#### Abstract

The contribution of $B$ meson decays to nonphotonic electrons, which are mainly produced by the semileptonic decays of heavy-flavor mesons, in $p+p$ collisions at $\sqrt{s}=200 \mathrm{GeV}$ has been measured using azimuthal correlations between nonphotonic electrons and hadrons. The extracted $B$ decay contribution is approximately $50 \%$ at a transverse momentum of $p_{T} \geq 5 \mathrm{GeV} / c$. These measurements constrain the nuclear modification factor for electrons from $B$ and $D$ meson decays. The result indicates that $B$ meson production in heavy ion collisions is also suppressed at high $p_{T}$.

DOI: 10.1103/PhysRevLett.105.202301
PACS numbers: 25.75.-q, 25.75.Cj

The suppression of nonphotonic electron yields from semileptonic decays of $D$ and $B$ mesons for $p_{T}$ up to $9 \mathrm{GeV} / c$ in central $\mathrm{Au}+\mathrm{Au}$ collisions at Relativistic Heavy Ion Collider (RHIC) has been observed to be large [1], and similar to that of light quark hadrons [2]. Because of the dead cone effect, heavy quarks were expected to lose less energy than light quarks [3] if the dominant energy loss mechanism is gluon radiation [4]. Various models have been proposed to explain the large suppression of nonphotonic electron yields [5-7]. Theoretical calculations of the nonphotonic electron suppression crucially depend on the $B / D$ ratios because the amount of radiative energy loss depends on the quark mass. Measuring the bottom quark contribution to nonphotonic electron yields in $p+p$ collisions is therefore important in order to understand the production of heavy quarks and to provide a baseline for the energy loss measurement of heavy quarks in the hot and dense medium produced in central $\mathrm{Au}+\mathrm{Au}$ collisions.

In this Letter, we report a determination of the relative contribution from $B$ decays to nonphotonic electron yields $\left(r_{B}\right)$ by measuring the azimuthal correlations between nonphotonic electrons and charged hadrons ( $e_{\text {non } \gamma}-h$ ), and between nonphotonic electrons and $D^{0}$ mesons ( $e_{\text {non } \gamma}-$ $D^{0}$ ) in $p+p$ collisions at $\sqrt{s}=200 \mathrm{GeV}$ by the STAR experiment at RHIC. We fit the experimental $e_{\text {non } \gamma}-h$ correlations using a combination of PYTHIA calculations [8] for $D$ and $B$ meson decays and extract $r_{B}$ as a function of $p_{T}\left(2.5<p_{T}<9.5 \mathrm{GeV} / c\right)$. An independent measurement of the $r_{B}$ is obtained from $e_{\text {non } \gamma}-D^{0}$ correlations, by selecting the charge combinations $e^{-}-D^{0}\left(\rightarrow K^{-}\right)$ and $e^{+}-\bar{D}^{0}\left(\rightarrow K^{+}\right)$, which provide relatively pure samples of $B$ decays and charm pairs on near and away side $(\Delta \phi \sim \pi)$ [9]. The combined measurements of the $B$ decay contribution and of the nuclear modification factor $\left(R_{A A}\right)$ for heavy-flavor decay electrons in $\mathrm{Au}+\mathrm{Au}$ collisions constrain the value of the $R_{A A}$ for electrons from $B$ meson decays.

The $p+p$ data used in this analysis were taken by the STAR experiment [10] during the 2005 and 2006 RHIC runs. The main detectors for this analysis are the Time Projection Chamber (TPC) and the Barrel Electromagnetic Calorimeter (BEMC). The BEMC has a Shower Maximum Detector (SMD): proportional gas chambers with strip readout at a depth of $\sim 5$ radiation lengths $\left(X_{0}\right)$ designed to measure shower shapes and positions. The acceptance
for electrons in pseudorapidity and azimuth is $|\eta|<0.7$ $(0<\eta<0.7$ in the 2005 run $)$ and $0<\phi<2 \pi$. The BEMC also serves as a trigger detector for high $p_{T}$ electrons or photons, where single-tower transverse energy thresholds of 2.6 and 5.4 GeV were used. The total sampled luminosity was $11.3 \mathrm{pb}^{-1}\left(0.65 \mathrm{pb}^{-1}\right)$ for the 5.4 GeV ( 2.6 GeV ) trigger threshold. We used triggered events with primary vertices located within 35 cm of the TPC's geometrical center along the beam direction.

