Molecular Dominoes Triggered by Mechanical Stimulation and Solid Seeding as

Single-Crystal-to-Single-Crystal Transformation

Abstract

Numerous studies have focused on the mechanical control of solid structures and phase changes in molecular crystals. However, the molecular level understanding of how macroscopic forces affect the molecules in a solid remains incomplete. Here, we report that a small mechanical stimulus or solid seeding can trigger a single-crystal-to-single-crystal transformation from a kinetically isolated polymorph of phenyl(phenyl isocyanide)gold(I) exhibiting blue photoluminescence to a thermodynamically stable polymorph exhibiting yellow emission without the need for heating or solvent. The phase transformation initiates at the location of the mechanical stimulation or seed crystal, extends to adjacent crystals, and can be readily monitored visually by the accompanying photoluminescent color change from blue to yellow. The transformation was characterized using single crystal X-ray analysis. Our results suggest that the transformation proceeds through self-replication, causing the complex to behave as 'molecular dominoes'.

Introduction

Single-crystal-to-single-crystal (SCSC) transformations in molecular crystals are known to be induced by various external perturbations, such as heat, light, static pressure and exposure to small molecules.[1–11] The crystal structures can be compared before and after the structure change using single crystal X-ray diffraction (XRD) analysis, providing a molecular level understanding of the solid state reactions and phase transformations.[12,13] Anisotropic addition of a bulk force, such as shearing, ball-milling or grinding, can also alter the solid structure of the molecular crystals, and numerous studies have suggested that this transformation can include direct crystal-to-crystal conversion.[14–21] However, anisotropic forces also induce crystal collapse, making them unsuitable for single crystal X-ray analysis. To date, the observation of a SCSC transformation induced by a mechanical stimulus has not yet been reported.

In this paper, we report the first observation of the SCSC transformation of phenyl(phenyl isocyanide)gold(I) (**1**), which was triggered by applying a small mechanical force to the crystal surface or by contact with a crystal seed of the opposite polymorph. The phase change first occurred at the initial contact area and subsequently progressed spontaneously throughout the entire crystal. Single crystal X-ray analysis was performed on the resulting crystals, providing molecular level information on the phase transformation. Distinctive structural changes were observed, including a transition from

3

CH/π to aurophilic intermolecular interactions.[23–25] The phase change was accompanied by a drastic luminescence color change caused by the switching of the intermolecular interactions. This color change allowed the progression of the phase change to be clearly visualized.

Results

Synthesis of 1 and its polymorph I_b. During the course of our studies on the luminescence mechanochromism of gold(I) complexes,[14] we synthesized **1** in high yield (89%) through the reaction of chloro(phenyl isocyanide)gold(I) with phenyllithium for 1 h at −78 °C (Figure 1a). Careful but rapid crystallization from a hexane/dichloromethane solution produced crystals of **1** in the I_b phase. Blue photoluminescence was observed from I_b crystals under UV irradiation with emission maxima at 460 and 490 nm [quantum yield $\Phi^{em} = 0.15$, lifetime: $\tau_1 = 1.47$ μs ($A_1 = 0.92$), $\tau_2 = 72.1$ μs ($A_1 = 0.08$), $\lambda_{ex} = 355$ nm] (Figure 1b, blue solid line; Figure 2a). The excitation spectrum of I_b displayed a peak at 315 nm (Figure 1b, blue dotted line). The crystal structure of I_b was determined by the XRD of a single crystal (Figure 2a–d; Supplementary Figure S1; Supplementary Tables S1 and 2). I_b was found to be triclinic (*P-1*, $a = 6.0214(5)$ Å, $b = 9.0729(8)$ Å, $c = 11.4498(10)$ Å, $\alpha = 102.159(7)°$, $\beta = 101.468(7)°$, $\gamma = 102.358(7)°$ at 123 K, $Z = 2$, $R_1 = 3.3\%$, $_wR_2 = 8.2\%$, GOF = 1.056, calculated density: 2.169 g/cm^3). X-ray analysis, elemental analysis, thermal gravimetric analysis (TGA) and ^{1}H NMR measurements of I_b indicated that there was no solvent inclusion in the crystals

(Supplementary Figures S2 and S3; Supplementary Table S3; Supplementary Notes S1). Each of the

molecules in I_b formed a herringbone-like structure with a head-to-tail arrangement of the phenyl

ligand on the gold atoms, and the isocyanide phenyl moiety twisted with a dihedral angle of 71.6°

(Figure 2b).[22] There were large distances (> 4.65 Å) between the gold atoms of adjacent molecules,

indicating the absence of aurophilic interactions, which typically possess Au···Au distances of less

than 3.5 Å in solid-state structures.[23,24] Time-dependent density functional theory (TDDFT)

calculations were performed based on the crystal structure of I_b, affording insight into its excitation

by metal-perturbed ligand-to-ligand charge transfer (LLCT) (Supplementary Figures S4–8;

Supplementary Tables S4–S6).

