Data Fig. 2a). N-terminal peptides

726 were divided into groups with (n = 1,707) or without (n = 1,069) cleavage of the initiator

methionine. The frequency of the 20 genetically encoded amino acids at the position after the start codon was subsequently calculated separately for both groups and displayed as a pie chart. For N-terminal peptides with the same amino acids at the position after the start codon, the percentage of peptides with N-terminal acetylation was also calculated and displayed as bar plot. This analysis was also performed separately for the groups with or without cleavage of the initiator methionine (Extended Data Fig. 2b,c).

Gene isoforms annotated in Araport11 were considered as 'identified', if they were detected with a TPM intensity larger than our limit of detection cutoff (1 TPM; transcript level) or with an isoform-specific peptide (protein level) in at least one tissue sample (Extended Data Fig. 2f, Supplementary Data 3). A selection of isoform-specific peptides was synthesized together with the sORF peptide collection at JPT Peptide Technologies (Berlin, Germany) and the synthetic peptides were used for validation of the experimental spectra identifications as described above.

Transcription factor, transcription regulator, kinase and phosphatase family annotations and classifications are based on reports by Zheng et al. [16] and Yang et al. [17]. Proportional coverage of these families within our dataset was calculated by counting how many of them could be identified on transcript, protein or phosphoprotein level, respectively (Extended Data Fig. 2k).

Tissue groups and tissue characteristics: Tissue samples were assigned to tissue groups as follows, based on their origin or common morphology: flower (sepal, petal, stamen, carpel, silique, flower); fruit (silique septum, silique valves); seed (embryo, seed, seed imbibed); pollen (pollen); leaf (cauline leaf, leaf distal, leaf proximal, leaf petiole, senescent leaf, cotyledons, shoot tip); stem (node, internode, flower pedicle, hypocotyl); root (root, root tip, root upper zone); callus (egg-cell like callus, callus); cell culture (cell culture early, cell culture late) (Fig. 1a,b).

To provide a measure of tissue similarity, the Pearson correlation coefficient was calculated for the gene expression of all pair-wise tissue combinations. The Pearson correlation coefficient is a measure of the linear correlation between two variables, in this case the expression levels in two tissue samples. Correlations were computed both on protein level and transcript level and displayed as separate heatmaps for both omics levels (Extended Data Fig. 1a). For three examples of morphologically highly similar tissue pairs, the gene expression levels were also displayed as scatter plots using protein abundance or transcript abundance measurements, respectively (Extended Data Fig. 1b).

758   Tissue or tissue group specificity of genes was calculated based on iBAQ or TPM abundance

759   values, respectively [77]. Genes were assigned to categories in the following order: 'tissue

760   specific', 'tissue enhanced', 'group-specific', 'group-enhanced', 'shared' and 'mixed'. Genes

761   were considered 'specific', if they were only detected in a particular tissue or tissue-group and

762   'enhanced' if their abundance was at least five-fold higher in a particular tissue or tissue-group

763   as compared to the average levels in all other tissues. Genes that were detected in all 30

764   tissues but did not show enhanced expression in a tissue or tissue group were classified as

765   'shared'. All remaining genes are contained in the 'mixed' category (Extended Data Fig. 3a).

766   Genes detected in all tissues on either protein or transcript level were assigned to the core

767   datasets (core_transcript n= 8,405; core_protein n = 7,734; core_intersection n = 5,043). This

768   classification does not consider gene expression levels and should not be confused with the

769   tissue-specificity classification described in the previous paragraph.

770   Hierarchical clustering analysis for tissues representing flower parts or the whole flower was

771   performed on $\log_2$-transformed, z-scored protein intensities (iBAQ values) in Perseus using

772   Euclidean distance and average linkage (Extended Data Fig. 3b). The flower organ identity

773   model was restricted to the simplified ABC model, thus only displaying homeotic genes for the

774   A, B and C classes [78], namely the expression of MADS-box transcription factors *APETALA1*

775   (*AP1*) for class A, *APETALA3* (*AP3*) and *PISTILLATA* (*PI*) for class B and *AGAMOUS* (*AG*) for

776   class C. Class A expression specifies sepal formation, the combination of class A and B

777   specifies petal formation, the combination of class B and C specifies stamen formation and

778   class C expression specifies carpel formation in developing flowers.

779   For the cumulative abundance calculation of five representative tissues (flower; pollen; root tip;

780   leaf proximal; seed), proteins (iBAQ) and transcripts (TPM) were first ranked from highest to

781   lowest individual intensity (Extended Data Fig. 3e). The running total was then plotted against

782   the rank order. The names or identifiers of the five most abundant transcripts or proteins (rank 1

783   to 5) are listed in descending order for the respective tissue. Shared IDs among the top 100

784   most abundant transcripts (TPM) and proteins (iBAQ) were calculated for each individual tissue

785   (Extended Data Fig. 3f). For the genes representing the highest abundant protein in at least one

786   tissue, the contribution to the total protein amount in an individual tissue was calculated by

787   dividing the iBAQ intensity (not log transformed) of the respective protein by the summed total

788   iBAQ intensity (not log transformed) in this tissue (Extended Data Fig. 3g).

789   Principal component analysis (PCA) of proteome and transcriptome data was performed in

790   Perseus for the intersection of the core datasets (n = 5,043) on $\log_2$-transformed and z-scored

791　iBAQ and TPM intensities (Extended Data Fig. 3h). Subcellular localization information was

792　downloaded from SUBA (download 11/2016; unambiguous localizations n = 3,506) [44]

793　(Supplementary Data 2) and used to calculate the intensity contribution of proteins assigned to

794　a specific compartment for the different tissue groups. For this, the percentage of proteins with

795　the same SUBA annotation was calculated by dividing the summed protein intensity (iBAQ, not

796　log transformed) of each SUBA category by the total summed iBAQ intensity (not log

797　transformed) within each tissue. To compare tissue groups, the respective protein intensity

798　proportion was then averaged for all tissues within one group. These averaged proportions were

799　subsequently plotted for each subcellular compartment (Extended Data Fig. 3i).

800　***Protein/mRNA relation***: The Pearson correlation value between median protein (median iBAQ

801　of 30 tissues) and median transcript (median TPM of 30 tissues) abundances was calculated

802　using the set of genes with abundance measurements on both protein and transcript level in

803　more than ten tissues (more than 10 pairwise complete observations; n = 14,069). The

804　scatterplot of median transcript (TPM) and protein abundance (iBAQ) was displayed together

805　with their marginal histograms (Fig. 2a). Tissue-specific Pearson correlation values between

806　protein and transcript abundance were calculated using all genes from the core proteome and

807　core transcriptome intersection dataset (n = 5,043; Extended Data Fig. 4a). The core dataset

808　was used here to base the Pearson correlation value comparison between tissues on the same

809　set of genes in all tissues.

810　The data subset with more than 10 pairwise complete observations on protein and transcript

811　level (n = 14,069) was also used for all further calculations involving protein-to-mRNA ratios

812　(PTR) (Fig. 3d, Extended Data Fig. 5). PTR values are calculated by building the ratio between

813　protein abundance (iBAQ) and the corresponding transcript abundance (TPM) for each gene

814　and were calculated separately for each tissue. The tissue PTR values were then used to

815　calculate the median and median absolute deviation (MAD) of PTR values across all 30 tissues

816　(Extended Data Fig. 5). The variation of PTR values across tissues indicates, whether protein

817　and transcript levels of a given gene are regulated in a similar (small PTR variation) or different

818　way (high PTR variation) between individual tissues. To estimate the proportion of genes with

819　rather stable or variable PTR values, the PTR MAD values were distributed into five equal parts,

820　so that 20% of all genes from this analysis are contained in one part (5 MAD quantiles: Q1-Q5).

821　For each gene, the median PTR values were plotted against their MAD across tissues and the

822　MAD quantiles indicated in the plot (Extended Data Fig. 5a). GO-term analysis for the median

823　PTR distribution (median PTR across all tissues) was performed using the 1D enrichment

824 function from Perseus [74] with Benjamini-Hochberg FDR threshold set to 0.01 (Supplementary

825 Data 4). In this function, a two-sided Wilcoxon-Mann-Whitney test is employed to test for

826 systematically larger or smaller PTR values within a GO category as compared to the global

827 distribution of all values.

828 In a similar way, the variation of phospho ratios across tissues indicates, whether p-site levels

829 are driven by protein abundance (small phospho ratio variation) or p-site stoichiometry (high

830 phospho ratio variation) changes, respectively. Phospho ratios were calculated by building the

831 ratio between a p-site abundance (intensity) and the abundance of its corresponding protein

832 (iBAQ). For this, we used the set of p-sites, with abundance measurements on both p-site and

833 protein level in more than ten tissues (more than 10 pairwise complete observations; n =

834 13,793). Phospho ratios were calculated separately for each tissue and subsequently combined

835 to calculate the median phospho ratio and phospho ratio MAD across all 30 tissues. To estimate

836 the proportion of p-sites which closely resemble the protein abundance profile, the phospho

837 ratio MAD values were again distributed into five equal parts (5 MAD quantiles: Q1-Q5), and the

838 median phospho ratio values plotted against their MAD across tissues each p-site. MAD

839 quantiles were indicated in the plot (Extended Data Fig. 5c).

840 To provide further information about inter-tissue variability, MAD quantiles were also calculated

841 and displayed for the expression levels on protein (iBAQ; n = 14,069), transcript (TPM; n =

842 14,069) and p-site (peptide intensity; n = 13,793) levels, respectively (Extended Data Fig. 5b,d).