Electrons were identified by measuring ionization energy loss $(d E / d x)$ and track momentum $(p)$ from TPC, the energy $(E)$ deposition in the BEMC, and the shower profile in the SMD. A significant fraction of the hadron background was rejected by selecting tracks with a measured $d E / d x$ in the TPC between -1 and +3 standard deviations from the expected mean $d E / d x$ for electrons. Based on calibrations of the SMD response to electrons and hadrons, tracks whose shower projection occupies more than 1 strip in both $\phi$ and $\eta$ SMD planes were selected as electron candidates. We required the energy-to-momentum ratio to be in the range $0.3<p / E<1.5$. The hadron contamination in the electron sample after applying these cuts is $\sim 2 \%$ up to $5 \mathrm{GeV} / c$, increasing to $\sim 10 \%$ at $9 \mathrm{GeV} / c$.

The electron sample has two components: (i) nonphotonic electrons and (ii) photonic electronsthose from photon conversion in the detector material between the interaction point and the TPC and Dalitz decays, mainly from $\pi^{0}$. Photonic electrons were identified by pairing electrons with oppositely charged partner tracks, determining the conversion or decay vertex, and calculating the invariant mass of the $e^{+} e^{-}$pair $M_{e^{+} e^{-}}$[11]. To improve the invariant mass resolution, the so-called 2D invariant mass was calculated using only $p_{T}$ and $p_{Z}$, which is equivalent to setting the opening angle in the transverse plane to zero [11]. Monte Carlo simulations indicate that the cut of $0.1 \mathrm{GeV} / c^{2}$ removes almost all photon conversion candidates for which the decay partner is reconstructed in the TPC. The efficiencies for photonic electron reconstruction $\left(\epsilon_{e_{\gamma}}\right)$ range from $65 \%$ at $3.0 \mathrm{GeV} / c$ to $80 \%$ at $8.0 \mathrm{GeV} / c$, as determined from GEANT simulations. For the $e_{\mathrm{non} \gamma}-h$ analysis, we first removed the electrons that have an opposite-sign partner such that $M_{e^{+} e^{-}}<0.1 \mathrm{GeV} / c^{2}$ from the inclusive electron sample. The remaining electrons form the "semiinclusive" electron sample. The nonphotonic electron yields can be expressed as,

$$
\begin{equation*}
N_{e_{\text {non } \gamma}}=N_{e_{\text {semi }}}+N_{e_{\text {like }}}-N_{e_{\gamma}^{\text {not-reco }}}-N_{h} . \tag{1}
\end{equation*}
$$

$N_{e_{\text {semi }}}$ is the number of semi-inclusive electrons. $N_{e_{\gamma}^{\text {not-reco }}}$ represents the number of photonic electrons which are not reconstructed by the invariant mass method and is defined as: $\left(1 / \epsilon_{e_{\gamma}}-1\right)\left(N_{e_{\text {unlike }}}-N_{e_{\text {like }}}\right) . N_{e_{\text {ike }}}$ is the number of nonphotonic electrons that were rejected by the conversion cuts because they happened to form a pair with a random track which is determined using like-sign pairs. $N_{h}$ is the remaining background from hadron contamination in the electron sample. Other weak decay contributions such as $K_{e 3}$ are negligible due to their long $c \tau$, and charmed baryons (mostly $\Lambda_{c}$ ) is expected to be very small contribution since the baryon yield is small compared to the meson yield ( $\Lambda_{c} / D^{0} \sim 0.1$ in PYTHIA) and the branching ratio for semileptonic decays is smaller for baryons than mesons. The $e_{\text {non } \gamma}-h$ azimuthal distributions were calculated as

$$
\begin{align*}
\frac{d N^{e_{\mathrm{non} \gamma}-h}}{d(\Delta \phi)}= & \frac{d N^{e_{\mathrm{semi}}-h}}{d(\Delta \phi)}+\frac{d N^{e_{\text {like }}-h}}{d(\Delta \phi)} \\
& -\frac{d N^{\text {not-reco }}-h}{d(\Delta \phi)}-\frac{d N^{h-h}}{d(\Delta \phi)} \tag{2}
\end{align*}
$$

where each term is normalized to be per nonphotonic electron trigger. Each angle-difference distribution on the right-hand side of Eq. (2) was experimentally determined. The distribution $d N^{e_{\gamma}^{\text {not-reco }}-h} / d(\Delta \phi)$ was constructed from $d N^{e^{\text {reco }}-h} / d(\Delta \phi)$ by removing the conversion partner to account for the fact that the partner electron is not reconstructed.