Solution-phase preparation of polymorph II_y. The slow crystallization of **1** from a

hexane/dichloromethane solution produced the polymorphic crystals II_y, which exhibited a

significantly different crystal structure compared with that of I_b. The II_y crystals exhibited a strong

yellow emission (λ_{max} = 571 nm) under UV irradiation (365 nm) (Figure 1b, red solid line and Figure

2e). A higher emission quantum yield [Φ^{em} = 0.43] and shorter emission lifetime [τ_1 = 0.17 μs (A_1 =

0.20), τ_2 = 0.65 μs (A_2 = 0.80), λ_{ex} = 355 nm] were observed compared with those for I_b. The

excitation spectrum of II_y displayed a peak at a longer wavelength (432 nm) than that of I_b (Figure

1b, red dotted line). The crystal structure of II_y was in the tetragonal system with a space group of

I-42d (Figure 2f–h, a = 13.4781(4) Å, c = 24.8079(8) Å at 123 K, Z = 16, R_1 = 2.5%, $_wR_2$ = 5.4%,

GOF = 1.093, calculated density: 2.224 g/cm^3, Supplementary Figure S9; Supplementary Tables S1

and S2). X-ray analysis, elemental analysis and ^{1}H NMR measurements of **II$_y$** indicated that there

was no solvent inclusion in the crystals (Supplementary Figure S2; Supplementary Table S3;

Supplementary Note 1). The molecules of **II$_y$** adopted a nearly flat conformation with a dihedral

angle between the isocyanide phenyl group and the gold-coordinated phenyl group of 3.1°. Oblique

head-to-tail dimers contained a short Au⋯Au distance of 3.177 Å, suggesting the presence of

significant aurophilic interactions.[23,24] Each dimer interacted with adjacent dimers through

isocyanide carbons separated by just 3.186 Å to form 1-D chain-like structures comprising dimer

units (Supplementary Figure S9). TDDFT calculations of a model structure based on the **II$_y$** crystals

indicated a metal–metal to ligand charge transfer characteristic that was facilitated by the short

Au⋯Au distance (Supplementary Figures S4, S10, S11; Supplementary Tables S4 and S7).[23,24]

Luminescent mechanochromism of I$_b$. The blue luminescent **I$_b$** displayed a significant

luminescence mechanochromism (Figure 3a).[14–17] The ball-milling of **I$_b$** for 3 min afforded the

powder **II$_{y(ground\ Ib)}$**, which was identical to crystalline **II$_y$** in terms of its photoluminescence and solid

state structure. Similar to **II$_y$**, **II$_{y(ground\ Ib)}$** exhibited a luminescence maximum at 567 nm, an emission

quantum yield of 0.38, and emission lifetimes of τ_1 = 0.27 μs (A$_1$ = 0.34) and τ_2 = 0.68 μs (A$_1$ =

0.66) at an excitation wavelength of 355 nm (Figure 2b, black solid line) with an excitation peak at

400 nm (Figure 2b, black dotted line). The powder XRD pattern of the ball-milled sample ($II_{y(ground}$

$_{Ib)}$, Figure 1c, black solid line) matched the simulated diffraction pattern based on the single crystal

X-ray analysis of II_y (Figure 1c, red solid line), and no trace of I_b was found in the ball-milled

sample (Figure 1c, blue solid line). These results indicate that the ball-milling process induced direct

crystal-to-crystal transformation of I_b to II_y.

SCSC transformation. The ball-milling described above involves a considerable mechanical

stimulus; we next conducted the mechanical triggering experiment with a much smaller stimulus. A

small pit was formed on the surface of an I_b crystal using a needle under atmospheric conditions

(Figure 3b). A yellow luminescent spot was initially observed at the location of the small pit.

