Abstract

Inflammation resolution counterbalances excessive inflammation and restores tissue homeostasis after injury. Failure of resolution contributes to the pathology of numerous chronic inflammatory diseases. Resolution is mediated by endogenous specialized proresolving mediators (SPMs), which are derived from long-chain fatty acids by lipoxygenase (LOX) enzymes. 5-LOX plays a critical role in the biosynthesis of two classes of SPMs, lipoxins and resolvins. Cytoplasmic localization of the nonphosphorylated form of 5-LOX is essential for SPM biosynthesis, whereas nuclear localization of phosphorylated 5-LOX promotes proinflammatory leukotriene production. We previously showed that MerTK, an efferocytosis receptor on macrophages, promotes SPM biosynthesis by increasing the abundance of nonphosphorylated, cytoplasmic 5-LOX. Here, we found that activation of MerTK in human macrophages led to ERK-mediated expression of the gene encoding sarcoplasmic/endoplasmic reticulum calcium ATPase 2 (SERCA2), which decreased the cytosolic Ca²⁺ concentration and suppressed the activity of calcium/calmodulin-dependent protein kinase II (CaMKII). This in turn reduced the activities of the mitogen-activated protein kinase (MAPK) p38 and the kinase MK2, resulting in the increased abundance of the nonphosphorylated, cytoplasmic form of 5-LOX and enhanced SPM biosynthesis. In a zymosan-

Data and materials availability: All data needed to evaluate the conclusions of this study are available in the paper or the supplementary materials.

induced peritonitis model, an inflammatory setting in which macrophage MerTK activation promotes resolution, inhibition of ERK activation delayed resolution, which was characterized by an increased number of neutrophils and decreased amounts of SPMs in tissue exudates. These findings contribute to our understanding of how MerTK signaling induces 5-LOX-derived SPM biosynthesis and suggest a therapeutic strategy to boost inflammation resolution in settings where defective resolution promotes disease progression.

Summary

One-sentence summary: Signaling by the receptor MerTK in macrophages promotes ERK activation and the resolution of inflammation.

INTRODUCTION

Timely resolution responses after acute inflammation are essential for tissue homeostasis (1, 2), and impaired resolution is the underlying cause of various chronic inflammatory diseases, including cardiovascular disease, inflammatory bowel disease, multiple sclerosis, arthritis, and asthma (3–7). Inflammation resolution is an active, highly coordinated process that is controlled by various endogenous specialized pro-resolving mediators (SPMs), such as lipoxins, resolvins, protectins, and maresins (1, 8, 9). SPMs counterbalance pro-inflammatory mediators during acute inflammation and trigger resolution by blocking neutrophil infiltration, enhancing the clearance of dead cells (efferocytosis), and repairing tissue damage without compromising host defense (1, 10).

SPMs are synthesized by lipoxygenase (LOX) enzymes from long-chain fatty acids, such as arachidonic acid (AA), which is released from phospholipids by the action of cytosolic phospholipase A₂; docosahexaenoic acid (DHA); and eicosapentaenoic acid (EPA) (11). We and others have shown that the intracellular localization of 5-LOX determines whether it stimulates the production of proinflammatory leukotrienes or pro-resolving lipoxins. Nuclear 5-LOX, because of its proximity to leukotriene A₄ (LTA₄) hydrolase, leads to the conversion of AA to leukotrienes (LTB₄) in macrophages (12–14). In contrast, cytoplasmic 5-LOX, because of its proximity to 12/15-LOX, which is the murine ortholog of human 15-LOX and has both 12-LOX and 15-LOX activities (15–17), promotes the conversion of AA to lipoxins (LXA₄) or DHA to resolvins (RvD1) (14). The nuclear localization of 5-LOX is mediated by its phosphorylation at Ser²⁷¹ by mitogen-activated protein kinase (MAPK)-activated protein kinase 2 (MK2), which is downstream of the MAPK p38 (13, 18). Previous work showed that a p38-MK2 pathway is activated by cytosolic Ca²⁺-dependent calcium/calmodulin-dependent kinase II (CaMKII) (14, 19,20), and we showed previously that Ca²⁺-mediated CaMKII activation in macrophages increases the abundance of pro-inflammatory LTB₄ and decreases the amount of pro-resolving LXA₄ (14). However, the upstream regulators of CaMKII in this 5-LOX-derived SPM biosynthesis pathway remain unknown.

MerTK, a member of the Tyro-Axl-MerTK (TAM) family of receptor tyrosine kinases, is a macrophage receptor that mediates the binding and phagocytosis of apoptotic cells, a process known as efferocytosis. MerTK interacts with apoptotic cells through the bridging molecules Gas6 or protein S, which bind to MerTK on macrophages and to externalized

phosphatidylserine on apoptotic cells (21, 22). In addition to mediating efferocytosis, engagement of MerTK by apoptotic cells, Gas6, or protein S triggers two integrated but biochemically distinct responses, anti-inflammation and pro-resolution. Loss of these responses by genetic targeting of MerTK in mice can lead to chronic diseases of inflammation and impaired resolution, notably a lupus-like disease in older mice and atherosclerosis in hypercholesterolemic mice (23–26). The anti-inflammatory response involves a pathway that leads to the suppression of nuclear factor κ B (NF- κ B)-mediated signaling (27, 28). Evidence for a distinct pro-resolution response was revealed by studies using both cultured macrophages and various in vivo models (29, 30). For example, we demonstrated that MerTK signaling in macrophages and in mouse models of sterile peritonitis and ischemiareperfusion injury promotes SPM biosynthesis and enhances resolution by decreasing the amount of 5-LOX phosphorylated at Ser²⁷¹ (p-Ser²⁷¹-5-LOX) and increasing the abundance of cytoplasmic 5-LOX (30). Moreover, the ectodomain of MerTK can be cleaved by the protease ADAM metallopeptidase domain 17 (ADAM17), and in mice harboring a genetically engineered form of MerTK that is cleavage-resistant (*Mertk^{CR}*), SPM biosynthesis and inflammation resolution are enhanced, and atherosclerosis progression is suppressed (26, 30).