Figure 1 shows $d N^{e_{\text {non } \gamma}-h} / d(\Delta \phi)$ per trigger for nonphotonic electrons for two different trigger $p_{T}$ selections. Associated particles were required to have $p_{T}>$ $0.3 \mathrm{GeV} / c$ and $|\eta|<1.05$. The dotted (dashed) line in

FIG. 1 (color online). Distributions of the azimuthal angle between nonphotonic electrons and charged hadrons normalized per nonphotonic electron trigger. The trigger electron has (top) $2.5<p_{T}<3.5 \mathrm{GeV} / c$ and (bottom) $5.5<p_{T}<6.5 \mathrm{GeV} / c$. The curves represent PYTHIA calculations for $D$ (dotted curve) and $B$ (dashed curve) decays. The fit result is shown as the black solid curve.
the figure represents a PYTHIA version 6.22 calculation of the azimuthal correlations between electrons from $D(B)$ meson decay and charged hadrons $\left(f_{e_{D}}(\Delta \phi), f_{e_{B}}(\Delta \phi)\right)$ [12]. PYTHIA was tuned to reproduce the shapes of $p_{T}$ distributions for $D$ mesons measured by STAR [12,13]. The PYTHIA calculation shows that the near-side peak for $f_{e_{B}}(\Delta \phi)$ is broader than that for $f_{e_{D}}(\Delta \phi)$. These shapes are dominated by decay kinematics. The fragmentation function does not affect the shape in a significant way. The fraction of nonphotonic electrons from $B$ meson decay can be determined by fitting the near-side distribution function $(|\Delta \phi|<1.5)$ :

$$
\begin{equation*}
\frac{1}{N_{\mathrm{trig}}^{\mathrm{non} \gamma}} \frac{d N^{e_{\text {non } \gamma-h}}}{d(\Delta \phi)}=r_{B} f_{e_{B}}(\Delta \phi)+\left(1-r_{B}\right) f_{e_{D}}(\Delta \phi) \tag{3}
\end{equation*}
$$

where $r_{B}$ is the ratio of electrons from $B$ meson decay to the total nonphotonic electron yield, $r_{B}=N_{e_{B}} /\left(N_{e_{B}}+\right.$ $\left.N_{e_{D}}\right)=N_{e_{B}} / N_{e_{\text {non }}}$.

An independent measurement of $r_{B}$ was performed using $e_{\text {non } \gamma}-D^{0}$ correlations. $D^{0}$ mesons were reconstructed via their hadronic decay $D^{0} \rightarrow K^{-} \pi^{+}(\mathcal{B}=3.89 \%)$ by calculating the invariant mass of all oppositely charged TPC tracks in the same event. In this analysis, only events with a nonphotonic electron trigger were used for $D^{0}$ reconstruction. Furthermore, the kaon candidates were required to have the same charge sign as the nonphotonic electrons [9]. The combinatorial background of random pairs was evaluated by combining all charged tracks with the same charge sign from the same event. The requirement of a nonphotonic electron trigger suppresses the combinatorial background, yielding a signal ( $S$ )-to-background ( $B$ ) ratio of about $14 \%$ and a signal significance $(S / \sqrt{S+B})$ of $\sim 4.6$.