Subsequently, the domain exhibiting yellow emission gradually increased to nearly the entire crystal

after 9 h at room temperature. The transformation could also be triggered by contacting a seed crystal

of II_y with a crystal of I_b (Figure 3c). The luminescent color change initiated at the point of contact

and extended to the entire crystal after 15 h. This color change propagated through the contacting

surfaces of adjacent crystals; eventually, the blue luminescent crystals that were in contact with

neighboring yellow luminescent crystals became yellow, maintaining their transparency (Figure 3d

and e, Supplementary Figure 12). This solid-seeding phase change represents a self-replicating

7

progression of phase transformation. It should be noted that the rate of conversion was highly variable: some crystals changed rapidly, whereas others were slower.

Single crystal X-ray analysis was performed after the mechanical stimulus-triggered SCSC transformation of I_b. A yellow luminescent crystal was prepared by the mechanical pricking of a small region of one I_b crystal. After the initial contact area was removed to avoid affecting the quality of the XRD data, the yellow emissive crystal (denoted II_{yscsc}) was subjected to single crystal X-ray analysis. The crystal structure of II_{yscsc} obtained *via* SCSC was identical to that of II_y crystallized from the solution phase (Figure 3f; Supplementary Figure S13; Supplementary Tables S1 and S2; II_{yscsc}: $a = 13.4075(19)$ Å, $c = 24.9673(19)$ Å at 123 K, $Z = 16$, $R_1 = 8.8\%$, $_wR_2 = 21.7\%$, GOF = 1.316, calculated density: 2.233 g/cm^3).

Discussion.

The mechanical- or solid seeding-triggered phase change described in this study occurred at room temperature, whereas a thermal phase transformation of I_b to II_y required elevated temperatures of 64.5–74.9 °C (Supplementary Figure S3). No reverse phase change was observed when the sample was cooled. The I_b crystal could only be regenerated by the dissolution and recrystallization of II_y.

The thermal analysis suggested that I_b was a metastable, kinetically isolated form of **1**, and II_y was the thermodynamically favored form (Supplementary Figure S14). The thermodynamic analysis and the sample crystallization process revealed that **1** is a good example of the Ostwald rule: the less stable polymorphs (I_b) crystallize first, and the more stable polymorphs (II_y) form later.[1–3] In some reports, mechanical pricking or the presence of defects can accelerate the phase change near the thermal phase change temperature, resulting in polycrystalline formation.[1,3,13,25] However, the phase transformation of I_b occurred at much lower temperatures, suggesting that the transformation observed in our study was triggered purely by mechanical stimulation. To our knowledge, this is the first clear example of the mechanical- or solid seeding-triggered SCSC transformation of molecular crystals. In addition, the emergence of metallophilic interactions after the SCSC transformation of mother crystals lacking metallophilic interactions has not been reported previously.

The solid-state structures of I_b and II_y varied greatly (triclinic *P-1* and tetragonal *I-42d*) (See Supplementary Figure S15). Thus, the significant structural transformation cannot be explained by a simple conformational change or molecular reorientation. The phase change may proceed by a similar mechanism to the epitaxial mechanism proposed for the thermal phase transformation.[3,25] A small portion of the II_y daughter phase forms initially in the I_b mother phase through mechanical stress or contact with a seed crystal of II_y (Figure 4a and b). The molecules in the thermodynamically

unstable I_b phase diffuse across the narrow gap between phases I_b and II_y and rearrange to the II_y

phase through the formation of intermolecular aurophilic interactions (Figure 4c and d)

This phase transformation resembles dominoes, in that a mechanical stimulus (pushing) triggers

a state change in the entire assembly. The self-replicative nature of this molecular domino may

provide a new way to control nano or molecular structures through macroscopic mechanical

stimulation. The domino-like amplification of the optical response to the small mechanical stimulus

(from the small pit to the entire crystal) can be applied to the highly sensitive detection of

mechanical stimulation.

