Abstract

The quenching of Einstein A-coefficients was observed by measuring the branching ratio of visible and XUV line intensities for CIV. CIII. and NV ions.

- † Present address: Nagoya University, Nagoya, Japan
- ‡ Also at Dept. of Mechanical and Aerospace Engineering, Princeton University

1. Introduction

Since the formula for the Einstein A-coefficient was derived in the pioneering works of Weisskopf and Wigner(WW) based on Dirac's theory of light, it has been widely accepted as valid in any practically important cases. In essence, the expression WW obtained was the same as that for a classical oscillating dipole, except that the quantum mechanical dipole moment matrix element between the upper and the lower level of transition replaced the classical dipole moment. They also assumed an exponential decrease for the excitation probability of the upper state as Ansatz and proved it a posteriors.

However, the derivation of the Einstein A-coefficient has often been the subject of rigorous theoretical investigation on the basis of other theories of light.^{2.3} Even though essentially the same expressions as that of WW were obtained, it strongly suggests that the nature of radiative transition is not vet fully known. It was also noted by several authors⁴⁻⁷ that the rate of spontaneous radiative decay can deviate significantly from the Weisskopf-Wigner expression in certain environments where the atoms are located. Most notably, the spontaneous emission of radiation by an excited atom is completely suppressed in a cavity whose characteristic dimension is less than half the wavelength of the photon. It is believed that this effect is related to the decoupling of the vacuum field and the radiating atom. In quantum electrodynamics(QED), the excited atom is driven to emit a photon and decay to a lower state by the fluctuation in the vacuum field if the atom is located in free space or a cavity whose dimension is much larger than the radiation wavelength. As the dimensions of the cavity become small compared to the radiation wavelength, the density of modes accessible to the atom decreases significantly. In this situation. the excited atom can no longer decay as freely as in the large cavity, and the

radiative transition is effectively suppressed. A similar effect was also observed in the cyclotron radiation of an electron confined in a Penning trap⁸ and has been predicted in solid state cavities.⁹

In a previous work.¹⁰ the observation that the branching ratio of two radiative transitions originating from the same upper level decreased by about an order of magnitude at electron density of around 10^{19} cm⁻¹ compared to the ratio at 10^{18} cm⁻¹ led us to the conclusion that the coefficients of spontaneous emission were not constants. The term branching ratio in this paper denotes the ratio of the experimentally measured intensities of the visible and the XUV (extreme ultraviolet) light unless specified otherwise. The branching ratios were measured with a novel XUV-visible duo-multichannel spectrometer. The spontaneous emission intensity I_{nm} (in photons) for the transition $n \to m$ is proportional to the upper level population density, the A-coefficient and a geometrical factor, that is.¹¹

$$I_{nm} = k_n(r) N_n(n_e, T_e) A_{nm}. \tag{1}$$

Hence, the branching ratio for optically thin plasmas is the same as the ratio of the corresponding A-coefficients. Therefore, if the A-coefficients are constant and independent of the electron density or other environmental factors, the branching ratio should remain constant even as we observe regions of different electron density in the plasma. It was our primary finding that this was not true.

The observed change in the branching ratio could be attributed to the following reasons:

- (1) self-absorption of the visible light.
- (2) cutoff of the visible light in a region of high electron density where the plasma frequency $\nu_p = \sqrt{\frac{n_e e^2}{m\pi}}$ is larger than the visible light frequency $\nu_{\rm VIS}$.
- (3) refraction of the visible light out of the spectrometer line of sight.

- (4) improper alignment of the spectrometers.
- (5) stimulated emission of the XUV light at a level comparable to the spontaneous emission.
- (6) nonlinear detector sensitivity at low and high intensity.
- (7) other experimental errors, including misinterpretation of the data.
- (8) deviation of the spontaneous emission coefficients from the vacuum (or low density) value.

An extremely careful examination, including supplementary testing experiments, of the other possibilities (1-7) confirmed the hypothesis that in higher density plasmas the spontaneous emission coefficients decreased. This may be a result of free electrons interaction with atoms and ions.

In section 2, we describe measurements of the changes in the branching ratios on CIV (312 Å and 5801-5812 Å). CIII (574 Å and 5696 Å), and NV (209 Å and 4603-4620 Å) transitions, and recent results obtained from higher density plasmas produced by a ruby laser. These show an even larger decrease in branching ratio than could be obtained with a $\rm CO_2$ laser as reported in Ref. 10. In section 3, we attempt to explain this phenomenon, and in section 4, we state our conclusions.