Figure 2(a) shows the background-subtracted $K / \pi$ invariant mass distribution. The peak position and width were determined using a Gaussian fit to the data. The $K \pi$ invariant mass distribution was obtained for different $\Delta \phi$ bins with respect to the trigger electron, and the yield of the associated $D^{0}$ mesons was taken as the area underneath the Gaussian fit to the signal. Figure 2(b) shows the azimuthal correlation of $e_{\text {non } \gamma}-D^{0}$, which exhibits nearand away-side correlation peaks with similar yields. The results are fitted with the correlation functions for charm and bottom production from PYTHIA and MC@NLO simulations having the relative $B$ contribution as a free parameter [9]. The observed away-side correlation peak can be attributed to prompt charm pair production $(\sim 75 \%)$ and $B$ decays ( $\sim 25 \%$ ), whereas the contributions to the nearside peak are mainly from $B$ decays. We determined $r_{B}$ by fitting the measured $e_{\text {non } \gamma}-D^{0}$ correlation with PYTHIA and MC@NLO and used the average of the two fits for the final value.

Figure 3 shows $r_{B}=N_{e_{B}} /\left(N_{e_{B}}+N_{e_{D}}\right)$ extracted from $e_{\text {non } \gamma}-h$ correlations (filled circles) and $e_{\text {non } \gamma}-D^{0}$

FIG. 2 (color online). (a) Background-subtracted invariant mass distribution of $K \pi$ pairs requiring at least one nonphotonic electron trigger in the event. The solid line is a Gaussian fit to the data near the peak region. (b) Distribution of the azimuthal angle between nonphotonic electron (positron) trigger particles and $D^{0}\left(\bar{D}^{0}\right)$. The solid (dashed) line is a fit of the correlation function from PYTHIA (MC@NLO) simulations to the data points.
correlations (open circle) as a function of $p_{T}$. The vertical lines represent the statistical errors and the systematic uncertainties are shown as brackets. The systematic uncertainties due to electron identification $(\sim 7 \%)$, photonic electron rejection $(\sim 6 \%)$, the fit range $(\sim 10 \%)$ and the normalization of the azimuthal distribution ( $\sim 10 \%$ ), PYTHIA and MC@NLO predictions for $e_{\text {non } \gamma}-D^{0}(\sim 5 \%)$, and the $D^{0}$ signal extraction were estimated by varying the associated cut parameters and adding the individual contributions in quadrature. $r_{B}$ increases with electron $p_{T}$ and reaches approximately $0.5\left(N_{e_{B}} / N_{e_{D}} \sim 1\right)$ around $p_{T}=$ $5 \mathrm{GeV} / c . r_{B}$ from the $e_{\text {non } \gamma}-D^{0}$ correlation measurement at $p_{T} \sim 5.5 \mathrm{GeV} / c$ is consistent with $r_{B}$ from $e_{\text {non } \gamma}-h$ correlations. The curve in the figure is $r_{B}$ from a FONLL pQCD calculation including theoretical uncertainties [14]. Similar ratios at $2<p_{T}<7 \mathrm{GeV} / c$ using a different

FIG. 3. Transverse momentum dependence of the relative contribution from $B$ mesons $\left(r_{B}\right)$ to the nonphotonic electron yields. Error bars are statistical and brackets are systematic uncertainties. The solid curve is the FONLL calculation [14]. Theoretical uncertainties are indicated by the dashed curves.
method have also been reported [15]. $J / \psi$ di-electron decays can also contribute to nonphotonic electrons and STAR measurement of $J / \psi$ at high $p_{T}$ indicates that $J / \psi$ decays could contribute nearly $10 \%$ around $p_{T} 5 \mathrm{GeV} / c$. The estimated effect of the electrons from $J / \psi$ decays on $r_{B}$ is a few percent, much smaller than the current statistical and systematic uncertainties, and no correction was applied to our data.

Next, we explore the implications of the measured $r_{B}$ for the $R_{A A}$ of electrons from $B$ meson decay in heavy ion collisions. The $R_{A A}$ for heavy-flavor nonphotonic electrons $\left(R_{A A}^{\mathrm{HF}}\right)$ is given by

$$
\begin{equation*}
R_{A A}^{\mathrm{HF}}=\left(1-r_{B}\right) R_{A A}^{e_{D}}+r_{B} R_{A A}^{e_{B}}, \tag{4}
\end{equation*}
$$