Methods

Synthesis of 1. Chloro(phenyl isocyanide)gold(I) was prepared from chloro(tetrahydrothiophene)gold(I) and phenyl isocyanide using a method similar to that reported previously.[26] Chloro(phenyl isocyanide)gold(I) (100.7 mg, 0.30 mmol) and a magnetic stir bar were placed in a vial and sealed with a rubber septum. After the reaction vial was connected to a vacuum manifold through a needle, it was evacuated and then back filled with nitrogen. Dry THF (0.44 mL) was added *via* a syringe to dissolve the chloro(phenyl isocyanide)gold(I). A butyl ether solution of phenyllithium (0.164 mL, 1.83 M, 0.30 mmol) was added at −78 ºC under stirring. After 30 min, the reaction was quenched by the addition of a saturated aqueous solution of NH_4Cl (2 mL), extracted three times with CH_2Cl_2, washed with brine and then dried over $MgSO_4$. After filtration, the volatiles were removed under reduced pressure. Crude phenyl(phenyl isocyanide)gold(I) (**1**) was obtained as a pale purple solid (106.7 mg, 89%). The yield was determined by ^{1}H NMR spectroscopy using $Cl_2CHCHCl_2$ as an internal standard. **1** was recrystallized from CH_2Cl_2/hexane after filtration to remove an insoluble purple solid. **1** was fairly stable in air at room temperature, but readily decomposed at elevated temperatures (>80 °C), with metal deposition occurring on its surface. In solution, **1** remained intact in the dark for a short period (< 1 h) but readily decomposed under light. The data for ^{1}H and ^{13}C NMR and HRMS were included as Supplementary Information.

11

Crystal and Powder Sample Preparation (I_b, II_y). Typical preparation procedures are as follows. On the surface of a solution of **1** (prepared from I_b or II_y, 20 mg) in CH_2Cl_2 (1.0 mL)/hexane (2.0 mL) in a small glass vial, a stream of nitrogen gas was flowed through a needle connected to a nitrogen line for a few minutes to produce crystals of I_b. II_y crystals were obtained by the slow crystallization (typically 10 h) of a solution of **1** in CH_2Cl_2/hexane placed in a refrigerator. The ground sample of $II_{y(ground\ Ib)}$ was prepared with a ball mill (Taitec Bead Crusher μT-01, Koshigaya, Saitama, Japan). Typically, I_b (50 mg) was treated in a micro tube ($\phi13 \times 49$ mm) with a screw cap at a shaking speed of 4600 r/min for 3 min (60 s three times) using a stainless bead (1/8 inch).

Single Crystal and Powder X-ray Analysis. Measurements for I_b, II_y, and II_{yscsc} were made on a Rigaku R-AXIS RAPID diffractometer using graphite monochromatic Mo-K$_\alpha$ radiation. The diffraction data were collected at −150 °C. The structure was solved by direct methods and expanded using Fourier techniques. Non-hydrogen atoms were refined anisotropically. Hydrogen atoms were refined using the riding model. All calculations were performed using the CrystalStructure crystallographic software package, except for refinement, which was performed using SHELXL-97. The powder diffraction data for $II_{y(ground\ Ib)}$ were recorded at room temperature on a Rigaku SmartLab diffractometer with Cu-K$_\alpha$ radiation and a D/teX Ultra detector covering 5–50° (2θ). The diffraction data were collected at 20 °C. The powder simulation patterns for I_b and II_y were

generated from the single crystal X-ray structures collected at 20 °C. The powder patterns for $\mathbf{I_b}$ and

$\mathbf{II_y}$ displayed in Figure 1b were generated using Mercury 3.0.

Supplementary Note 1. Qualitative Analysis of Crystals.

Elemental Analysis: Values of the elemental analysis for $\mathbf{I_b}$, $\mathbf{II_y}$, $\mathbf{II_{y(ground\ Ib)}}$, and $\mathbf{II_{yscsc}}$ prepared by mechanical stimulation and crystal seeding methods (Table S2, entries 1–5) were consistent with the calculated values for **1**. A deviation in the percentage of carbon in the $\mathbf{II_y}$ prepared by heating $\mathbf{I_b}$ was observed (entry 6, Calcd: 41.40; Obs: 40.96), representing the partial chemical decomposition of **1**. This partial decomposition was also observed with a hot-stage microscope as a black precipitate of metallic gold. This demonstrates the high compound purity and the absence of any solvents in $\mathbf{I_b}$ and $\mathbf{II_y}$ crystals.

NMR analysis of $\mathbf{I_b}$ and $\mathbf{II_y}$: NMR measurements of $CDCl_3$ solutions of $\mathbf{I_b}$ and $\mathbf{II_y}$ crystals were conducted to confirm the sample purity and the absence of solvents (Figure S2). The crystals were completely dissolved in $CDCl_3$, and the NMR measurements were conducted using these solutions. Solvent levels higher than a 1% molar ratio are capable of being detected by the NMR measurement. However, no impurities and solvents were detected in these samples, indicating no solvent inclusion in either $\mathbf{I_b}$ or $\mathbf{II_y}$ crystals.