The objective of this study was to address a critical gap in this field, namely, the mechanism by which MerTK activation triggers resolution signaling in macrophages. More specifically, we sought to understand how engagement of MerTK increases the abundance of non-phosphorylated, cytoplasmic 5-LOX and the subsequent biosynthesis of LXA₄ and RvD1. We showed that the Gas6-MerTK pathway suppressed the aforementioned Ca²⁺-CaMKII-p38-MK2-phospho-5-LOX signaling pathway by decreasing the concentration of cytosolic Ca²⁺. Cytosolic Ca²⁺ abundance was decreased through the MerTK-mediated activation of the MAPK extracellular signal-regulated kinase (ERK), which in turn stimulated the activity of SERCA, the calcium ATPase that pumps cytoplasmic Ca²⁺ back into the endoplasmic reticulum.

RESULTS

Gas6, through MerTK, suppresses the phosphorylation of CaMKII, p38, MK2, and 5-LOX and increases the ratio of lipoxins to leukotrienes in human monocyte-derived macrophages

RvD1 increases the abundance of nonphosphorylated cytoplasmic 5-LOX and the production of LXA₄ in macrophages by suppressing the CaMKII-p38-MK2 cascade (14). Given that MerTK activation also affects 5-LOX and LXA₄ in a similar manner (30), we investigated the effect of MerTK activation on these three kinases. Human monocyte-derived macrophages (referred to as “human macrophages” throughout the study) were treated with *MERTK*-specific siRNA or scrambled control RNA and then incubated with conditioned medium from HEK 293 cells expressing the MerTK activator Gas6 or control conditioned medium, which was followed by analysis of the phosphorylated forms of the three kinases as a measure of their activation. Consistent with our previous findings from mouse macrophages (30), treatment of human macrophages with Gas6 increased the abundance of p-MerTK (Fig. 1A). As was the case with RvD1 in a previous study (30), Gas6 reduced the

abundances of p-CaMKII, p-p38, and p-MK2 in scrambled siRNA-treated macrophages, and, as we showed previously, Gas6 reduced the abundance of p-Ser271-5-LOX (Fig. 1A). The bands corresponding to the total and phosphorylated forms of MK2 and 5-LOX were at the correct molecular mass and were verified by demonstration of their reduction in intensity in siMK2- and siALOX5-treated cells, respectively (fig. S1A). These effects of Gas6 were not seen in MerTK-silenced macrophages (Fig. 1A), suggesting that Gas6 suppressed the phosphorylation of these kinases through its effect on MerTK. Note that even under control conditions, that is, with cells incubated with conditioned medium from mock-transfected HEK 293 cells, basal p-CaMKII abundance in MERTK siRNA-treated cells was modestly increased compared to that in scrambled siRNA-treated macrophages. This was likely due to the low amount of Gas6 in the control medium, because when cells were incubated in PBS instead of control medium, basal p-CaMKII abundance was not affected by MERTK siRNA (fig. S1B). Protein S, another ligand for TAM receptors that activates MerTK, but not Axl (31, 32), also suppressed the CaMKII-p38-MK2-5-LOX cascade (fig. S1C).

Consistent with our previous data (14, 30), Gas6 reduced the ratio of p-Ser271-5-LOX to total 5-LOX in a MerTK-dependent manner (Fig. 1A) and, accordingly, increased the amounts of immunoreactive lipoxin A4 (iLXA4) and resolvin D1 (iRvD1), as determined by ELISA measurements, in scrambled siRNA-treated macrophages but not in siMERTK-treated macrophages (Fig. 1B). Furthermore, as predicted by the decrease in p-Ser271-5-LOX abundance, Gas6 decreased the amount of arachidonic acid (AA)-dependent immunoreactive leukotriene B₄ (iLTB₄) in a MerTK-dependent manner (Fig. 1C). These data suggest that Gas6, through MerTK, suppresses a kinase cascade that phosphorylates 5-LOX and concomitantly increases lipoxins at the expense of leukotrienes in human macrophages.

Gas6 inactivates CaMKII by increasing SERCA2 abundance and reducing cytosolic Ca²⁺ concentrations

With respect to how Gas6-MerTK signaling might suppress CaMKII activity, we tested whether the pathway reduced the cytosolic concentration of Ca²⁺, which would in turn reduce CaMKII activity (33–35). Consistent with this possibility, we found that Gas6 decreased the fluorescence intensity of the Ca²⁺ indicator Fluo3-AM (36, 37) in a time-dependent manner in scrambled siRNA-treated macrophages, but not in siMERTK-treated macrophages (Fig. 2A). These flow cytometric data were confirmed by confocal imaging of the cells (fig. S1A). Furthermore, the cytosolic Ca²⁺ chelator BAPTA-AM mimicked the effect of Gas6 in terms of suppressing the phosphorylation of CaMKII, p38, MK2, and 5-LOX (fig. S2B). Note that the effects of Gas6 and BAPTA-AM were not additive, suggesting that they act through the same mechanism.