843 **_Features for protein level prediction models_:** Since a substantial proportion of variation in

844 protein levels remained unexplained when using transcript level information alone (Pearson

845 correlation between protein and transcript abundance in tissues 0.28-0.79), additional molecular

846 features, that could explain protein abundance variations, were tested for their influence on

847 protein abundance in a model selection approach. Predictors selected for this analysis were:

848 mRNA levels, codon usage, non-synonymous to synonymous substitutions (_Dn/Ds_) ratios,

849 which are a measure of evolutionary conservation, gene/coding sequence (CDS) length, exon

850 number, gene position on the chromosome, cytosine methylation, the number of putative protein

851 interactions and mRNA sequence motifs (kmers of size 3 to 7 nucleotides):

852 Codon usage statistics for the _A. thaliana_ genome were obtained from Kazusa

853 (www.kazusa.or.jp/codon/current/species/3702) and parsed to extract NCBI gene identifiers.

854 These identifiers were mapped to their corresponding UniProt entries and Ensembl/TAIR10

855 annotations using the UniProt Retrieve/ID mapping tool. The extracted TAIR10 annotation was

856   merged with the Kazusa codon usage dataset. Codon frequencies were calculated for each
857   gene by dividing the count (x 3) of a given codon by the full length of the coding sequence.

858   The *Dn/Ds* substitution rates were calculated from CDS pairs between *Arabidopsis thaliana* and
859   its closest relative *Arabidopsis lyrata*. Reciprocal best BLAST with an e-value cutoff of ≤ 1E-08
860   was used to identify ortholog sequences. Individual CDS pairs were aligned using PRANK [79]
861   and Gblocks [80] was applied to eliminate poorly aligned positions in an alignment with a cutoff of
862   8 contiguous non-conserved positions and without allowing for gap positions. The yn00 package
863   in the program PAML [81] for pairwise sequence comparison was used to estimate substitution
864   rates, *Dn* and *Ds*, respectively.

865   The total number of exons and the total gene lengths were obtained from Araport11. The
866   distance of each gene from the chromosomal centromeres were calculated to capture potential
867   position-specific effects.

868   *A. thaliana* (Col-0) Whole Genome Bisulphite Sequencing (WGBS) data was obtained from van
869   der Graaf et al. 2015 [82]. For each gene, methylation levels were calculated for contexts CG,
870   CHG and CHG (where H = adenine, cytosine, thymine) separately. Per gene methylation levels
871   were defined as:

$$g_i = \frac{1}{max(j)} x \sum \frac{Nm_j}{N_j}$$

872   Here, *max(j)* is the total number of cytosines, Nm_j is the number of methylated reads and N_j the
873   total number of reads at the jth cytosine.

874   Arabidopsis protein-protein interactions were downloaded from STRING [30] and the number of
875   protein interaction partners extracted for each gene.

876   All of these features have previously been associated with transcriptional activity and/or protein
877   abundance levels in Arabidopsis and/or other species [83-88]. For a detailed feature set description
878   see Supplementary Data 5.

879   ***De novo motif identification***: Motifs in the mRNA CDS, 3' or 5'UTR region were identified as
880   previously described [23]. Briefly, protein expression levels were log_{10} transformed and median
881   centered. For genes with two or more transcript isoforms, the transcript isoform reported to have
882   the largest summed iBAQ values across all tissues was defined as the major transcript isoform
883   per gene and used to compute all sequence feature and mRNA levels. Raw RNA-seq reads
884   were trimmed to remove adapter contaminations and poor quality base calls using Trimmomatic

885   0.39 with parameters (ILLUMINACLIP:Illumina-PE.fasta:2:30:10; LEADING:3; TRAILING:3;

886   SLIDINGWINDOW:4:20; MINLEN:36). Trimmed RNA-seq reads were mapped to the Araport11

887   transcriptome annotation with Kallisto version 0.46.0 using default parameters. To estimate the

888   levels of mature mRNA, the number of reads mapping to exonic and intronic regions of the

889   transcripwere counted separately and then normalized by the total exonic and intronic region

890   lengths, respectively. Normalized intronic counts were subtracted from the normalized exonic

891   counts to obtain the mature mRNA counts. The resulting normalized exonic counts per sample

892   were corrected by the DESeq2 [89] library size factor and $\log_{10}$ transformed. Transcripts with 10

893   reads per 1kb were treated as transcribed. Tissue-specific protein-to-transcript ratios (PTR)

894   were computed using the normalized protein and transcript levels. GEMMA software [90] was

895   used to identify de-novo motifs in 5'UTR, CDS and 3'UTR regions using the tissue-specific

896   PTRs as response variable. GEMMA uses a linear mixed model, in which the effect of each

897   individual kmer on the median PTR across tissues is assessed while controlling for the effect of

898   other kmers (random effects), region length and GC percent (fixed effects). The motif search

899   was performed for kmers ranging from 3-7 nucleotides. Obtained p-values were adjusted for

900   multiple testing with Benjamini-Hochberg's false discovery rate (FDR) and jointly computed

901   across the p-values of all tissues. Gemma was run using the median PTR with FDR<0.1 and

902   covariates set to 'false'. 82 significant putative motifs were obtained based on their sequence

903   (5'UTR n = 32; 3'UTR n = 38; CDS n = 12) and sub-sequence (initial, all, end) region. 39 motifs

904   that lie in the 'initial' and 'end' sub-sequences were further selected. The presence or absence

905   of each enriched motif with respect to each gene was extracted in form of a binary matrix and

906   used for downstream multivariate feature selection analysis.

907   ***Model-based feature selection***: Tissue-specific protein expression data was merged to the

908   feature matrix. Preliminary pair-wise correlation analysis showed only weak to moderate

909   correlation between individual features. In addition, Variance Inflation Factors (VIF) were

910   calculated for each feature using the fmsb R package [91]. The result showed low VIFs,

911   suggesting that multicollinearity was not an issue for downstream analyses.

912   Two model selection approaches were implemented, stepwise regression and Lasso regression

913   [92,93]. To select the most predictive features for protein abundance in each tissue, we used a

914   forward-backward model selection approach in a multiple regression framework. The method

915   was implemented using stepwiseAIC() function in R [94], which compares the fit of nested models.

916   To ensure that the comparison of model AICs were not affected by unequal sample size,

917   missing data were removed prior to the analysis.

918   Because stepwise regression can occasionally lead to over-fitting [95], a Lasso regression was

919   implemented as an alternative model selection procedure. Lasso regression performs L1

920   regularization, which adds a penalty equivalent to the absolute of the magnitude of regression

921   coefficients and tries to minimize them. The strength of the penalty was controlled via the tuning

922   parameter λ [93]. Lasso was implemented using the glmnet package [96] in R. Model training was

923   performed on a random selection of genes (50% of the dataset) and implemented using the

924   cv.glmnet() function. The optimal value for λ was extracted and used to re-build the model using

925   the glmnet() function. Finally, the fitted model was used to obtain predictions in the remaining

926   50% of the genes.

927   For each tissue, stepwise and Lasso regression models were compared. Stepwise regression

928   yielded only slightly higher coefficients of determination (R^2) values compared to Lasso,

929   suggesting over-fitting was not an issue (Supplementary Data 5). As stepwise regression

930   yielded more parsimonious models in general, we used this approach for further analysis.

931   Selected features here could explain on average 52% of protein abundance variation (37% in

932   pollen, 62% in cell culture early) (Supplementary Data 5). For each tissue, features from the

933   best fitting models were summarized in an incidence matrix along with the effect direction

934   (positive or negative effect on protein levels). To determine the importance of each feature to

935   the overall model fits, R^2 variance decomposition was performed using the 'genici' metric which

936   is implemented in the relaimpo R package [97] (Extended Data Fig. 4c). Relative feature

937   contributions were averaged across all tissues (Fig. 3b).

938   Since many of the detected motifs appear in a tissue-specific manner (predictive only in tissue

939   subset), we clustered tissues according to the presence or absence status of 5'UTR motifs in

940   each tissue model (Extended Data Fig. 4d). Seed and pollen tissues form a distinct subcluster,

941   which might be connected to the increased/decreased PTR levels in these tissues compared to

942   the other tissues (Fig. 3c;Extended Data Fig. 4a). In contrast to the motif analysis, Dn/Ds ratios

943   were consistently (and positively) associated with protein abundance in all 30 tissues

944   (Supplementary Data 5). To explore the relationship between Dn/Ds ratios and protein

945   abundance in more detail, groups of genes with low or high (bottom 5% or top 5% of Dn/Ds

946   distribution) were compared to each other with regard to protein levels (Extended Data Fig. 4e).

947   ***Seed tissue PTR regulation*:** The PTR value distribution was plotted for the median PTR

948   (median across all tissues, see above) and selected tissues (seed, seed imbibed, pollen, cell

949   culture young). Seed and pollen tissues show particularly low Pearson correlation between

950   protein and transcript abundance levels (Extended Data Fig. 4a). Cell culture early in

951   comparison shows the highest Pearson correlation among the analyzed tissues. Tissue-specific

952   'outliers' with especially high or low PTR as compared to all other tissues were selected if their

953   PTR value was outside two standard deviations of the mean of the median PTR distribution. For

954   seed, this resulted in 469 genes with 'high' and 571 genes with 'low' PTR. In order to interpret,

955   whether this change in seed PTR values was caused by differential regulation on transcript

956   and/or protein level, the fold change between seed protein and transcript abundance and the

957   median protein and transcript abundance of all tissues was calculated. Genes with at least

958   4fold-change in either protein or transcript abundance were considered regulated (less/more

959   transcript and/or less/more protein in seed compared to all tissues). The percentage of genes

960   with high or low PTR levels in the seed tissue, which are regulated in the same manner

961   (less/more transcript and/or protein) was calculated and displayed as arrow plot (Fig. 3e). About

962   a quarter of each gene set (high PTR 27%; low PTR 24%) show no regulation based on our

963   4fold-change cutoff.