Single Crystal and Powder X-ray Analysis: The maximum peaks in the final differential maps for $\mathbf{I_b}$, $\mathbf{II_y}$, and $\mathbf{II_{yscsc}}$, (0.75 $e^-/Å^3$, 0.72 $e^-/Å^3$, 2.32 $e^-/Å^3$, respectively, Table S2) were below 0.075 Z_{max} $e^-/Å^3$ (for complex **1**, 5.925). This indicates that no residual electron density can be assigned to other molecules, such as solvent, present in the crystal.

TGA Analysis: The thermal gravimetric analysis (TGA) was performed under a nitrogen atmosphere under heating to 200 °C with a heating rate of 5 °C min^{-1} using a Bruker AXS TG-DTA 2010 (Figure S3b). The phase change from $\mathbf{I_b}$ to $\mathbf{II_y}$ was observed near 60–75 °C, although no significant mass loss or transition steps from $\mathbf{I_b}$ to $\mathbf{II_y}$ were observed. The partial decomposition of the complex began near 85 °C and was accompanied by mass loss. The mass loss ceased at 140 °C, with 52.3% of the original mass of the residue remaining. This residue corresponds to the Au composition of the complex (Au/ $C_{13}H_{10}AuN$ = 52.2%).

Supplementary Note 2. Thermal Analysis Using Differential Scanning Calorimetry (DSC) and Thermal Gravimetric Analysis (TGA).

The mechanical- or solid seeding-triggered phase change occurred at room temperature, but a thermal phase transformation was also observed at elevated temperatures using differential scanning calorimetry (DSC) analysis. Multiple exothermic peaks for the transition from I_b to II_y were observed at 64.5–74.9 °C upon heating at a rate of 10 °C/min, with a corresponding change in emission color from blue to yellow (Figure S3a). An endothermic peak was also recorded at 100.5 °C and was accompanied by the partial decomposition of the sample surface. The sample melted at 125.5 °C, corresponding to the melting point of II_y; at this temperature, he color of the sample also changed from pale yellow to black. No reverse phase change was observed when the sample was cooled. The thermal analysis suggested that I_b was a metastable, kinetically isolated form of **1** (Figure S15). This phase can transition to the thermodynamically favored form II_y by heating at 64.5–74.9 °C or by mechanical triggering at room temperature. The small exothermic peaks observed near 64.5–74.9 °C correspond to the energy release accompanying the phase change, as shown in Figure S13a.[2] The use of mechanical pricking to trigger the thermal phase transformation has also been reported. In this case, the phase change occurred near the temperature of the thermal phase change.[1–3] However, the phase transformation of I_b occurred at a much lower temperature than the thermal phase change, suggesting that this transformation was triggered purely by mechanical stimulation. To our knowledge, this is the first clear example of solid seeding-triggered SCSC transformation. In addition, the emergence of metallophilic interactions after the SCSC transformation of mother crystals lacking metallophilic interactions has not been reported previously.

Supplementary Note 3. DFT Calculations.

General Calculation Methods: All calculations were performed using the Gaussian 09W (revision C.01) program package.[29] In the DFT and TDDFT calculations, SDD with 19 valence electrons was used for gold atom and cc-pVDZ was used for all other atoms, where B3LYP functionals were employed.[30–32] Molecular orbitals were drawn by the GaussView 5.0 program. The fully optimized geometry for monomeric PhAu(CNPh) (**1**) in CHCl₃ was calculated using Tomasi's polarizable continuum model (PCM).[33] The geometry for the TDDFT calculation of the tetrameric structures of **1** in **I$_b$** and **II$_y$** were optimized using redundant coordinates of C, N, and Au, which were taken from the corresponding X-ray structures, in which the positions of the heavy atoms were fixed and H atoms were equilibrated.[34–37] The results are summarized in Tables S4–7 and Figures S4–11.

TDDFT calculation of monomeric 1 in CHCl₃: We tested various calculation methods, including CAM-B3LYP, M062X, and LC-BLYP; however, only B3LYP provided acceptable values for the excitation (Figure S5). We therefore employed the B3LYP method for the TDDFT calculations of **1** in the solution and solid states (**I$_b$** and **II$_y$**). The calculation results indicated that the lowest energy transition in solution corresponds to the highest occupied molecular orbital (HOMO)/lowest unoccupied molecular orbital (LUMO) transition, which arises due to ligand (phenyl on the gold atom) to ligand (isocyanide) charge transfer (LLCT, Figure S4, S6 and Table S5).