We considered the hypothesis that Gas6-MerTK signaling suppressed CaMKII activity by increasing the abundance of sarcoplasmic-endoplasmic calcium ATPase (SERCA), which transports cytosolic Ca²⁺ into the endoplasmic reticulum (38, 39). Indeed, Gas6 induced increases in the mRNA that encodes SERCA2, *ATP2A2*, and in SERCA2 protein in human macrophages in a MerTK-dependent manner (Fig. 2B). The Gla domain of Gas6, whose gamma carbons are posttranslationally carboxylated, was required for the induction of

ATP2A2 expression, because Gla-deleted Gas6 (Gla-less Gas6) (37) was unable to induce an increase in *ATP2A2* mRNA abundance (fig. S3A). Moreover, apoptotic cells increased *ATP2A2* expression in macrophages (fig. S3B), as did protein S (fig. S3C), a TAM ligand that activates MerTK but not Axl. As further evidence that Axl does not play a substantial role in this pathway, treatment of macrophages with siAXL did not suppress the ability of Gas6 to induce *ATP2A2* expression (fig. S3D). To further determine whether SERCA plays a role in the Gas6-mediated suppression of CaMKII activity, we treated macrophages with thapsigargin, a SERCA inhibitor (40, 41), and tested whether this treatment blocked Gas6-mediated suppression of the kinase pathway. As predicted, thapsigargin abolished the Gas6-mediated suppression of the phosphorylation of CaMKII, p38, MK2, and 5-LOX (Fig. 2C). Consistent with the proposed sequence of this pathway, we found that *ATP2A2* mRNA abundance was increased after 3 hours of Gas6 treatment, whereas p-5-LOX was not decreased in abundance until 5 hours after stimulation (fig. S3, E and F). Together, these data support the hypothesis that Gas6-MerTK signaling suppresses CaMKII phosphorylation, thereby affecting the downstream pathway, by inducing *ATP2A2* expression and reducing the cytosolic Ca²⁺ concentration.

Gas6-MerTK signaling induces *ATP2A2* mRNA and SERCA2 protein expression and the downstream kinase-5-LOX pathway by activating ERK1/2

Gas6-MerTK signaling activates ERK in various cell types, including macrophages (42–45), and ERK1/2 induces *Atp2a2* expression in mouse macrophages (46). We therefore investigated whether Gas6-MerTK-induced *ATP2A2* expression was mediated through ERK1/2 activation. Gas6, protein S, and apoptotic cells increased the abundance of p-ERK in macrophages (Fig. 3A and fig. S4, A and B), and the Gas6-induced increase in p-ERK abundance was substantially reduced in MerTK-silenced macrophages compared to that in control cells (Fig. 3A). ERK activation was upstream of *ATP2A2* expression and the CaMKII-p38-MK2–5-LOX pathway, because both U0126, an inhibitor of the ERK-activating kinases MEK1/2 (47, 48), and ERK-specific siRNA (siERK) suppressed the Gas6-induced expression of *ATP2A2* mRNA and SERCA2 protein, as well as the phosphorylation of components of the CaMKII-p38-MK2–5-LOX cascade (Fig. 3, B and C and fig. S4, C and D). Consistent with these data, U0126 blocked the ability of Gas6 to increase the abundance of iLXA₄ and to decrease that of iLTB₄ (Fig. 3D).

MerTK signaling in other scenarios is dependent on tyrosines in its cytoplasmic tail (49, 50). We therefore investigated whether specific tyrosines in MerTK were required for ERK1/2 activation and the suppression of CaMKII phosphorylation. We took advantage of chimeric constructs in which the cytoplasmic tail of wild-type (WT) mouse MerTK, “kinase-deficient” (KD) MerTK, or various tyrosine-to-phenylalanine MerTK mutants are fused with the extracellular domain of CD8 (CDMer) (49, 51). When HEK 293 cells are transfected with plasmid encoding CDMer-WT, MerTK signaling is constitutively active, whereas signaling is not seen in cells transfected with plasmid encoding CDMer-KD (49, 51). We found that in WT CDMer-expressing cells, there was a marked increase in ERK1/2 phosphorylation compared with that in mock-transfected or CDMer-KD-expressing cells (Fig. 4A). Furthermore, cells expressing CDMer with mutations at Tyr⁸⁶⁷ and Tyr⁹²⁴ showed very little ERK1/2 phosphorylation, whereas ERK1/2 phosphorylation was normal in cells

expressing CDMer with a mutation in Tyr⁸²⁵ (Fig. 4A). We used flow cytometry to detect cell-surface CD8 and found equivalent expression of the WT and mutant receptors (fig. S5).