2. Experiment

In this section, we describe: (1) experimental arrangements, (2) the branching ratio measurement experiment on CO₂-laser-produced CIV and CIII ions, (3) measurement of the branching ratio on ruby-laser-produced CIV ions, (4) measurement of the branching ratio on CO₂-laser-produced NV ions, and (5) measurement of the light attenuation, e.g., by self-absorption and refraction, due to the plasma.

The experimental setup is shown in Fig. 1. The arrangement primarily consists of the lasers, the target chamber, the spectrometers, and the supporting systems.

such as vacuum pumps and the data acquisition system. The ruby laser is on top of the CO_2 laser and the two laser beams run parallel to each other. The CO_2 laser beam is focused onto the target by a NaCl lens of local length f=50 cm, and the ruby laser beam is focused by a quartz lens of focal length f=25 cm after being redirected by a periscope into the CO_2 laser beam axis. The position of the focusing lens for the ruby laser beam can be adjusted up to ± 3 cm to provide optimal conditions for the generation of different ionization stages. The XeCl laser beam is positioned at approximately 45° to the CO_2 laser and the ruby laser. The characteristics of these lasers are summarized in Table 1.

The plasma was created by interaction of the laser beam with a solid target in the vacuum chamber. The typical length of the target was 24 mm and each step was 4 mm long. Several targets of various widths ranging from 200 µm to 4 mm were tested in this experiment. Even though narrower targets of width $\approx 200~\mu\mathrm{m}$ gave results unaffected by XUV self-absorption, the signal to noise ratio was unacceptably low. Moreover, these targets tended to be easily destroyed after a few shots of laser irradiation. Targets of width larger than 1 mm did not have this problem, but it was clear that there was XUV self-absorption close to the target. As a compromise, the targets were fabricated at 300 μm - 500 μm for the measurement of the branching ratio. Targets of larger widths were used only to demonstrate the XUV self-absorption. The target had several steps (typically 6) as shown in Fig. 1, and plasmas at various distances from the target surface could be observed by moving the target up and down with a micrometer with vacuum feedthrough. The distance from observation region to target surface increased by 200 μm with each step. The radiation emitted from the plasma first passed through a narrow slit S of 200 µm width, which was fixed in the target chamber at a distance of 15 mm from the target. The width of this slit S was also chosen as a trade-off between

the signal-to-noise ratio and the spatial resolution of the measurement. Since the distance between the slit S and the target surface varied by 200 μ m, we chose the slit width S to be 200 μ m as well. A larger slit width would give better signal-to-noise ratio, but would also nullify the resolution provided by the target steps.

We used one or more of the lasers to produce the plasma. For the measurement of the branching ratio, we primarily used the CO₂ laser for producing plasmas with density $n_e < 10^{19} {\rm cm}^{-3}$, the ruby laser for $n_e < 10^{21} {\rm cm}^{-3}$, and the NeCl laser for $n_e < 10^{22} {\rm cm}^{-3}$.

In order to record the XUV and the visible spectra simultaneously from exactly the same plasma region, we used a specially constructed XUV-visible duomultichannel spectrometer. The radiation emitted by the plasma, after passing through the narrow slit S in the target chamber, enters the spectrometer through the entrance slit as shown in Fig. 1(b). Here again, it was necessary to optimize the width of the entrance slit for the maximum signal-to-noise ratio as well as the maximum signal for the visible spectrum. The typical width was between 100 μ m and 200 µm. The grating separates this beam into the 0th, the 1st, and other higher order diffractions. 600 or 1200 rulings mm grating was used. The 0th order beam is sent to the visible multichannel spectrometer by the periscope consisting of a small mirror placed immediately after the grating in the vacuum, and another large mirror in the air in front of the focusing lens. Other higher order beams reach the XUV multichannel detector directly. The small mirror was placed very carefully at the point of focus of the 0th order beam on the Rowland circle. Special precautions were taken in order not to block the path of the 1st order beam containing the wavelengths of our interest. The focusing lens in front of the visible spectrometer focuses this 0th order beam to a narrow image of the XUV entrance slit at the place of the visible entrance slit. Both the entrance slit and the exit slit

were removed from the visible spectrometer. The position of the focusing lens was adjusted for the minimum instrumental broadening on the detector. The full width at half maximum (FWHM) of the mercury 5461 A was 1.6 A, which we took as the instrumental broadening of the visible spectrometer.