where $R_{A A}^{e_{D}}\left(R_{A A}^{e_{B}}\right)$ is the $R_{A A}$ for electrons from $D(B)$ mesons. From Eq. (4), $R_{A A}^{e_{D}}$ and $R_{A A}^{e_{B}}$ are related by the $B$ decay contribution to the nonphotonic electron yields $\left(r_{B}\right)$ in $p+p$ collisions. We have taken the $R_{A A}^{\mathrm{HF}}$ measurement from PHENIX $[16,17]$ and fit the $R_{A A}^{\mathrm{HF}}$ above $p_{T}>$ $5 \mathrm{GeV} / c$ to a constant value and obtained: $R_{A A}=$ $0.167_{-0.0485}^{+0.0562}(\text { stat })_{-0.0815}^{+0.0512}$ (syst) $\pm 0.0117$ (norm), where the statistical and systematic errors are evaluated from weighted average over these $p_{T}>5 \mathrm{GeV} / c$ points. We also calculate the weighted mean $r_{B}$ value for $p_{T}>$ $5 \mathrm{GeV} / c$ including statistical and systematic errors from our measurement: $r_{B}=0.54 \pm 0.0349$ (stat) $\pm$ 0.0666 (syst). Then using Eq. (4) we calculate a likelihood distribution for $R_{A A}^{e_{B}}$ as a function of $R_{A A}^{e_{D}}$ and the results are shown in Fig. 4. The most probable values for the $R_{A A}^{e_{D}}$ and $R_{A A}^{e_{B}}$ correlation are shown by the line with open circles and the $90 \%$ Confidence Limit curves are represented by dashed lines. This result indicates that $B$ meson yields are suppressed at high $p_{T}$ in heavy ion collisions

FIG. 4 (color online). Confidence level contours for nuclear modification factor $R_{A A}$ for electrons from $D\left(R_{A A}^{e_{D}}\right)$ and $B\left(R_{A A}^{e_{B}}\right)$ meson decays and determined by combining the $R_{A A}$ results and the $r_{B}$ measurement for $p_{T}>5 \mathrm{GeV} / c$. Three different models of $R_{A A}$ for $D$ and $B$ are described in the text.
presumably due to energy loss of the $b$ quark in the dense medium [5] or of the heavy-flavor hadrons due to dissociation [6] or elastic scattering [7]. Our conclusion does not change if we use the $R_{A A}$ measurement from [1] and ignore the $J / \psi$ feed down contributions.

For comparison, we also show model calculations in Fig. 4. Model I includes radiative energy loss via a few hard scatterings with initial gluon density $d N_{g} / d y=1000$ [5]. Model II includes cold nuclear matter effects, partonic energy loss and collisional dissociation [6]. Model III assumes a large elastic scattering cross section associated with resonance states of $D$ and $B$ mesons in the QGP [7]. The model contours in Fig. 4 are calculated from the $p_{T}$ dependences of $R_{A A}$ for $D$ and $B$ decay in the interval $5<$ $p_{T} \leqq 9 \mathrm{GeV} / c$. For model I and II, the uncertainties are also taken into account. The experimental results are consistent with models II and III but are incompatible with model I. Recently AdS/CFT theory has also been used to calculate the heavy quark energy loss in a strongly coupled quark-gluon plasma matter, for example [18,19]. The theory also predicts strong suppressions for charm and bottom, and the ratio of the nuclear modification factors is proposed to differentiate AdS/CFT calculation from others [20].

In summary, we measured the relative contribution from $B$ decays to the nonphotonic electron production in $p+p$ collisions at $\sqrt{s}=200 \mathrm{GeV}$ by using azimuthal correlations between nonphotonic electrons and hadrons $\left(h, D^{0}\right)$. Our result indicates that the $B$ decay contribution increases with $p_{T}$ and is comparable to the contribution from $D$ meson decay at $p_{T} \geq 5 \mathrm{GeV} / c$. Our measurement is consistent with the FONLL calculation. The ratio of $N_{e_{B}} /\left(N_{e_{D}}+N_{e_{B}}\right)$ combined with the large suppression of nonphotonic electrons indicates that $R_{A A}$ for electrons from $B$ hadron decays is significantly smaller than unity and therefore $B$ meson production is suppressed at high $p_{T}$ in heavy ion collisions. The constraint on $R_{A A}^{e D}$ and $R_{A A}^{e B}$ will help to differentiate theoretical model calculations for heavy quark energy loss in the dense medium.