To test the role of Tyr⁸⁶⁷, we used retroviruses encoding human WT MerTK or the Y872F mutant MerTK mutant (Tyr⁸⁷² in human MerTK is equivalent to Tyr⁸⁶⁷ in mouse MerTK) to transduce macrophages lacking endogenous MerTK (macrophages from *Mertk*^{-/-} mice). Transduced macrophages expressing WT MerTK recapitulated the Gas6-induced increase in p-ERK1/2 abundance and decrease in p-CaMKII abundance, and, consistent with the data from experiments with CDMer-expressing HEK 293 cells, these effects of Gas6 were abrogated in macrophages expressing the Y872F mutant MerTK (Fig. 4B). These changes in the abundances of p-ERK1/2 and p-CaMKII were verified by flow cytometry (fig. S6A). Flow cytometry also showed that WT and Y872F MerTK were similarly abundant on the cell surface, indicating similar transfection efficiencies of the two constructs, and that Gas6 induced the phosphorylation of WT but not Y872F MerTK (fig. S6B). These data, when considered together with the data from experiments using U0126 and siERK, show that the ability of Gas6 to activate the SERCA-CaMKII-5-LOX pathway depends on ERK1/2 activation through a mechanism requiring specific tyrosine residues in the cytoplasmic tail of MerTK.

MEK inhibition delays inflammation resolution in zymosan-induced peritonitis

To determine whether the MEK-ERK pathway was required for resolution of inflammation in a model in which resolution is dependent on MerTK, we turned to zymosan-induced peritonitis (30). WT mice were injected intraperitoneally with zymosan in the absence or presence of U0126, and then the number of exudate neutrophils was measured over time to follow the inflammation and resolution stages. The number of neutrophils peaked at 12 hours (T_{max}) and then declined in both groups of mice, but the decline was slower in the U0126-treated mice: the time to a 50% reduction in the peak value (T_{50}) was ~21 hours in vehicle (DMSO)-treated mice as compared to ~29 hours in the U0126-treated mice, yielding resolution intervals ($R_i = T_{50} - T_{max}$) of 9 and 17 hours, respectively (Fig. 5A). These data are consistent with notion that MEK1/2 inhibition delays inflammation resolution.

In the next set of experiments, we injected the mice with U0126 during the period when resolving macrophages accumulate in the peritoneum (64 hours after injection with zymosan) (52, 53) and then conducted our assays 8 hours later. We also compared WT and *Mertk*^{-/-} mice in this experiment to determine whether MerTK and MEK-ERK inhibition acted in the same pathway to stimulate resolution. As predicted from the earlier data (Fig. 5A), the number of neutrophils was greater in the U0126-treated WT mice (Fig. 5B), indicating impaired resolution (14, 30). As reported previously (30), loss of MerTK also resulted in impaired resolution, and the effects of U0126 and MerTK deletion were not additive (Fig. 5B, 2nd pair of bars). The amount of p-CaMKII in peritoneal macrophages from zymosan-treated WT mice was also increased by U0126 and MerTK deletion in a nonadditive manner (Fig 5C), and the amount of pro-resolving iLXA₄ in these cells was decreased by both U0126 and MerTK deletion, also in a non-additive manner (Fig 5D). These data suggest that the MerTK-ERK-CaMKII-lipoxin pathway functions to resolve inflammation in vivo (fig. S7).

DISCUSSION

The data herein reveal a signaling pathway in human macrophages that links MerTK activation with the suppression of CaMKII activity, LXA₄ and RvD1 synthesis, and the resolution of inflammation. A key question is how MerTK becomes activated in vivo to dampen inflammation and promote resolution. Likely candidates include apoptotic cells and Gas6, both of which increase in abundance with inflammation (54, 55). Other MerTK ligands that might be involved include protein S, Tubby, tubby-like protein 1 (Tulp1), and galectin-3 (56). However, the relative contribution of different MerTK activators in inflammation and resolution remains unknown and almost certainly varies in different physiologic and pathophysiologic settings. MerTK signaling also suppresses the transcriptional activity of NF-κB in response to lipopolysaccharide (LPS) (27, 50, 57, 58), suggesting that MerTK both suppresses inflammation and enhances resolution through separate signaling pathways and effector mechanisms. Furthermore, the NF-κB-suppressing action of MerTK, similar to its pro-resolution function described here, requires the presence of Tyr⁸⁶⁷ in its cytoplasmic tail (50).

A key mediator in the MerTK-induced resolution of inflammation is the suppression of CaMKII activity, which is also the case with RvD1-mediated resolution in macrophages (14). In this context, a study from our group showed that in fat-fed *Ldlr*^{-/-} mice, genetic targeting of *Camk2g* in myeloid cells, which encodes the major isoform of myeloid CaMKII, CaMKIIγ, improves efferocytosis, decreases necrosis, and increases fibrous cap thickness in advanced atherosclerotic lesions, suggesting an improved resolution response (59). Furthermore, myeloid cell-specific deletion of *Camk2g* led to an increase in MerTK cell surface abundance through a pathway involving induction of the *Mertk* inducer, liver X receptor α (LXRα) (59). These findings are suggestive of a positive feedback cycle in inflammation resolution and efferocytosis in which MerTK activation suppresses CaMKII activity, which then leads to increased MerTK abundance. Indeed, the improvements in atherosclerotic plaque endpoints seen in mice with myeloid cell-specific CaMKII deletion were very similar to those seen in *Ldlr*^{-/-} mice with genetically increased MerTK activity, and in that case we showed directly that the ratio of SPMs to leukotrienes in atherosclerotic lesions was increased (26). In another scenario relevant to resolution, mice lacking CaMKII in cardiomyocytes exhibit a blunted inflammatory response after myocardial infarction (60). As with deletion of MerTK, deletion of CaMKII may also directly suppress inflammation. For example, the inflammatory response in macrophages treated with LPS and other Toll-like receptor activators in vitro has been associated with CaMKII activation (61–63).