964   For the low PTR gene set, a high proportion of genes with lower protein abundance in the seed

965   tissue was observed. A protein level chase experiment was performed, to investigate whether

966   this reduction was due to translational inhibition or increased protein degradation in seeds.

967   Protein level (iBAQ, not log transformed) fold changes in CHX, MG132 and DMSO-treated

968   samples were calculated relative to the baseline protein expression at 0h (control sample). The

969   average protein level fold change for the subset of genes with either high or low PTR in seeds

970   (see above) was subsequently determined for each time point and plotted separately for 'high'

971   and 'low' PTR genes (Fig. 3f). To test for significant fold change differences between treatment

972   time points, a one-way analysis of variance (ANOVA) and post-hoc Tukey HSD test was

973   performed using the stats package in R (Extended Data Fig. 4i). For this, the data was

974   normalized for changes in the proteome caused by seed germination, by calculating the $\log_2$

975   fold change in protein abundance (iBAQ) between seed samples treated with cycloheximide

976   (CHX) or MG132 and the time-point matched DMSO control. Outlier values were removed for

977   the boxplot visualization but are included in the ANOVA and post-hoc Tukey analysis.

978   ***Co-expression analysis***: To compare gene co-expression information in our dataset to prior

979   knowledge about various associations between genes pairs, the Pearson correlations between

980   all pair-wise gene combinations on both transcript and protein level (core dataset intersection; n

981   = 5,043) was calculated. The correlation coefficient value for a given gene pair on transcript

982   level was then plotted against the correlation coefficient value of the same pair on protein level

983   (Extended Data Fig. 6a). Protein-protein association data was downloaded from STRING [30]

984   (www.string-db.org; 3702.protein.links.detailed.v10.5.txt.gz; download 07/2018), the

985   experimental STRING subscores calculated for each gene pair and the information merged to

986   the correlation value matrix. The scatterplot of transcript level versus protein level correlations

987   was then divided into 50 x 50 bins along the x- and y-axis and the mean experimental STRING

988   subscore for all gene pairs within a bin was calculated. Mean subscores were log_2 transformed

989   and visualized as a heatmap together with their marginal histograms (Extended Data Fig. 6a).

990   For a subset of genes, pair-wise co-expression was further investigated. Pairs used in this

991   analysis were genes, that are either annotated as duplicated [31] or as protein interactors (AtPIN

992   [33], download 08/2017), respectively. The Pearson correlation between the expression levels of

993   gene-pairs across tissues was calculated for gene pairs with abundance measurements in more

994   than ten matching tissues on both protein and transcript level (more than 10 pairwise complete

995   observations). The duplicated gene set was further filtered for 3 unique peptide identification of

996   each paralog. Top3 intensities were used as protein abundance measure for the duplicate gene

997   set since the subsequent ratio comparison was also performed with top3 intensities. Paralog

998   genes often have high sequence identity on amino acid level, which can lead to distorted ratios

999   due to uneven assignment of shared (razor) peptides to only one of the paralogs. Duplicated

1000   genes (n = 3,612) were divided into three subsets: duplications caused by a whole genome

1001   duplication event (WGD, n = 2,104), local duplication (local, n = 408) or transposon-mediated

1002   duplication (transposed, n = 1,100). For each subset the distribution of Pearson correlation

1003   values between duplicates on either transcript or protein levels was plotted (Extended Data Fig.

1004   6b). A set of random gene pairs (n = 27,353) was generated for comparison, filtered like the

1005   duplicated gene set (number of pairwise complete observation, 3 unique peptides) and the

1006   Pearson correlation value distribution displayed in the same way. To compare relative protein

1007   expression levels between paralogs, the ratio between the protein abundance (top3) of one

1008   paralog and the protein abundance (top3) of the other paralog was calculated (Extended Data

1009   Fig. 6c). As an example for the intensity proportion of paralog genes in different tissues, the

1010   top3 intensity (not log transformed) of MAC5A and MAC5B was plotted as proportion of the

1011   summed top3 intensity (not log transformed) of both paralogs (Extended Data Fig. 6c). For 57

1012   paralog gene pairs with phenotypic information about asymmetric loss-of-function mutant

1013   combinations [32], we build the average top3 intensity proportion of the first paralog

1014   (dupl1/(dupl1+dupl2)) across 30 tissues and plotted them in descending order together with the

1015   phenotype information (Extended Data Fig. 6d).

1016 A set of well-studied, stable protein complexes (26S proteasome, COP9 signalosome,
1017 Chaperonin, Cellulose synthase) was selected to estimate the protein level (iBAQ) co-
1018 expression expected for stable interaction partners. For this, the Pearson correlation coefficient
1019 values between all pair-wise subunit combinations of an individual complex were calculated and
1020 displayed in a density plot (Extended Data Fig. 6e). Based on this analysis, a Pearson
1021 correlation coefficient cutoff of >0.5 was subsequently used as indication for stable protein
1022 interactions. The protein interactor gene set (AtPIN) was used to test the recovery of annotated
1023 protein-protein interactions based on co-expression data from this study. Again, the distribution
1024 of Pearson correlation values between gene pairs (here interactors) on either transcript or
1025 protein level (iBAQ) was plotted. This was done for the whole AtPIN dataset (n = 57,152) and
1026 the following subsets: interactions identified by yeast-two hybrid experiments (Y2H, n = 7,621),
1027 by affinity-purification mass spectrometry (AP-MS, n = 17,982) or by both Y2H and AP-MS (n =
1028 829).

1029 **Size exclusion chromatography and complex analysis:** Reproducibility between the three
1030 SEC experiments was tested by comparing the elution behavior of the same proteins. The
1031 coefficient of determination between protein peaks in the different experiments was above 0.7
1032 (flower-root R^2 = 0.82; flower-leaf R^2 = 0.78; root-leaf R^2 = 0.7). Protein peak elution between
1033 the samples was also consistent across the whole SEC gradient range (Extended Data Fig. 7b).

1034 To assign proteins to potential complexes, peak correlation profiling was performed. For this,
1035 the R package CCprofiler v0.1 was used to analyze the peptides.txt output table from MaxQuant
1036 [62,98]. Peptide table entries were restricted to the maximum molecular weight per gene name for
1037 the quantification of protein groups. This step removed peptides mapping to smaller isoforms of
1038 each gene. The restricted proteinGroups.txt served as the trace annotation input table for
1039 CCprofiler. The calibration table of the SEC column was based on the high molecular weight gel
1040 filtration calibration kit (GE Healthcare, Chicago, USA). The peptides table was split into the
1041 different tissues and the resulting tables converted into the input format for CCprofiler. All
1042 subsequent steps were performed separately for each tissue table.

1043 The peptides table was imported, converted into a traces object, where a trace object is the
1044 SEC-elution profile of a specific peptide and annotated with the corresponding fractions and
1045 additional external information (e.g. molecular weight of the respective fraction, molecular
1046 weight of the respective protein) based on the aforementioned calibration and restricted
1047 proteinGroups tables. Traces not containing at least three consecutive peptide identifications
1048 across fractions, as well as traces with a sibling peptide correlation of less than 0.2 between

1049 peptides originating from the same protein were filtered out. Based on the remaining traces,
1050 protein features (elution peak positional information) consisting of highly correlated peptides
1051 (correlation higher than 0.9) were detected using CCprofiler's sliding window algorithm.
1052 Peptides were randomly assigned to proteins in order to control the false discovery rate of
1053 protein features at 5% (random decoy model). Subsequently, protein traces were calculated by
1054 summing up the intensities of the top two most abundant peptide traces.

1055 Next, complex hypotheses consisting of target and decoy protein complexes were constructed
1056 based on a previously-published mapping of Arabidopsis orthologues to mammalian protein
1057 complexes from CORUM [99,100]. Proteins were only mapped to the same decoy complex if they
1058 were not interacting with each other directly (minimum path length of two). These target and
1059 decoy complexes were used during the detection of complex features consisting of highly
1060 correlated proteins using the same sliding window algorithm as above in order to control the
1061 false discovery rate of complex features at 5% (target-decoy model).

1062 Both protein features (elution peak positional information) and protein traces (quantitative
1063 information) were then used to generate an input matrix for weighted gene correlation network
1064 analysis (WGCNA) [101], which was used to find clusters of proteins with correlated SEC elution
1065 profiles. Protein traces were restricted to the ones, which were part of at least one protein
1066 feature. Each protein trace was duplicated for each protein feature it was part of and all
1067 intensities outside of the respective protein feature were set to zero. With this, protein traces
1068 were effectively split into separate elution peaks corresponding to distinct (sub)complexes.
1069 Afterwards, elution peaks, which met either of the following criteria were filtered out: (1) The
1070 absolute difference between the molecular weight at the apex of the elution peak and the
1071 monomer molecular weight of the corresponding protein was smaller than twice the monomer
1072 molecular weight. (2) The absolute difference between the molecular weight at the apex of the
1073 elution peak and the monomer molecular weight of the corresponding protein was less than 200
1074 kDa. (3) The apex of the elution peak was in fraction 77 (void fraction). (4) The apex of the
1075 elution peak was in fraction 4 (monomer range).