In Fig. 2 are shown the spectra obtained in the vicinity of CIV 312 Å and 5801-5812 A(the shaded lines) at distances of 0.2 mm and 0.4 mm from the target, respectively. The branching ratio R was calculated from the ratio of the shaded areas of the visible and the XUV lines, which gave R=0.92 at d=0.2 mm and R=0.29 at d=0.4 mm. The XUV line was instrumentally broadened mostly due to the entrance slit of 200 μ m width on the spectrometer. The broadening of the visible line is due to the Stark effect. Results from the measurement of changes in the branching ratio on CIV ions were presented in our earlier work. ¹⁰ In this paper, we add more detailed analysis of the line profiles and present new results from the supplementary testing experiments.

To justify the claim made in this experiment, it is crucial to prove that the branching ratio we measured was truly the ratio of the spontaneous emission intensities and that the measurement was not affected by absorption or cutoff. The evidence that visible lines were not absorbed (or self-absorbed) is manifested in the near perfect coincidence of the experimentally measured profile of CIV 5801 A(J=3/2) and 5812 A(J=1/2) and the convolution of their Lorentzian profiles with a 2:1 intensity ratio. Figure 3 shows the fitting of the experimental data and the convolution of Lorentzian profiles of CIV visible lines shown in Fig. 2. If there had been any absorption, the intensity ratio of the two lines would be smaller than the theoretical ratio of 2:1, since stronger line would be more absorbed. This analysis also strongly suggests that the plasma was optically thin for visible transitions. Absorption or self-absorption of XUV lines would tend to increase the branching

ratio $R = I_{\rm VIS} \ I_{\rm XUV}$ and thus decrease the effect of quenching of the A-coefficient of the visible transition.

As another remark on the analysis of the visible spectrum, we discuss uncertainties arising from the integration of the experimental profile used in the calculation of the branching ratio R. If the line is very broad, the boundary of the line profile to be integrated becomes less distinct, and this may introduce error in the integration. This can be quite a serious problem in the correct estimation of the total intensity when the background level is noisy or not smooth. Therefore, it is important to choose the end points of integration very carefully (and conservatively) in order not to underestimate the intensity of the visible transition at high plasma density. However, it is our belief the uncertainty in integration cannot account for the observed change in the branching ratio. Figure 4 shows three cases of integration with different end points and the comparison of these values with the theoretical curve based on the assumption that the line profiles are Lorentzian. The end points we used for the actual calculation of the area are the same as the end points of the tentative background level line marked 1. This shows that as long as this tentative background level line does not deviate visibly from the adjacent background level, the error in the integration of the profile is relatively small compared to the observed change in branching ratio.

To prove experimentally that the measurement was not affected by absorption, we also measured the transmissivity of the plasma at various distances from the target. The experimental setup is shown in Fig. 5(a). The CO₂ laser beam was split into two identical beams by a NaCl window tilted at $\approx 30^\circ$ with respect to the plane perpendicular to the beam axis. The resulting separation of the two plasmas created at the target 50 cm away from the focusing lens was 2.5 mm. The narrower target was 500 μ m wide and the other target was 2.7 mm wide. The positions of

the beams were adjusted so that the plasmas were created at the center of the left target and at the edge of the right target. To measure the transmissivity of the plasma on the left target, we first obtained spectra from the left plasma and the right plasma separately by blocking one of the laser beams. Then we obtained the spectra with two plasmas. The measured intensities are denoted by I_1 (left plasma), I_2 (right plasma), and I_{1-2} (together), respectively in Fig. 5. The transmissivity I_2 was taken to be

$$T = \frac{I_{1-2} - I_1}{I_2}.$$

The result shows that there was insufficient absorption of visible light to account for the observed order of magnitude change in the branching ratio.

We observed the same effect of quenching of spontaneous emission in ruby-laser-produced CIV plasmas of higher density as well as in other ions, namely, in CIII and NV produced by the CO₂ laser. Figure 6 shows the spectra obtained in the vicinity of CIII 574 Å and 5696 Å(the shaded lines) at distances of 0.6 mm and 1.3 mm from the target, respectively. The branching ratio R was calculated from the ratio of the shaded areas of the visible and the XUV lines. It is shown clearly in Fig. 6 that while the XUV intensity drops by a factor of 4, the visible intensity even increases slightly as the distance d increases from 0.6 mm to 1.3 mm. The result of the measurement for CIII is presented in Fig. 7. We also measured the changes in the branching ratio for the CIV 312 Å and 5801-5812 Å lines with the ruby laser and NV 209 Å and 4603-4620 Å lines with the CO₂ laser. The results are shown in Figs. 8 and 9. In ruby-laser-produced plasmas, we could observe larger changes in the branching ratio due to higher n_e as compared with CO₂-laser-produced plasmas.