Activated receptor tyrosine kinases can recruit growth factor receptor binding protein 2 (Grb2) to their phosphorylated tyrosine residues, leading to the activation of a Ras-Raf-MEK-ERK1/2 cascade (64). Tyr⁸⁷² in human MerTK (which is equivalent to Tyr⁸⁶⁷ in murine MerTK) binds to Grb2 and initiates cell survival signaling (51, 65). Consistent with this finding, we found that Tyr⁸⁷² was required for Gas6-induced ERK activation and suppression of CaMKII activity. Note that ERK can trigger both inflammatory and anti-inflammatory responses (66–68). With regard to our findings, ERK cooperates with SPMs to promote resolution. For example, inhibition of ERK by a MEK1 inhibitor abolishes the RvE1-mediated phagocytosis of zymosan A by human macrophages (69). As another

example, annexin A1, a pro-resolving mediator, activates ERK and inhibits the interaction of neutrophils with the endothelium (70). Furthermore, ERK1/2 signaling is activated in macrophages in which apoptotic cells were recognized by the efferocytosis receptor LDL receptor-related protein 1 (LRP1), and ERK activation then facilitates internalization of the apoptotic cells by the macrophages (71). Thus, it is possible that LRP1-mediated efferocytosis also activates the resolution pathway described here and that ERK activation in MerTK-activated macrophages contributes to the internalization of apoptotic cells in addition to enhancing resolution. Finally, mouse macrophages that are resistant to the actions of insulin, which occurs in the setting of type 2 diabetes, show ERK-mediated suppression of *Atp2a2* mRNA and SERCA2 protein and depletion of endoplasmic reticulum Ca^{2+} , suggesting that ERK promotes cytoplasmic Ca^{2+} release into the cytoplasm by suppressing SERCA in this setting (46). These findings, when considered our findings and those in the aforementioned CaMKII-atherosclerosis study, suggest a possible mechanism linking insulin resistance and type 2 diabetes to accelerated atherosclerotic vascular disease.

In summary, we have elucidated a previously uncharacterized MerTK signaling pathway in macrophages that leads to an enhanced resolution response. In view of the role of impaired resolution in many critical chronic inflammatory diseases, the therapeutic potential of these findings warrants consideration. On the one hand, direct administration of resolving mediators is undergoing extensive pre-clinical testing for various inflammatory diseases, with early human trials in progress (72). However, the possibility of stimulating a natural pathway of resolving mediator synthesis is appealing. The challenges of leveraging the pathway described here for that purpose include identifying specific MerTK activators that do not have non-MerTK-mediated adverse effects (56), such as those that have been implicated in oncogenesis (73). In-depth study of MerTK signaling pathways in different in vivo settings will be needed to determine if and how these challenges can be overcome (74).

MATERIALS AND METHODS

Preparation of human monocyte-derived macrophages and mouse bone marrow-derived macrophages (BMDMs)

To generate human macrophages, monocytes were isolated from the buffy coats of de-identified healthy volunteers (New York Blood Center) as previously described (30). Briefly, buffy coats were gently layered onto Histopaque solution (Sigma) as 1:1 ratio (vol/vol) and centrifuged at 1,500 x g for 25 min. Leukocytes were removed from the middle layer, washed with RPMI medium, and then centrifuged at 1,500 x g for 5 minutes. This wash step was repeated once, and then the cell pellet was suspended in RPMI medium and plated into 12-well plates. After 3 to 4 hours, when monocytes were adherent, the medium was exchanged for RPMI containing 10% (vol/vol) FBS, 1% pen-strep, and 10 ng/ml recombinant human GM-CSF (PeproTech), and the cells were incubated for 7 to 10 days to allow macrophage differentiation. To generate mouse BMDMs, bone marrow cells were cultured in DMEM containing 10% (vol/vol) FBS, 1% pen-strep, and macrophage-colony stimulating factor, as described previously (14, 30).

siRNA treatment

Human macrophages were incubated in medium containing 50 nM ON-TARGETplus human MERTK siRNA, MK2 siRNA, ALOX5 siRNA, ERK siRNA, or scrambled siRNA (Dharmacon) and Lipofectamine RNAiMAX (Thermo Scientific). After 72 hours, the experiments were conducted as indicated in the figure legends.

Treatment of macrophages with Gas6 or protein S

Conditioned medium containing γ -carboxylated Gas6 was harvested from human Gas6-expressing HEK 293–6E cells incubated with 2 μ g/ml vitamin K, as described previously (30, 32). The concentration of Gas6 in the medium was 250 nM as determined by comparing the Gas6 signal from a Western blot, quantified by densitometry, with that of a standard curve generated through Western blotting and quantification of multiple concentrations of commercial recombinant human Gas6 (R&D Systems). Macrophages were washed with PBS three times, pre-incubated for 1 hour in serum-free DMEM, and then incubated in serum-free DMEM with a 1:25 dilution of conditioned medium, equivalent to 10 nM γ -carboxylated Gas6, or an equal volume of conditioned medium from non-transfected HEK293 cells, which is referred to in the figures as “control” (Con) at the indicated times. Alternatively, macrophages were treated with 100 nM protein S, which was purified from human plasma (Haematologic Technologies).