1076 The remaining elution peaks were restricted to the intersection with the core protein dataset
1077 across tissues described above (see section on tissue groups), generating the SEC WGCNA
1078 input dataset. At the same time, an additional WGCNA input dataset was generated based on
1079 the core protein dataset across tissues and restricted to the intersection with the SEC WGCNA
1080 input dataset. Proteins with several SEC elution peaks were duplicated to match the SEC
1081 WGCNA input dataset. WGCNA was carried out separately for each of these datasets. Signed

34

1082 co-expression similarities were calculated between all pairs of proteins with at least seven

1083 pairwise-complete observations using the following formula:

$$s_{ij} = \frac{1 + cor(x_i, x_j)}{2}$$

1084 Here, s_{ij} is the signed co-expression similarity between two proteins x_i and x_j (based on their

1085 Pearson correlation across tissues). Adjacency matrices were calculated with $A = [s_{ij}]$ for

1086 several values of $\beta \in [1,30]$.

$$a_{ij} = s_{ij}^{\beta}$$

1087 Here, a_{ij} is the adjacency between two proteins x_i and x_j.. The adjacency function parameter β

1088 was selected to be 30 for the construction of signed protein co-expression networks. The

1089 topological overlap matrix $\Omega = [\omega_{ij}]$ of the two networks was calculated with:

$$\omega_{ij} = \frac{l_{ij} + a_{ij}}{min\{k_i, k_j\} + 1 - a_{ij}}$$

1090 Here, $l_{ij} = \sum_u a_{iu} a_{uj}$ and $k_i = \sum_u a_{iu}$. Hierarchical clustering was performed on the topological-

1091 overlap-based dissimilarity matrices $D = [1 - \omega_{ij}]$ using average linkage. Correlation clusters

1092 ('Modules') were detected using adaptive branch pruning [102] using the 'Dynamic Hybrid' method

1093 set to respect the dendrogram topology during PAM operations and requiring at least 30

1094 members per module. Similar clusters in the SEC or tissue dataset were merged, if the

1095 dissimilarity of their module eigengenes was smaller than 1-MPC or 1-MTC, respectively. MPC

1096 is the median peak correlation of the FDR-filtered complex features from CCprofiler (known

1097 complexes), while MTC is the median tissue correlation of the very same complex features

1098 (pairwise correlation between proteins mapping to a specific complex feature). The resulting

1099 modules for both datasets were then mapped to each other using a combination of Fisher's

1100 Exact test and manual curation. Enrichment of functional annotations from Corum [100], GO [73],

1101 KEGG [103] and Reactome [104] were calculated in each cluster using Fisher's Exact Test. All p-

1102 values were adjusted for multiple-testing by calculating FDRs [105] (Supplementary Data 8).

1103 In order to quantify how well complexes can be detected using the tissue atlas (TA) or SEC

1104 WGCNA output, we calculated a summary statistic termed 'complex index'. Protein interactor

1105 information was downloaded from UniProt [6] (https://uniprot.org; 12/2018) and manually curated

1106 for the presence of large (> 4 subunits) and small (≤ 4 subunits) complexes (Extended Data Fig.

1107 7e; Supplementary Data 9). The complex index (C) was calculated using the following formula:

$$C = \frac{Sm}{S} \times \frac{Sm}{M}$$

1108   Here, S_m is the number of subunits detected as present in the same module. S is the total
1109   number of subunits identified in the restricted datasets for either SEC or TA experiments and M
1110   is the total number of entries in the respective module. C is a measure of how well complex
1111   subunits co-occur (either by co-elution or by co-expression) and thus are detected in the same
1112   module and also quantifies the resolution of the detection method (module size). The complex
1113   index is 1, when all subunits of a complex are identified in the same module and no other
1114   proteins are contained in the module.

1115   **Complex stoichiometry analysis:** Absolute SEC protein elution traces of selected complexes
1116   (chaperonin, 26S Proteasome, CSN, CESA) were plotted using top3 intensities (not log
1117   transformed). Relative subunit proportions or stoichiometry for selected protein complexes
1118   within individual tissues of the TA dataset were calculated using top3 intensities (based on the 3
1119   most abundant unique peptides). Top3 intensity rather than iBAQ intensity was used, in order to
1120   avoid distorted ratios caused by shared (razor) peptide assignment. In the case of paralog
1121   genes with high protein sequence similarity, peptides were not required to be unique for one
1122   gene, but rather for one 'paralog group'. The three most abundant peptides within a paralog
1123   group were then used for the top3 calculations.

1124   For the example of the coatomer complex, the relative proportion of paralog genes in different
1125   tissues was calculated by plotting the top3 intensity (not log transformed, unique for gene) of
1126   each paralog as proportion of the summed top3 intensity (not log transformed) of all paralogs
1127   (Extended Data Fig. 7d). For the calculation of subunit stoichiometry ratios of selected
1128   complexes (chaperonin, 26S Proteasome, CSN, CESA), the top3 intensity (not log transformed)
1129   of a subunit was divided by the average top3 intensity (not log transformed) of all complex
1130   subunits. Subunit ratios were first calculated for each tissue and subsequently averaged across
1131   all 30 tissues (chaperonin, 26S Proteasome, CSN) or only across tissues where the respective
1132   subunits are mainly expressed (CESA4/7/8: node, internode, silique septum, silique valves;
1133   CESA1/3/6: all other) (Extended Data Fig. 7g).

1134   **Subnetwork extraction:** *De novo* network enrichment was performed to identify tissue- or
1135   tissue group-specific subnetworks and to link them to a molecular function. In contrast to gene
1136   set overrepresentation or gene set enrichment analysis [106], this approach is suited to identify
1137   previously uncharacterized functions from large-scale molecular interaction networks.
1138   KeyPathwayMiner [107] was used to extract tissue- and tissue group-specific subnetworks from

1139 transcriptomics and proteomics datasets. To enrich subnetworks with proteins that deviate in
1140 their expression from other tissues, we employed z-scored expression values. These reflect
1141 how many standard deviations the expression in a given tissue is away from the expression
1142 range found in all other tissues:

$$z_{x,g} = \frac{x - \mu_{X \setminus x}}{\sigma_{X \setminus x}}$$

1143 Here x is a specific tissue or tissue group of interest, g a gene μ the mean and σ the standard
1144 deviation. Based on the following rule, a one-column indicator matrix I(x,g) was constructed as
1145 input for KeyPathwayMiner for each tissue or tissue group x:

$$I(x,g) = \begin{cases} 1 \ if \ |z_{x,g}| > 2 \\ 0 \ else \end{cases}$$

1146 Here each row corresponds to a gene g. STRING {Szklarczyk, 2017 #513} *A. thaliana* network
1147 (v. 10.5, download 10/2018) was used as the molecular interaction network, considering only
1148 high confidence interactions with a score > 900. Subnetworks extracted via KeyPathwayMiner
1149 were made available for individual tissues or tissue groups as part of the ATHENA web
1150 application.

1151 ***Phosphorylation sites and motif analysis:*** Serine (S), threonin (T) and tyrosine (Y) content
1152 and p-site number of individual proteins was calculated based on the longest sequence in case
1153 of ambiguous isoform identifications (Fig. 5a, Extended Data Fig. 8g). Likewise, the schematic
1154 depiction of phosphorylation (p-site) localization in LATE EMBRYOGENESI ABUNDANT (LEA)
1155 and receptor-like kinase proteins was based on the p-site localization in the longest isoform
1156 sequence (Extended Data Fig. 8h,i). Functional domain assignment for receptor-like protein
1157 kinase (RLKs) sequences was done using smart (http://smart.embl-
1158 heidelberg.de/smart/batch.pl) [106] and p-sites were manually assigned to specific domains based
1159 on their localization in the protein (Extended Data Fig. 8i).

1160 For motif analysis within our dataset, sequence windows of 15 amino acids centered on the
1161 identified class I p-sites (15 mers) were assigned to a motif class of either 'proline-directed',
1162 'acidic', 'basic' or 'other' by following a binary decision tree [36] (Extended Data Fig. 8d).
1163 Assignment to these categories was done sequentially as follows: proline amino acid at position
1164 -1 (Proline-directed), 5 or more aspartic acid (D) or glutamic acid (E) at position +1 to +7
1165 (acidic), arginine (R) or lysine (K) at position -3 (basic), D or E at position +1,+2 or +3 (acidic), 2
1166 or more R or K at position -6 to -1 (basic) and otherwise (other).

1167   P-sites with high confident localization scores (class I) were divided into S, T and Y p-site

1168   datasets. Motif extraction was performed separately for each motif class category (proline-

1169   directed, acidic, basic, other) using the motif-X algorithm, implemented in the rmotifx R package

1170   [35] (Supplementary Data 10). Cutoff settings were: min-seq.= 30, pval.cutoff = 1e-6 (S and T

1171   datasets); min-seq.= 10, pval.cutoff = 1e-5 (Y dataset). Motif-X calculates the fold-increase of a

1172   respective motif in the 'foreground' (p-site dataset) compared to the 'background' dataset (non-

1173   phosphorylated peptides). To avoid mass spectrometry-based residue biases, all peptides from

1174   our dataset that contained an STY amino acid and had only been identified in non-

1175   phosphorylated form were used as the background for all motif-X analyses (258,395

1176   sequences). These peptide sequences were centered on STY and extended where necessary

1177   along the N- and C-terminal window to generate 15 mers. Position weight matrix sequence

1178   logos were drawn using the 'bits' method for amino acid sequences in the ggseqlogo R package

1179   [109] (Extended Data Fig. 8e, Supplementary Table 2). The motif-X fold increase for S motifs was

1180   plotted for motifs with 2, 3 and 4 fixed amino acid positions (Extended Data Fig. 8f).