Measurements of the branching ratio between two transitions that share the same upper level is independent of several factors concerning the population changes that could affect the line intensities. Here lies the simplicity of the principle involved

in this experiment. Even though the measurement of the temporal behaviour of the lines can be of assistance in understanding the change of the branching ratio, it was not deemed to be essential. The decay time of a transition is, except for the resonance transitions, not equal to the reciprocal of the corresponding A-coefficient but to the radiative lifetime of an excited level, which is given by the reciprocal of the sum of all the transition probabilities, i.e.,

$$\tau_i = \frac{1}{\sum_k A_{ik}}.$$

Hence, all the transitions that branch from the same upper level should have the same temporal behaviour but with different amplitudes proportional to the A-coefficients. Therefore, assuming the plasma density was constant while the emission lasted so that the A-coefficients did not change, we would have

$$\frac{N_3(t_i)A_{32}\Delta t_i}{N_3(t_i)A_{31}\Delta t_i} = C(\text{constant}), \tag{2}$$

where $N_3(t_i)$ is the upper level population at time t_i and Δt_i is the incremental time interval. If we take $\Delta t_i \rightarrow 0$ and integrate over time, Eqs. (1) and (3) will give

$$\frac{I_{32}^T}{I_{31}^T} = \frac{\int I_{32}(t)dt}{\int I_{31}(t)dt} = \frac{k_{32}}{k_{31}}C.$$

which is also constant. I_{32}^T and I_{31}^T are the time-integrated intensities. This shows that change of the branching ratio R can be deduced from the change of the ratio of the time-integrated intensities alone.

3. Theory

The theoretical effort has been on going since we obtained the preliminary results from the experiments measuring the branching ratio in CIV. However, there does

not exist yet a theoretical model that can clearly and unequivocally explain this phenomenon. In this section, we describe our initial unsuccessful attempt, and then go on with a suggestion for possible future approaches.

We first speculated that the screening of the atomic potential by the surrounding plasma could modify the Coulomb field experienced by the electron and thus significantly change the transition probabilities. Several authors¹² have tried to obtain solutions to the Schrödinger equation for a particle in a screened Coulomb potential. Roussell and O'Connell calculated the spontaneous emission probabilities in the dipole approximation as a function of Debye-Hückel screening length r_D for a hydrogen atom (Z=1) and showed that the spontaneous emission probabilities began to drop sharply at $r_D=50a_0$, where a_0 is the Bohr radius.

In our case, the Schrödinger equation was solved numerically for CIV ions in the electric potential of the surrounding plasma. This potential was approximated by using the Debye radius $r_D \propto n_e^{-\frac{1}{2}}$, assuming T_e , the electron temperature, to be constant. The transitions of the valence electron were assumed to occur in the internal potential of two bound electrons $(1s^2)$, approximated by a uniform charge cloud of radius R_0 and influenced by the external field. Therefore, the potential V(r) was given by

$$V(r) = \begin{cases} \left[\frac{Z'e^2}{2R_0} \left\{ 3 - \left(\frac{r}{R_0} \right)^2 \right\} - \frac{Ze^2}{r} \right] e^{-R_0 + r_E}, & \text{if } r \le R_0: \\ - \left[\frac{(Z - Z')e^2}{r} \right] e^{-r_{FD}}, & \text{otherwise.} \end{cases}$$

where e is the electron charge, r is the distance from the center of the charge cloud, Z=6 and Z'=2 for CIV, and R_0 was taken to be much smaller than r_D . Once the eigenfunctions were obtained by solving the Schrödinger equation, it was straightforward to obtain the branching ratio between the two transitions. In dipole

approximation, the Einstein A-coefficients are given by

$$A(nl - n'l') = \frac{4 \Delta E^3}{3(2l-1)} S(nl, n'l').$$

W.iere

$$S(nl, n'l') = \sum_{m,m'} < nlm \ d \ n'l'm' > 2.$$

The theoretical branching ratio R between the two transitions, $n_3l_3 - n_2l_2$ and $n_3l_3 - n_1l_1$, is then given by