Western blotting

Cell extracts were resolved on 4 to 20% gradient SDS-polyacrylamide gels and transferred to 0.45- μ m nitrocellulose membranes. The membranes were blocked in Tris-buffered saline/0.1% Tween 20 (TBST) containing 5% (wt/vol) nonfat milk at room temperature for 1 hour and then incubated with the primary antibody in TBST containing 5% (wt/vol) nonfat milk or 5% (wt/vol) BSA at 4°C overnight. The membranes were then incubated with the appropriate secondary antibody coupled to horseradish peroxidase (HRP), and proteins were detected with the ECL Supersignal West Pico chemiluminescent substrate kit (Thermo Scientific). Antibodies used for Western blotting were as follows: anti-p-CaMKII (Thr²⁸⁶) (Novus); anti-CaMKII (Santa Cruz Biotechnology); anti-SERCA2, anti-p-ERK1/2 (Thr²⁰²/Tyr²⁰⁴), anti-p-5-LOX (Ser²⁷¹), anti-5-LOX, anti-p-MK2 (Thr³³⁴), anti-MK2, anti-p-p38 MAPK (Thr¹⁸⁰/Tyr¹⁸²), anti-p38 MAPK, and anti-HRP- β -actin (Cell Signaling Technologies); anti-p-MerTK (FabGennix, PMKT-140AP); and anti-MerTK (Abcam, ab52968).

SPM ELISA assays

Human macrophages in 12-well plates were incubated for 7 hours at 37°C with vehicle or 10 nM γ -carboxylated Gas6. The cell culture medium were then harvested for analysis by (i) the Neogen LXA₄ ELISA kit, which has the following cross-reactivities according to the manufacturer: 15-epi-LXA₄ (24%), 5(S),6(R)-DiHETE (5%), LXB₄ (1%), and 15-HETE (0.1%); (ii) the Cayman LTB₄ ELISA kit, which has cross-reactivities to 5, 6-DiHETE (0.07%), 5(R)-HETE (3.7%), 15(R)-HETE (0.98%), 15(S)-HETE (0.4%), 5(S)-HETE (6.6%), 20-hydroxy LTB₄ (2.7%), 6-*trans*-12-epi LTB₄ (0.31%), and 6-*trans* LTB₄ (0.11%); or (iii) the Cayman RvD1 ELISA kit, which has cross-reactivities to 5(S),6(R)-LXA₄ (20%),

17(R)-RvD1 (4.2%), and 10(S),17(S)-DiHdoHE (0.7%). We refer to these lipid mediators as iLXA₄, iLTB₄, and iRvD1, respectively, where “i” stands for “immunoreactive.” The data are reported as fold-change in abundance in the experimental group relative to that in the control group, which was set at 1.0. Similar analyses were conducted on peritoneal exudates for the zymosan experiments. In all cases, 50 µl of sample was assayed as per the manufacturer’s instructions.

Fluo3-AM loading

Human macrophages were loaded with 1.25 µM Fluo3-AM (Thermo Fisher) for 30 min at room temperature in loading buffer containing 150 mM NaCl, 5 mM KCl, 1 mM MgCl₂, 1 mM CaCl₂, 20 mM HEPES, 10 mM glucose, 1× PowerLoad (Thermo Fisher) to solubilize the Fluo3-AM dye, and 2.5 mM probenecid (Thermo Fisher) for dye retention. Fluo3-AM was then removed, and the cells were chased in loading buffer without PowerLoad and probenecid for 30 min at room temperature. Cytosolic Ca²⁺ was monitored by flow cytometry (FACSCanto II) or with a Nikon A1 confocal microscope.

Transfection of HEK-293T cells with plasmids expressing CDMer constructs

Retroviral expression vectors pLXSN expressing a chimeric receptor (CDMer) generated from the extracellular and transmembrane domains of human CD8 (amino acids 1 to 209) and the intracellular region (amino acids 521 to 994) of WT MerTK, K614M kinase-deficient (KD) MerTK, Y825F MerTK, Y867F MerTK, or Y924F MerTK were generated and used to transfect HEK 293T cells as described previously (49, 50).

Generation of human WT and Y872F *MERTK* pMSCV vectors for transduction into *Mertk*^{-/-} mouse macrophages

Human *MERTK* (NM_006343.2) was cloned into pMSCV-puro retroviral vector (Addgene) at the *XhoI* and *EcoRI* restriction sites (Genewiz). Tyr⁸⁷² of human *MERTK* was mutated to phenylalanine using the PCR-based Quikchange mutagenesis system (Stratagene). BOSC23 cells (5 × 10⁶ cells) were transfected with 1 µg of pMSCV-WT *Mertk* or pMSCV-Y872F *MERTK* together with 1 µg of pCL-Eco (Addgene) and 2 µg of pMD2.G (Addgene) using 16 ml of LipoD293 transfection reagent (SigmaGen). Conditioned medium were collected 48 hours after transfection and filtered through 0.45-micron filters. The medium were then used to transduce BMDMs from *Mertk*^{-/-} mice.

Zymosan A-induced peritonitis

Eight- to ten-week-old C57BL/6J mice were injected intraperitoneally with 0.1 mg of zymosan A (Sigma) per mouse. Peritoneal exudates were collected by lavage with 3 ml of cold PBS after 72 hours. Peritoneal leukocytes and exudate fluids were separated by centrifuging at 500 × g for 10 min. Mice were randomly assigned to treatment groups. All procedures were conducted in accordance with the Columbia University Standing Committee on Animals guidelines for animal care.