1181   Published p-site motifs were retrieved from PhosPhAT4.0 [9] and the Human Protein Reference

1182   Database [110] (HPRD; www.hprd.org) and divided into groups depending on the number of fixed

1183   amino acid positions within the motif sequence. These motifs were subsequently matched to the

1184   p-site or background dataset in order to calculate detection frequency and fold increase (p-

1185   site/background dataset) of a reported motif (Supplementary Data 10).

1186   ***AGCVIII protein expression and mutant phenotypic* characterization**

1187   For the relative expression analysis of AGC kinases across tissues, the AGC1 and AGC3

1188   subfamilies of Arabidopsis AGCVIII kinases were selected [21]. The summed total intensity of

1189   AGC1 and AGC3 subfamily kinases (top3, not log transformed) was calculated for each tissue.

1190   Relative protein amounts of individual kinases in different tissues were calculated as the top3

1191   intensity (not log transformed, unique for gene) of each kinase in proportion to the summed top3

1192   intensity (not log transformed) of all AGC1 and AGC3 kinases (Fig. 2c). For clear visualization

1193   only the D6PK family (D6PK, D6PKL1, D6PKL2, D6PKL3), AGC1.5, AGC1.6 and AGC1.7 were

1194   colored in the plot.

1195   Mutant alleles of the *D6PK* family kinase genes, *d6pk-1*, *d6pkl1-1*, *d6pkl2-2* and *d6pkl3-2*, and

1196   their combinations were previously described [111]. Embryos were prepared omitting fixation with

1197   ethanol/acetic acid as previously described [112]. Embryos were analyzed with a Zeiss Axio

1198   Imager.M2, Axiocam 512 camera and 20x/0,8 Plan Apochromat objective using differential

1199   interference contrast (DIC).

1200 For promoter:GUS constructs of *AGC1.5*, *AGC1.6* or *AGC1.7*, 2916 bp, 1207 bp, or 2214 bp

1201 fragments upstream from the respective start codon were cloned into the *Sal*I and *Eco*RI sites of

1202 pCAMBIA1391Z. Flowers from transgenic plants, obtained by the floral-dip method [50], were first

1203 incubated in 90% cold acetone for 15 min followed by a β-glucuronidase (GUS)-staining solution

1204 (50 mM sodium phosphate pH 7.0, 10 mM EDTA, 2 mM potassium ferricyanide, 2 mM

1205 potassium ferrocyanide, 0.1% Triton-X100, 0.5 mg/ml 5-bromo-4-chloro-3-indolyl-β-D-

1206 glucuronide) over-night in the dark. Following a wash in 70% ethanol, flowers were incubated in

1207 ethanol/acetate (6:1) for removing of chlorophyll and then rehydrated in a graded ethanol series

1208 (90%, 70%, 50%, 30%). Samples were mounted in chloral hydrate/glycerol/water (8 g:1 ml: 2

1209 ml) for imaging. The experiment was performed two times and GUS signal was observed for

1210 12/18 *AGC1.5p::GUS*, 0/20 *AGC1.6p::GUS* and 12/18 *AGC1.7p::GUS* independent lines.

ABA response of RCAR phosphomutants

1212 Preparation and analysis of Arabidopsis protoplasts was performed as described [113]. Briefly,

1213 protoplasts from three weeks-old Col-0 plants (10^5 protoplasts; 0.1 ml) were transfected with 5

1214 μg of reporter construct (*pRD29B::LUC*), 3 μg of *p35S::GUS* plasmid as internal control and

1215 3 μg of effector plasmid. The effector plasmids drive expression of respective RCAR and PP2C

1216 cDNAs under control of the 35S promoter [114]. RCAR10 phosphomimic reporter constructs

1217 (RCAR10$_{S32D}$; RCAR10$_{S113D}$) were obtained by site-directed mutagenesis using primer pairs

1218 S32D_F/S32D_R and S113D_F/S113D_R, respectively (Supplementary Data 11). The

1219 protoplast suspension was incubated at various levels of ABA as indicated and reporter

1220 expression was determined after 18 h of incubation at 25°C. Three biological replicates per data

1221 point were performed for each assay. All data points were normalized to the empty vector

1222 control. Structural modeling for RCAR10 was performed with SWISS-MODEL [115] using RCAR11

1223 as template model (PDB ID 3k3k [45,116]) and modified with UCSF CHIMERA [117].

Phenotypic characterization of QKY phosphomutants

1225 The pCAMBIA2300-based pQKY::mCherry:QKY construct was described previously [42]. The

1226 pQKY::mCherry:QKY$_{S262A}$ and pQKY::mCherry:QKY$_{S262E}$ plasmids were obtained using the Q5

1227 site-directed mutagenesis kit (NEB, #E0554S) according to the manufacturers recommendation.

1228 Primers are Q5SDM S262A_F and Q5SDM S262A_R for pQKY::mCherry:QKY$_{S262A}$ and

1229 Q5SDM S262E_F and Q5SDM S262E_R for pQKY::mCherry:QKY$_{S262E}$ (Supplementary Data

1230 11). All PCR-based constructs were confirmed by sequencing. Floral tissue for quantitative real-

1231 time PCR (qPCR) was harvested from plants grown under long day conditions. With minor

1232 changes, tissue collection, RNA extraction and qPCR analysis were performed as described

1233 [118,119]. For detection of *mCherry:QKY*, expression by qPCR, primers mCherry-qRT-For/mCherry-

1234 qRT-Rev were employed (Table). Average *mCherry:QKY* expression was calculated relative to

1235 the expression of three control genes (AT4G33380; AT2G28390; AT5G46630) (Supplementary

1236 Data 11) and normalized to the wild type control for visualization. *A. thaliana* (L.) Heynh. var.

1237 Landsberg (*erecta*) (L*er*) was used as wild type strain. The likely null allele *qky-9* (L*er*) has been

1238 described previously [43]. *qky-9* mutant plants were transformed using Agrobacterium strain

1239 GV3101/pMP90 [120] and the floral dip method [50]. Transgenic T1 plants were selected on

1240 Kanamycin (50 μg/ml) and transferred to soil for further inspection. Plants were grown as

1241 described earlier [43]. Four out of 17 independent T1 transformants showed a wild type phenotype

1242 for the S262A transgenic line, while 13/17 T1 transformants displayed no (7/17) or partial (6/17)

1243 rescue, a notable decrease in functionality compared to the wild type construct (14/17 rescue,

1244 2/17 partial rescue, 1/17 no rescue). For the S262E transgene, 11 out of 13 independent T1

1245 transformants showed a wild type phenotype (1/13 partial rescue, 1/13 no rescue).

1246 Floral organs were imaged using a Leica SAPO stereo microscope equipped with a digital MC

1247 170 HD camera (Leica Microsystems GmbH, Wetzlar, Germany). Images were adjusted for

1248 color and contrast using ImageJ/Fiji software [121]. Confocal laser scanning microscopy of *qky-9*

1249 *pQKY::mCHerry:QKY*, *qky-9 pQKY::mCHerry:QKY$_{S262A}$* and *qky-9 pQKY::mCHerry:QKYS$_{262E}$*

1250 six days-old seedling roots was performed with an Olympus FV1000 setup using an inverted

1251 IX81 stand and FluoView software (FV10-ASW version 01.04.00.09) (Olympus Europa GmbH,

1252 Hamburg, Germany) equipped with a water-corrected 40x objective (NA 0.9) at 3x digital zoom.

1253 Confocal high sensitivity detection (HSD) was employed involving two gallium arsenide

1254 phosphide photomultipliers (GaAsP PMTs) mounted equidistantly to the probe. The experiment

1255 was performed two times independently with 2 and 12 roots for *qky-9 pQKY::mCHerry:QKY*, 6

1256 and 15 roots for *qky-9 pQKY::mCHerry:QKY$_{S262A}$* and 15 roots for *qky-9*

1257 *pQKY::mCHerry:QKYS$_{262E}$*.

1258 ***Locus identifiers***

1259 Gene locus identifiers are listed for all gene names mentioned in the manuscript

1260 (Supplementary Data 11).

Author contributions

JM performed (phosho)proteomic and transcriptomic experiments under the supervision of BK. SR and HS performed AGC kinase experiments in plants under the supervision of GJ and CS. MP, AC and XC performed phosphomutant analysis under the supervision of EG and KS. PC and SS generated and provided plant material. JM, MF, MM, DL, SA, DPZ, TM, CD, AD and RRH performed data analysis under the supervision of BK, KFXM, PF, MB, TH and FJ. ML, PS and TS generated Arabidopsis resource databases under supervision of MW and JB. JM, CS and BK conceptualized the project and wrote the manuscript. All authors edited the manuscript.

Competing interests

MW and BK are founders and shareholders of OmicScouts GmbH and msAId GmbH. They have no operational role in the companies. MF and DPZ are founders and shareholders of msAId GmbH. TM and MB are employees and/or shareholders of Cellzome GmbH. The remaining authors declare no competing interests.

Data and software availability

The data supporting the findings of this study are available within the paper, the supplementary information and the public repositories. Source data for main Figure 1-5 and Extended Data Figure 1-9 are included. Transcriptome sequencing and quantification data are available at ArrayExpress (www.ebi.ac.uk/arrayexpress) under the identifier E-MTAB-7978. The raw mass spectrometric data and MaxQuant result files have been deposited to the ProteomeXchange Consortium via PRIDE [122], with the dataset identifier PXD013868.