TDDFT calculation of the tetrameric model compound of I$_b$: The coordinates of the model structure were generated by the partial optimization of the hydrogen atoms because the accuracy of the position of hydrogen in single X-ray analysis is not reliable. The TDDFT calculations were conducted using this modified atom coordinate. The low-lying singlet excited states were computed from the π orbital of the phenyl ligand to the π* orbital of the isocyanide ligand (Figures S4, S7 and S8; Table S6). The calculated values for these LLCT transitions (325.77, 354.2, 356.48, and 387.12 nm) were consistent with the observed excitation peaks from 320 to 380 nm, with an edge at 400 nm (main text, Figure 1b, blue dotted line).

TDDFT calculation of the model tetrameric structure of II$_y$: The low energy excitation peak (432 nm) observed for **II$_y$** crystals corresponds to the highest occupied molecular orbital (HOMO)/lowest unoccupied molecular orbital (LUMO) transition mixed with the HOMO-1/LUMO+1 transition (408.65 nm) and can be attributed to the σ* (gold d_z) to isocyanide π* transition (metal–metal to ligand charge transfer, Figures S10, S11; Table S7). However, it is difficult to fully explain the emission mechanism using this TDDFT approach based on ground state structures. The aurophilic interactions in **II$_y$** crystals should increase the emission wavelength by destabilizing the occupied d_z orbitals of the gold atoms (Figures S4 and 11; Table S4). In addition, the crystal structure of **II$_y$** allows the gold d_z orbitals to contribute more to the excited states than in **I$_b$**, facilitating intersystem crossing from singlet to triplet excited states and phosphorescence from the lowest triplet excited state to the singlet ground state. The observation of a shorter emission lifetime and increased emission quantum yield compared to **I$_b$** is consistent with increased intersystem crossing.[38]

Supplementary Methods

1. Materials and Methods

Materials were obtained from commercial suppliers and purified by standard procedures unless otherwise noted. Solvents for synthesis were purchased from commercial suppliers, degassed *via* three freeze-pump-thaw cycles, and further dried over molecular sieves (4A). Solvents for recrystallization were purchased from commercial suppliers and used as received. NMR spectra were recorded on a JEOL JNM-ECX400P (Japan) spectrometer (^{1}H: 400 MHz and ^{13}C: 99.5 MHz). Tetramethylsilane (^{1}H) and CDCl$_3$ (^{31}C) were used as external standards. Mesitylene or 1,1,2,2-tetrachloroethane were used as an internal standard to determine the NMR yield. Absorption and emission spectra were recorded on Hitachi U-3300 and F-7000 spectrometers, respectively. The emission quantum yields (Φ^{em}) of the solid samples were recorded on an F-7000 spectrometer with an integrating sphere. Emission lifetime measurements were conducted using a streak camera (Hamamatsu Photonics, C4334) as a photo detector under excitation at 355 nm (Continuum Surelite-II, 355 nm, 6 ns pulse width). For the emission and absorption spectroscopy of a solution of the gold(I) complex, the sample solution was degassed by purging with a stream of nitrogen or argon gas for at least 30 min. Elemental analyses and low- and high-resolution mass spectra were recorded at the Center for Instrumental Analysis, Hokkaido University. Photographs were captured using Olympus BX51 and SZX7 microscopes with Olympus DP72, Nikon D5100 and RICOH CX1 digital cameras.

2. ^{1}H and ^{13}C NMR Data for Phenyl(phenyl isocyanide)gold(I) (1).

^{1}H NMR (400 MHz, CDCl$_3$): δ = 7.51–7.57 (m, 1H), 7.42–7.50 (m, 6H), 7.18 (t, J = 7.2 Hz, 2H), 7.04–7.10 (m, 1H); ^{13}C NMR (100 MHz, CDCl$_3$): δ = 162.6, 160 (m), 140.3, 131.1, 129.9, 127.4, 126.6, 126.1, 125 (m); HRMS (FAB$^+$): 377.0476 [(M)$^+$, 377.0479 (C$_{13}$H$_{10}$AuN)].