Flow cytometric assays

For the zymosan-induced peritonitis experiments, peritoneal exudate cells harvested at the times indicated in the figure legend were washed in FACS staining buffer (PBS containing 3% [vol/vol] FBS). The cells were incubated for 5 min at 4°C with Fc block (BD Biosciences) and then labeled with Pacific Blue–Ly6G (clone 1A8, eBioscience) to detect polymorphonuclear neutrophils (PMNs). To detect p-CaMKII in exudate macrophages, cells were stained with PE-F4/80 (clone BM8, eBioscience) for 30 min at 4°C to stain macrophages, which was followed by fixation and permeabilization of the cells. Permeabilized cells were then incubated with rabbit anti-p-CaMKII for 1 hour at 4°C and then with Alexa Fluor 647–conjugated goat anti-rabbit secondary antibody for 30 min at 4°C. For the flow cytometric assay of p-ERK and p-CaMKII in WT MerTK-expressing vs. Y872F MerTK-expressing *Mertk*^{-/-} macrophages, the cells were first incubated with APC-MerTK (Clone #125518, R&D Systems) to label transduced macrophages. After fixation and permeabilization, the cells were incubated with rabbit anti-p-ERK or anti-p-CaMKII antibodies, which was followed by incubation with PE-conjugated anti-rabbit secondary antibody. The cells were suspended in FACS buffer and analyzed for the mean fluorescence intensity (MFI) of p-ERK and p-CaMKII in APC-MerTK⁺ cells gated using a FACSCanto II (BD Biosciences) flow cytometer and FlowJo software.

Apoptotic cell preparation and addition to macrophages

Jurkat cells were exposed to ultraviolet light at 254 nm for 5 min using a lamp from Ultra-Violet Products Ltd and then incubated in a 37°C incubator with 5% CO₂ for 3 hours to induce apoptosis as previously described (75). Apoptotic Jurkat cells (ACs) were added to human macrophages in the presence of FBS-containing medium for the times indicated in the figure legend. ACs were then removed by rinsing five times with cold PBS, and the abundances of *ATP2A2* mRNA or p-ERK and total ERK were assayed as indicated in the figure legends.

Statistical analysis

All results are shown as means ± SEM. Two-tailed *P* values were calculated using a Student's *t* test for just two groups. With more than two groups, one-way ANOVA with post-hoc *t* tests were used for group comparisons. One-way ANOVA was also used with two factors, for example, genotype and treatment, in order to allow for interaction. For example, in Fig. 5, U0126 effects could be different between WT and *Mertk*^{-/-}

Editor's summary:**Promoting resolution**

The active and coordinated process of inflammation resolution is critical for tissue homeostasis, and defective resolution is associated with chronic inflammatory diseases. Specialized proresolving mediators (SPMs) are fatty acid derivatives that counteract the effects of proinflammatory factors, triggering resolution and tissue repair. SPM biosynthesis depends on the cytosolic localization of the nonphosphorylated form of the lipoxygenase 5-LOX, whereas the nuclear translocation of phosphorylated 5-LOX results in inflammatory leukotriene production. Cai *et al.* showed that signaling by the efferocytosis receptor MerTK in macrophages activated an ERK-dependent pathway that inhibited the phosphorylation of 5-LOX, thus promoting SPM production. Inhibition of ERK activation in a mouse model of peritonitis delayed resolution, suggesting that the MerTK-ERK pathway might be therapeutically manipulated to promote inflammation resolution.