Corresponding author: Bernhard Kuster (kuster@tum.de)

Extended data figure legends

1473 **Extended Data Figure 1 | Descriptive analysis of the multi-omic tissue atlas.**

1474 a, Pairwise global Pearson expression correlation analysis of all 30 tissues (n = 1 measurement
1475 per tissue) on the transcriptome level (lower triangle) and proteome level (upper triangle) using
1476 all identified gene loci. The data shows that proteins correlate more strongly between tissues
1477 than transcripts. Turquoise squares mark examples for morphologically highly similar tissues.
1478 Tissues are coloured as in Figure 1: Flower (light grey), seed (dark brown), pollen (yellow), stem
1479 (dark green), leaf (light green), root (dark grey), fruit (light brown), callus (magenta), cell culture
1480 (blue).

1481 b, Scatter plots showing highly reproducible abundance measurements for transcript (upper
1482 panels) and protein (lower panels) in morphologically similar tissues that were marked in panel
1483 a, namely node (ND) versus internode (IND), leaf distal (LFD) versus leaf proximal (LFP) and
1484 root (RT) versus root upper zone (RTUZ). *R* denotes the Pearson correlation coefficient and n
1485 denotes the number of transcripts or proteins shown in the plots.

1486 c, Percentage of genes encoded by a specific chromosome that were identified at the
1487 transcriptome, proteome or phosphoproteome level.

1488 d, Percentage of Swiss-Prot and TrEMBL protein database entries as well as protein evidence
1489 categories from UniProt that were identified at the transcriptome, proteome or
1490 phosphoproteome level. Evidence level: (1) 'protein evidence', (2) 'transcript evidence', (3)
1491 'homology', (4) 'predicted', (5) 'uncertain'.

1492 e, Comparison of protein identifications between an earlier Arabidopsis proteome study by
1493 Baerenfaller et al. based on 12 tissues [7], this study (30 tissues) and the number of protein-
1494 coding genes in Araport11.

1495 f, iBAQ intensity distribution of proteins identified in this study. Proteins also identified by
1496 Baerenfaller et al. are projected into the same plot.

1497 g, Left panel: Proportion of identified p-sites on S, T or Y residues with highly confident
1498 localization of the phosphorylation site within the identified peptide sequence (termed class I p-
1499 sites if the localization score is >0.75). Right panel: distribution of proteins for which
1500 phosphorylated S, T or Y residues were identified.

1501 h, Left panel: Venn diagram comparing phosphoprotein datasets from van Wijk et al. [8],
1502 PhosPhAT4.0 and this study. Right panel: Venn diagram comparing p-site localization
1503 confidence between class I sites identified in this study and the low and high confidence
1504 datasets reported by van Wijk et al.

Extended Data Figure 2 | Proteogenomics and dynamic range of transcript and protein expression.

a, Number of identified N-terminal (NT) or C-terminal (CT) peptides of proteins in either unmodified or phosphorylated form.

b, Frequency of amino acids following the initiator methionine in N-terminal peptides with (-X) or without cleavage of the initiator methionine (M-X). X denotes the amino acid following the start codon.

c, Frequency of protein N-terminal acetylation for amino acids in (b). Because trypsin was used for protein digestion, the frequencies for arginine (R) and lysine (K) could not be determined (n.d.).

d, Distribution of peptide-based sequence coverage of proteins in individual tissues and for the combined dataset (tissue abbreviations as in Figure 1). Boxes contain 50% of the data and show the median as a black line. The upper and lower quartile ranges are shown as whiskers. The number of proteins is indicated for each tissue.

e, Pie charts showing the percentage of proteins identified by <3, 3-10 or >10 peptides either allowing shared (razor) peptides or restricting to unique peptides only.

f, Left panel: number of protein isoforms detected at the transcript and protein level compared to the number of all annotated isoforms in Araport11. Right panel: Number of multiple isoforms of the same gene distinguished at the peptide level.

g, Validation of protein isoform and short open reading frame (sORF) identification by comparing the tandem mass spectra from the tissue atlas to those of synthetic peptide reference standards. The normalized spectral contrast angle (SA) was used as a similarity metric (see methods). Candidate isoforms and sORFs were considered valid if the SA of the spectra was >0.7. This data is reported in Supplementary Data 3.

h, Amino acid sequence and mirror plots of tandem mass spectra for two peptides of the sORF BIP138_4. The spectra pointing upwards were collected from tissue digests, those pointing downwards were collected from synthetic peptides. The normalized spectral contrast angle (SA) and Pearson correlation coefficient (R) were used as similarity metrics (see methods) and indicate that both high scoring spectra (n=1 acquired spectra) are near identical, thus validating the identification of this sORF as a expressed protein.

i, Dynamic range of transcript expression (grey) and proportion of transcripts that were also identified at the protein level projected into this plot (blue). OM: orders of magnitude. Note that for lower abundance transcripts, fewer proteins were detected.

1538 j, Dynamic range of protein expression and proportion of proteins with phosphorylation
1539 evidence. Note that protein expression spans 6 OM whereas transcript expression only spans 4
1540 OM (panel i). Further note that phosphorylation was detected across the entire protein
1541 expression range.

1542 k, Percentage of all annotated kinases (K), phosphatases (P), transcription factors (TF) and
1543 transcription regulators (TR) detected at the transcript, protein or phosphoprotein level.
1544 Numbers below the x-axis denote the number of genes for these protein classes in the AT
1545 genome.

1546 **Extended Data Figure 3 | Descriptive analysis of transcript and protein expression in**
1547 **tissues.**

1548 a. Distribution of expression specificity categories for protein and transcript identifications. See
1549 online methods for the definition of these categories. Briefly, there are very few transcripts and
1550 proteins that are only expressed in a single tissue. Note that the quantities of the shared
1551 transcripts or proteins can differ vastly between tissues (see below).

1552 b, Left panel: protein identifications shared between flower (FL) and flower organs showing an
1553 almost complete qualitative overlap of proteins. Sepal (SP), petal (PT), stamen (ST), carpel
1554 (CP). Right panel: clustering of z-scored protein intensities showing distinct quantitative
1555 expression differences between flower organs.

1556 c, Expression analysis of flower organ identity marker at the protein and transcript level.
1557 PISTILLATA (PI, green), APETALA3 (AP3, red), APETALA1 (AP1, orange), AGAMOUS (AG,
1558 blue). The expression of these markers is in line with the model of flower organ identity (AP1
1559 expression marking sepal, AP1, AP3, PI marking petal, AG, AP3, PI marking stamen and AG
1560 marking carpel).

1561 d, Total number of transcripts plotted against the total number of proteins detected in each
1562 individual tissue (n = 30 tissues) showing that the more genes are expressed as mRNAs, the
1563 more proteins can be detected in a tissue (Pearson correlation R = 0.79). Tissues are coloured
1564 according to tissue groups as in Figure 1.

1565 e, Cumulative abundance plots of intensity-ranked identifications of transcripts and proteins for
1566 five representative tissues. The five most abundant transcripts and proteins are listed in
1567 descending order for each tissue. Note that these are generally not the same. Further note that
1568 the characteristics of the plots are not the same for all tissues. In flower, the protein line rises
1569 more quickly than the transcript line. The opposite is true for pollen and a more even
1570 characteristic is observed in seed.

1571 f, Distribution of shared and unique identifications among the 100 most abundant transcripts and
1572 proteins in each tissue. Note that relatively few proteins and transcripts are found together on

48

1573 the list of the 100 most abundant transcripts and proteins. This demonstrates that the
1574 quantitative differences in transcript and protein expression are more important in defining a
1575 tissue than the qualitative expression of transcripts or proteins.

1576 g, List of 11 proteins which were found as the most abundant protein (in at least one tissue) and
1577 their proportion of the total iBAQ intensity in each tissue. Note that individual proteins can
1578 represent up to 9% of the total protein in a given tissue.

1579 h, Principal component analysis (PCA) of the core tissue proteomes and transcriptomes (i.e. the
1580 proteins and transcripts that were identified in every tissue) using z-scored abundances. Note
1581 that only about 30% of all protein and 20% of all mRNAs were detected in every of the 30
1582 tissues despite the fact that all tissues were deeply profiled at both protein and transcript level.
1583 This shows that strong qualitative and quantitative expression differences exist between tissues.
1584 The PCA separates tissues into photosynthetically active versus inactive tissues (component 1)
1585 and separates pollen from all other tissues (component 2) implying that the molecular
1586 composition of pollen is particularly different from all other tissues.

1587 i, Proportion of the total summed protein intensity for genes with specific subcellular
1588 compartment annotation (from SUBA [44], see methods) in the different tissue groups. The
1589 comparison of photosynthetically active and inactive tissues shows that e. g. a majority of the
1590 protein content in photosynthetically active tissues are contained in the plastids, whereas most
1591 protein is found in the cytosol for photosynthetically inactive tissues. Proteins with only one
1592 single subcellular compartment annotation were selected for the plot and the proportion of their
1593 iBAQ intensities were averaged for each tissue group. Nucleus (n = 1,393), endoplasmatic
1594 reticulum (n = 58), golgi (n = 68), peroxisome (n = 67), plastid (n = 525), mitochondrion (n =
1595 317), vacuole (n = 71), cytosol (n = 385), cytoskeleton (n = 1), plasma membrane (n = 268),
1596 extracellular (n = 351).

1597 **Extended Data Figure 4 | Relationships between transcript and protein levels.**

1598 a, Pearson correlation (*R*) of transcriptome and proteome expression (core datasets; n = 5,043)
1599 for each tissue.

1600 b, Pearson correlation (*R*) between measured and predicted protein abundance levels in all
1601 tissues. Predicted protein abundance levels were obtained from the best fitting feature selection
1602 model for each tissue (see methods). The number of genes used for the correlation analysis is
1603 indicated for each tissue.