$$R = \frac{A(n_3l_3 - n_2l_2)}{A(n_3l_3 - n_1l_1)}.$$

Figure 10 shows the result obtained for the cases $(5p \rightarrow 4s, 5p \rightarrow 1s)$ of the hydrogen atom (Z = 1.2' = 0) and $(3p \rightarrow 3s, 3p \rightarrow 2s)$ of the CIV ion (Z = 6.2' = 2) as functions of the Debye radius r_D . For the transitions between lower lying states in the hydrogen atom, we obtained the same results as Roussell and O'Connell. As r_D approaches $10a_0$, the branching ratio begins to increase very rapidly for the CIV ion in contrast to the hydrogen atom. For hydrogenic ions (Z > 1), the higher the Z number, the less drastic was this effect. The main cause for the change in CIV was the changes in the transition strength $S(nl \rightarrow n'l')$, while in the case of the hydrogen atom, it was the shift of energy levels. This result is not consistent with the experimental results in that no line shift was observed with increasing electron density, i.e., with decreasing Debye radius. This inconsistency clearly indicates that (1) the Debye-Hückel screened potential is not valid in our case since the plasma parameter

$$g = nr_D^3$$

is not much larger than 1 and/or (2) the electron density is still too low for the screening effect to become important. Assuming $T_e \approx 5 \text{ eV}$ and $n_e \leq 10^{19} \text{cm}^{-1}$.

we have $r_D \geq 100a_0$ and $g \geq 1.5$. r_D and g become larger as the electron density decreases if T_e is constant. This is far away from the region where the screening of the potential can alter the transition probability significantly, and we conclude that the quenching of the Einstein A-coefficients as observed in the experiment is due to some cause other than the screening of the static Coulomb potential by the surrounding plasma.

A different approach to the development of a theoretical model has been the modification of the Weisskopf-Wigner (WW) approximation of exponential decay of excited atoms. $^{13-16}$ Reference 14 is essentially an extension of the WW in the sense that the coupling between the first continuum of states to which the excited atom initially decays and the second continuum was taken into account. In this case, the decay rate of the initial excited state can decrease if the first continuum of states is itself unstable and coupled to a still lower lying continuum of states. Even though the probability that the excited state stays there remains exponential, the decay rate may be changed. If only the second continuum were considered in addition to the first continuum and if the coupling strengths V_{32} and V_{21} could be factored as $V_{32} = F_0G_0$ and $V_{21} = F_1G_1$, the modified decay rate γ would be 16

$$_{I}=\frac{\gamma_{GR}}{1-H_{1}}.$$
(3)

where γ_{GR} is the Fermi Golden Rule rate, and H_1 is an intrinsically positive quantity proportional to the square of the coupling strength V_{21} .

We are presently following this line of approach and exploring the possibility of relating the rapid depletion of the lower level of transition by collisional de-excitation to the suppression of radiative decay from the initially excited level 3(see Fig. 11). The transition between levels 2 and 1 is forbidden in the dipole approximation, and the level 2 would be metastable unless provided with other channels of decay. The

coupling between the levels 2 and 1 is provided by collisional de-excitation whose rate will increase linearly with the electron density n_e .

4. Conclusion

We described experiments that focus on the change of branching ratio in high density plasmas as well as our theoretical efforts to explain the phenomenon. Various possible explanations other than the decrease of Einstein A-coefficients in the high density regime were judged to be unfounded. At this time, we still lack a satisfactory theoretical explanation of why the branching ratio, hence the Einstein A-coefficient, changes in high density plasmas. However, we hope that progress in theoretical studies will provide such an explanation and lead to a better understanding of the atomic radiative processes in plasmas.

line intensity increases sharply near the target, the visible line intensity does not change very much.

- Fig. 8 Branching ratio $R = I_{\rm VIS} \ I_{\rm NUV}$ for NV 207 A and 4603-4620 A lines as a function of distance from the target surface. The plasma was produced by a CO₂ laser.
- Fig. 9 Branching ratio $R = I_{\rm VIS}/I_{\rm XUV}$ for CIV 312 Å and 5801-5812 Å lines as a function of distance from the target surface. The plasma was produced by a ruby laser for higher electron density $(n_{\tau} < 10^{21} {\rm cm}^{-1})$.
- Fig. 10 Theoretical branching ratio R obtained by solving the Schrödinger equation with Debye-Hückel screened Coulomb potential for CIV (3p-3s and 3p-2s) and H (5p-4s and 5p-1s) as functions of the Debye radius rp.
- Fig. 11 Hypothetical theory: radiative transition may be quenched when the coupling between levels 2 and I becomes large through the collisional deexcitation by electrons.