1604 c, Violin plots showing the spread in relative contribution of selected features to the prediction of
1605 gene-level protein abundance across tissues (n = 30 tissues) using our model. Violin shapes
1606 show the kernel density estimation of the data distribution and the median as white dot. Thick
1607 black bars denote the interquartile range.

1608   d, Specific nucleotide sequence motifs in 5'UTRs of mRNAs contribute to the prediction of
1609   protein levels in a subset of tissues. Clustering tissues based on the presence or absence of
1610   detected 5'UTR motifs shows that several features are repeatedly selected for inclusion in the
1611   model while others appear to be more tissue-specific.

1612   e, Based on the observation that the ratio of non-synonymous to synonymous nucleotide
1613   substitutions (Dn/Ds) between orthologous of *Arabidopsis thaliana* and *Arabidopsis lyrata*
1614   contributed to the prediction of protein levels (see above), we analysed this feature in more
1615   detail. Left panel: Distribution of the ratio of non-synonymous to synonymous nucleotide
1616   substitutions (Dn/Ds) for orthologous genes in *Arabidopsis thaliana* and *Arabidopsis lyrata*. The
1617   distribution is plotted for the example of 'leaf distal' (n = 6,447 genes). To compare evolutionarily
1618   conserved genes (defined by low non-synonymous to synonymous substitutions [Dn/Ds] ratios)
1619   and genes that evolve neutrally or are under positive selection (high Dn/Ds), we selected the
1620   bottom 5% and top 5% of the Dn/Ds ratio distribution, respectively. Right panel: evolutionarily
1621   conserved genes (low Dn/Ds ratio) show 10-20x higher protein abundance than genes under
1622   evolutionary pressure. Boxes contain 50% of the data and show the median as a black line.
1623   Whiskers denote 1.5 times the interquartile range. Outliers were omitted from the plot for clarity.

1624   f, Time course analysis of median protein abundance changes upon cycloheximide (translation
1625   block, CHX) or MG132 (proteasome block) treatment vs time-matched DMSO control samples
1626   (see methods). Boxes contain 50% of the data and show medians as black lines. Whiskers
1627   denote 1.5 times the interquartile range. Outliers were omitted from the plot for clarity but were
1628   included in the statistical tests below. Shown are either all proteins in the experiment (n = 8,920,
1629   grey), proteins that have a high (n = 425, red) or low (n = 254, blue) PTR in seed (defined as in
1630   main Figure 3d). Differences between time points were tested for significance within each
1631   subset (all; high PTR; low PTR) using one-way ANOVA (analysis of variance) and the post-hoc
1632   Tukey HSD (Honestly significant difference) test. *** HSD p-Value < 0.001 (all_CHX8-CHX16:
1633   p-Value < 1e-7; all_CHX8-CHX24: p-Value < 1e-7; all_CHX16-CHX24: p-Value = 0.0002;
1634   highPTR_CHX8-CHX24: p-Value = 0.0003; lowPTR_CHX8-CHX16: p-Value = 0.0000004;
1635   lowPTR_CHX8-CHX24: p-Value < 1e-7; lowPTR_CHX16-CHX24: p-Value < 1e-7).

1636   g, Representative images of seeds after 4 days of incubation with CHX, MG132 or DMSO
1637   control medium (n = 1). Germination was completely inhibited by CHX and partially inhibited by
1638   MG132 showing that the drug treatments were effective.

1639   **Extended Data Figure 5 | Correlations between transcriptomes, proteomes and**
1640   **phosphoproteomes.**

1641   a, Median protein to mRNA ratios (PTRs) across tissues plotted against the inter-tissue
1642   variation of these PTRs (expressed as median absolute deviation, MAD; proteins and
1643   transcripts had to be detected in at least 10 matching tissues to be included in the analysis).

1644 Examples for genes with low transcript/high protein (rbcL and petA), and high transcript/low
1645 protein (IAA8 and IAA13) are marked by arrows. The bar blot shows the MAD range segmented
1646 into 5 quantiles each containing the same number of genes (coloured bars and dashed lines). It
1647 is evident that most genes have reasonably stable PTRs across tissues.

1648 b, Same as panel a (dataset n = 14,069) but for transcript (left plot) and protein measurements
1649 (right plot). As can be seen, there is somewhat more variation in protein levels across tissues
1650 than there is mRNA variation (80% of all transcripts show a MAD of <1; 80% of all proteins
1651 show a MAD of 1.2). There is also more variation in the protein levels across tissues for low
1652 abundant proteins. This may in part due to technical limitations as low abundance proteins can
1653 generally be less accurately quantified.

1654 c, Same as panel a but for the ratio of phosphorylation site versus protein abundance. P-sites
1655 and proteins had to be detected in at least 10 matching tissues to be included in the analysis
1656 (n = 13,793).

1657 d, Same as panel b (dataset n = 13,793) but for phosphorylation site abundance. Note that p-
1658 site abundance shows somewhat greater variation across tissues than protein abundance (60%
1659 of all p-sites show MAD<1 compared to 80% of all proteins, see panel b). Again, this may in part
1660 due to technical limitations as p-site quantification is performed on a peptide level and does not
1661 benefit from aggregating multiple peptide quantifications into one value for protein quantification.

1662 **Extended Data Figure 6 | Inferring redundant gene function and physical interactions**
1663 **from co-expression analysis.**

1664 a, Scatter plot of Pearson correlation coefficients (R) as a measure for co-expression across
1665 tissues for all pairs of proteins (x-axis) and all pairs of transcripts (y-axis) (core dataset only, n =
1666 5,043) along with their marginal histograms. Colours denote the $\log_2$-normalized STRING
1667 scores of individual gene pairs as a measure of known or predicted direct (physical) or indirect
1668 (functional) associations. The data show that strong co-expression of transcripts or proteins or
1669 both are more strongly related (physically or functionally) than transcripts and proteins that are
1670 not.

1671 b, Co-expression analysis of duplicated genes (pairs had to be detected in at least 10 matching
1672 tissues to be included in the analysis). The density plots show the distribution of Pearson
1673 correlation coefficients (R) of co-expressed transcripts (grey) or proteins (blue) for genes that
1674 arose by whole genome duplications (WGD), local duplications (local) or transposon-mediated
1675 duplications (transposed). Randomly selected gene pairs are shown as control (random).
1676 Medians ($\bar{x}$) are given and displayed as dotted lines. The data shows that there is substantial
1677 co-expression of duplicated genes implying that these genes likely have redundant functions.

c, Left panel: Protein level Pearson correlation coefficient (R) values (from panel b) for all duplicate gene pairs (WGD, local, transposed) plotted against the protein abundance ratio of each pair (average across 30 tissues, see methods). Blue arrows point out one example each for a high or low ratio of protein expression for the duplicated genes. Right panel: Example for tissue-resolved protein intensity proportions (top3, see methods) for the duplicate pair: MAC5A and MAC5B. The data shows that irrespective of the tissue, MAC5A is always much higher expressed than MAC5B. Tissues are coloured as in Figure 1.

d, Upper panel: ranked protein abundance ratio for selected duplicate pairs (average ± SD; n = 30) and annotated for phenotypic effects (lower panel) in the loss-of-function mutant for either duplicate 1 or duplicate 2 (+). Absence of a phenotypic effect is marked by (-). The data shows that asymmetric protein expression within duplicate pairs can be associated with the occurrence of a phenotype in the loss-of-function mutant of the higher expressed duplicate protein implying a dominant functional role of the more highly expressed protein. Blue arrows point out MAC5A/MAC5B and PHB3/PHB4 as examples.

e, Inference of physical protein-protein interactions from co-expression data. Distribution of pair-wise Pearson correlation coefficients (R) of co-expressed proteins across (at least 10) tissues that are subunits of selected protein complexes. An R value of >0.5 (shaded in grey) was chosen as a cut-off for the selection of proteins for subsequent analysis in order to make sure that proteins present in well characterized protein complexes are retained. CONSTITUTIVE PHOTOMORPHOGENESIS9 SIGNALOSOME (CSN), CELLULOSE SYNTHASE (CESA).

f, Recovery of annotated protein-protein interactions by co-expression analysis. Distribution of Pearson correlation coefficients (R) of pairs of transcripts (grey) or protein (blue) that are annotated to interact physically in the AtPIN database [33] (pairs had to be detected in at least 10 matching tissues to be included in the analysis). Subsets of the AtPIN database, namely interactions detected by the yeast two-hybrid (Y2H) method, by affinity purification - mass spectrometry (AP-MS) or by both (Y2H+AP-MS) are displayed separately. R values >0.5 are shaded in blue (protein). Median ($\bar{x}$, dotted lines). The data shows that co-expression only recovers a minority of annotated physical interactions and that interactions supported by more than one line of experimental evidence also tend to show stronger co-expression.

Extended Data Figure 7 | Inferring protein complexes and subunit stoichiometry from proteome correlation profiling using size-exclusion chromatography – mass spectrometry.

a, Molecular weights of monomeric proteins (MW, determined from sequence) plotted against the MW determined from the apex of the elution profile for proteins identified by mass spectrometry in size-exclusion chromatography (SEC) fractions of flower tissue (sFL). The inset shows the MW calibration of the SEC column using a protein calibration standard (MW between

1714   44 and 690 kDa). The MW distribution of proteins annotated in Araport11 is shown on top of the
1715   scatterplot. It is apparent, that a large number of proteins show a much higher apparent MW
1716   than what would be expected from their sequences (data points above the x=y line). This
1717   implies that these proteins engage in physical protein interactions that are sufficiently stable
1718   during SEC separation.

1719   b, SEC traces of proteins from five well characterized protein complexes for flower, leaf and root
1720   tissue. Even though the resolution of SEC separations is not very high, it is apparent that the
1721   complex subunits show very strong co-elution behaviour and that the SEC separations of the 5
1722   complexes are reproducible between tissues. Acetyl-CoA carboxylase n = 4 proteins; Cell
1723   division control protein 48 (CDC48) n = 3 proteins; Ribulose bisphosphate carboxylase
1724   oxygenase (RubisCO) n = 4 proteins; Prefoldin n = 6 proteins; Succinate-CoA synthetase (SCS)
1725   n = 3 proteins.

1726   c, Intensity normalized SEC elution profile of proteins for flower tissue. Proteins are ordered
1727   based on the SEC fraction in which their intensity peaks and the data is displayed as heat map
1728   (n = 2,485 protein traces). Co-eluting proteins were grouped into so-called trace modules (see
1729   methods for details). Proteins in trace modules may represent members of protein complexes
1730   and thus serve as candidates for further experimental validation.

1731   d, In order to quantify how well protein complexes can be detected using co-expression analysis
1732   from data in the tissue atlas (TA) or by SEC-MS a summary statistic termed 'complex index' was
1733   calculated (see methods). The complex index is 1, when all subunits of a complex are identified
1734   in the same module and no other proteins are contained in the module. The bar plots show
1735   examples for complex indices obtained from the different data sets and are divided into large
1736   (>4 subunits) and small (≤4 subunits) protein complexes (according to UniProt). The data shows
1737   that co-expression alone generates many candidates of interactors but that combining co-
1738   expression and SEC-MS analysis is an efficient way to prioritize candidates for follow-up
1739   experiments.

1740   e, Subunit heterogeneity within the coatomer complex. The coatomer complex consists of 7
1741   subunits, five of which (α, β, β', ε and ζ) can be provided by 12 paralogs of these 5 genes. The
1742   plots show the protein proportions of these paralogs in all 30 tissues (data from tissue atlas).
1743   The data implies that the coatomer complex has a similar composition in most tissues. A
1744   notable exception are seed tissues in which subunit ζ-1 protein expression dominates over the
1745   two other paralogous proteins suggesting that the coatomer complex in seed tissue also
1746   preferentially contains the ζ-1 subunit. Tissues are coloured as in Figure 1.

1747   f, Absolute SEC intensity traces of individual complex subunits for determining subunit
1748   stoichiometry. Examples from left to right: the chaperonin complex (flower, 8 proteins, ratio of all
1749   subunits: 1:1), the 26S proteasome core and lid (flower, 14+17 proteins, ratio of all subunits:
1750   1:1), the COP9 Signalosome (flower, CSN; 8 proteins, ratio of all subunits: 1:1) and the

1751 CESA1/3/6 complex (root, 3 proteins, ratio of all subunits: 1:1). Note that CSN3 and CSN5 were
1752 detected both as part of the CSN complex and in monomeric form.

1753 g, Upper panels: total intensity of protein complex subunits across all tissues for the complexes
1754 shown in panel f (subunit intensities from the tissue atlas). Middle panels: Relative proportion of
1755 the complex subunits within each tissue. Lower panels: Estimation of subunit stoichiometry
1756 using the average ± SD (n = 30 tissues) of the proportions of subunits across tissues (see
1757 methods). For the CESA complex, the ratios were calculated for the subunit combinations
1758 CESA1/3/6 and CESA4/7/8. The data shows that the stoichiometries determined from the tissue
1759 expression data are generally well aligned with the expected 1:1 ratio of subunits in these
1760 complexes. As noted above, a substantial amount of CSN5 was detected as a monomer in the
1761 SEC analysis and the tissue expression atlas also shows higher relative expression of this
1762 protein compared to all other complex partners. This suggests that this protein is produced in
1763 excess over what is required for the COP9 complex (as has been observed by others before)
1764 and may therefore imply an additional function within the cell.

1765 **Extended Data Figure 8 | Kinases, phosphatases and phosphorylation motifs.**

1766 a, Percentage of annotated kinases and phosphatases family members detected at the protein
1767 or phosphoprotein level. Brackets denote the number of genes in each family in the Arabidopsis
1768 genome

1769 b, Tissue-resolved combined intensity (i.e. protein expression) of families of kinases (left) and
1770 phosphatases (right). Tissues are coloured as in Figure 1. Note that several tissues (notably
1771 pollen) stand out in terms of the expression of kinases and phosphatases implying that these
1772 tissues are particularly active in phosphorylation-mediated dynamic signalling.

1773 c, Upper panel: Pie chart of protein expression specificity categories (see methods for definition)
1774 for kinases and phosphatases. Lower panels: Distribution of tissue-enhanced kinases and
1775 phosphatases across the 30 tissues showing that several tissues (notably pollen) stand out in
1776 terms of the expression of certain kinases and phosphatases implying tissue-specific signalling.

1777 d, Pie charts showing the proportion of 'proline-directed', 'acidic', 'basic' and 'other' motif
1778 categories for phosphorylated serine (pS), threonine (pT) and tyrosine (pY) residues. Only class
1779 I p-sites (localization score > 0.75, methods) were considered in this analysis.

1780 e, Example motif logo plots for 'proline-directed', 'acidic', 'basic' and 'other' motifs. P-site motifs
1781 were identified using the motif-X algorithm (see Supplementary Table 2 for all 266 motifs). n
1782 denotes the number of phosphorylation sites that contain the respective motif; fc denotes the
1783 fold change (i. e. enrichment) of the motif in phosphorylated vs unmodified peptides (see
1784 methods).

1785 f, Enrichment of 'proline-directed' (yellow), 'acidic' (red), 'basic' (blue) and 'other' (grey)
1786 sequence motifs (circles) in the serine p-site dataset versus the same motifs detected in the
1787 background dataset of unmodified peptides (see methods). Motifs are shown for 2, 3 and 4 fixed
1788 amino acid positions. The p-site in each motif example is underlined. X denotes any amino acid.

1789 g, Number of identified p-sites for a given protein plotted against the sequence lengths of the
1790 same protein. LATE EMBRYOGENESIS ABUNDANT (LEA) proteins are marked by a circle and
1791 arrow.

1792 h, Schematic representation of the LEA protein sequences (black bars). Pink marks denote
1793 phosphorylated and blue marks unphosphorylated STY residues. It is evident, that almost all
1794 STY residues in LEA proteins can be phosphorylated.

1795 i, Schematic representation the sequences and domain topology of the receptor-like kinases
1796 STRUBBELIG RECEPTOR FAMILY4 (SRF4), FERONIA (FER) and CHITIN RECEPTOR
1797 KINASE1 (CERK1). It is apparent that p-sites often preferentially occur in specific domains,
1798 notably the juxtamembrane domain. Protein sequence regions covered by identified peptides
1799 are marked in blue and p-sites are marked in pink.

1800 **Extended Data Figure 9 | Functional analysis of phosphorylation mutants of RCAR10 and**
1801 **QKY.**

1802 a, Phosphorylation site (p-site) localization within the structure of REGULATORY
1803 COMPONENTS OF ABA RECEPTOR10 (RCAR10). The RCAR10 structure (blue) was
1804 modelled using the RCAR11 protein crystal structure (cornflowerblue) as a template [45]. ABA-
1805 binding loops are shown in turquoise, p-sites in pink and ABA ligand in yellow.

1806 b, RCAR10 expression across tissues at the protein (blue, iBAQ), transcript (grey, TPM) and p-
1807 site (pink, intensity) level.

1808 c, Tissue-resolved total protein intensity and relative proportions of the members of the protein
1809 phosphatase 2C (PP2C) co-receptor family. Note that seed tissues stand out in terms of overall
1810 expression as well as the dominance of AHG1 in these tissues.

1811 d, Measurement of ABA response when expressing RCAR or RCAR10 phosphomimetic mutant
1812 variants in combination with different PP2C co-receptors in protoplasts (see methods). Columns
1813 display the average ABA response (±SD, n = 3) and grey dots indicate individual
1814 measurements. The data shows that co-expression of the phosphatases HAI1-3 lead to similar
1815 responses of the phophomimic mutants, whereas other co-expressed phosphatases show
1816 diverse responses.

1817 e, QUIRKY (QKY) expression across tissues at the protein (blue, iBAQ), transcript (grey, TPM)
1818 and p-site (pink, intensity) level.

f, Members of the MULTIPLE C2 AND TRANSMEMBRANE DOMAIN-CONTAINING PROTEIN (MCTP) family clustered by sequence similarity (left) and schematic representation of their domain structures along with detected p-sites (right). MCTP11a, 12 and 13 were not detected in this study (n.d.). QKY (MCTP15) is marked in bold.

g, Number of independent transgenic plant lines (*qky*-9 mutant background) transformed with WT (QKY), phosphomutant (SA) or phosphomimic (SE) constructs that show complete, partial or no rescue of the mutant phenotype. qPCR results (average ± SD; individual data points as grey dots) show the relative transgene expression in wild type (WT), *qky*-9 mutant and selected transgenic lines. QKY wild type (grey), QKY_{S262A} (SA; blue), QKY_{S262E} (SE, purple).

h-j, Representative confocal images of six days-old *qky*-9 *pQKY::mCherry:QKY* (WT QKY; n = 14 roots), *qky*-9 *pQKY::mCherry:QKYS262A* (phosphomutant; n = 21 roots), *qky*-9 *pQKY::mCherry:QKYS262E* (phosphomimic; n = 15 roots) root epidermal cells of the meristematic zone. The punctate signal along the cell circumference shows the expected localization of QKY protein. Arrows indicate punctate structures. Scale bars 5 µm.