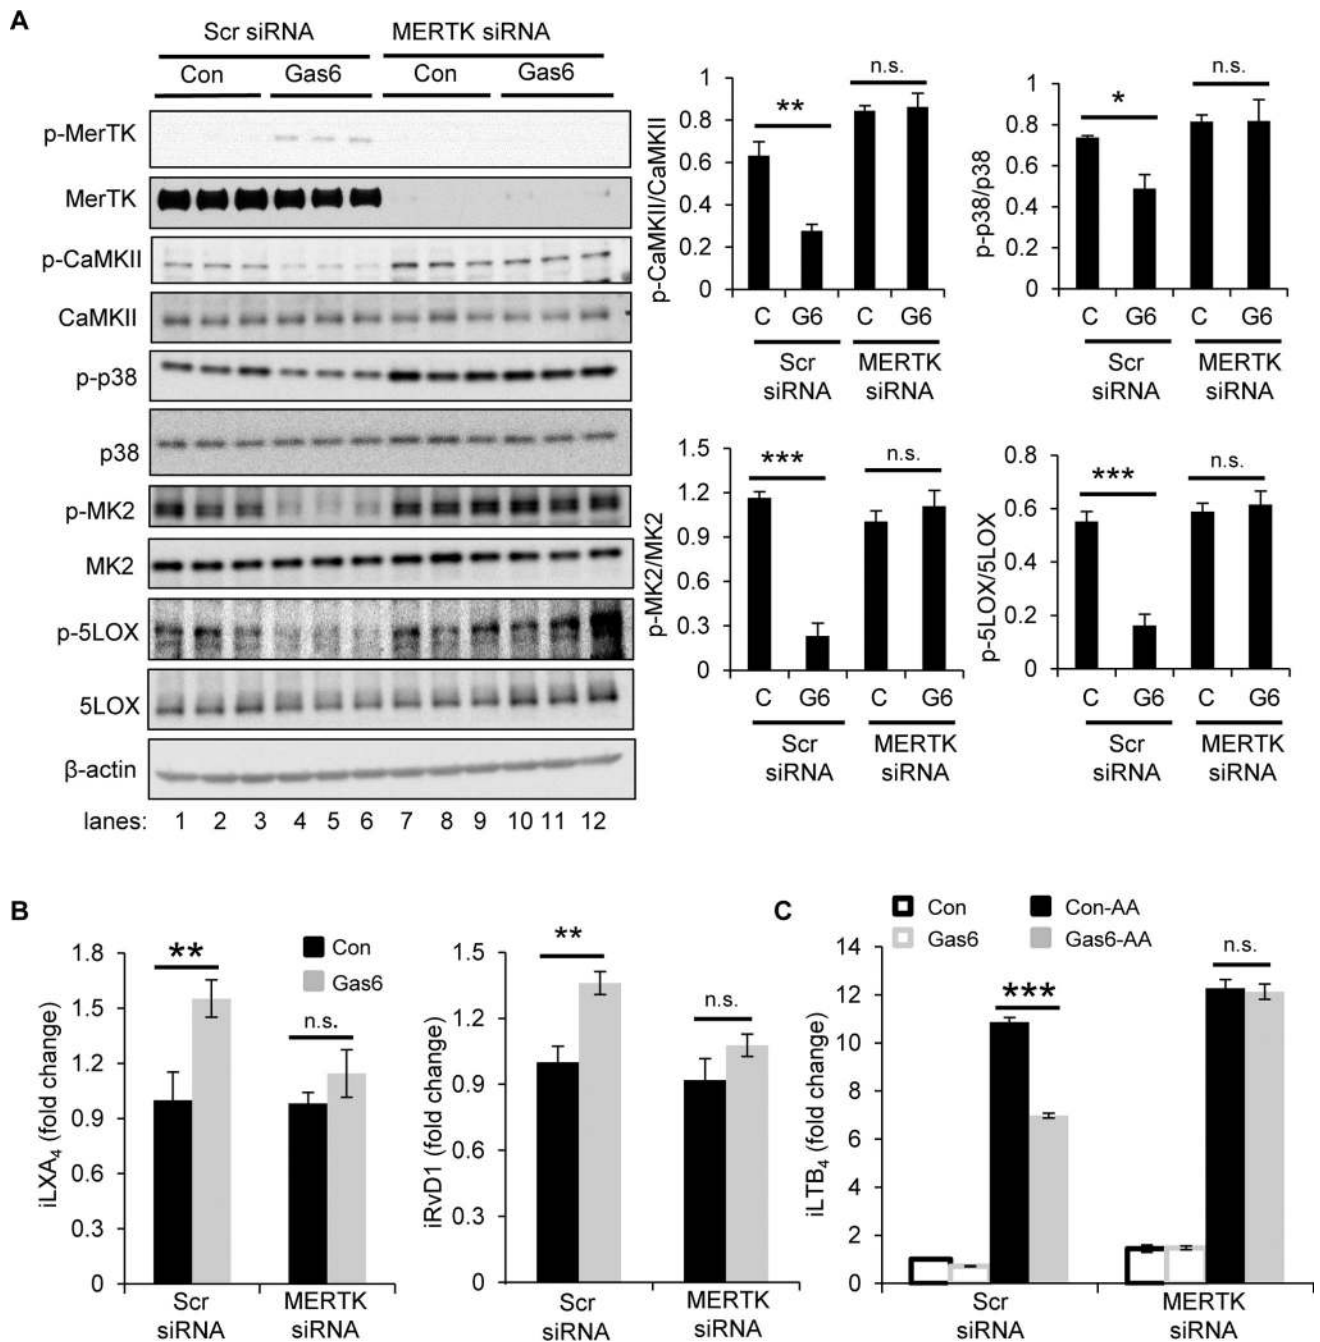

Fig. 1. MerTK is required for Gas6-mediated suppression of the CaMKII-p38-MK2-5-LOX-SPM signaling pathway in human macrophages.

(A to C) Human monocyte-derived macrophages were transfected with either scrambled siRNA or MERTK-specific siRNA. After 72 hours, the cells were incubated for 7 hours with control medium (Con) or 10 nM Gas6-conditioned medium. (A) Left: The macrophages were lysed and analyzed by Western blotting with antibodies specific for phosphorylated (p-) and total MerTK, CaMKII, p38, MK2, and 5-LOX; P-actin served as the loading control. Blots show samples from three different donors. Right: Bar graphs show the ratio of the amounts of phosphorylated protein to total protein, which was quantified by

densitometry with ImageJ software. Data are means \pm SEM of three different donors. $*P < 0.05$, $**P < 0.01$, $***P < 0.001$ vs. control medium by one-way ANOVA with post-hoc t-tests for group comparisons; n.s., not significant. (B) Medium from the indicated macrophages was assayed by ELISA to detect iLXA₄ and iRvD1. (C) During the last hour of Gas6 treatment, macrophages were incubated with or without 10 pM AA to induce leukotriene production. The amount of iLTB₄ in the culture medium was then analyzed by ELISA. Data in (B) and (C) are means \pm SEM of three to six donors. $**P < 0.01$, $***P < 0.001$ vs. control medium by one-way ANOVA with post-hoc t-tests for group comparisons; n.s., not significant.

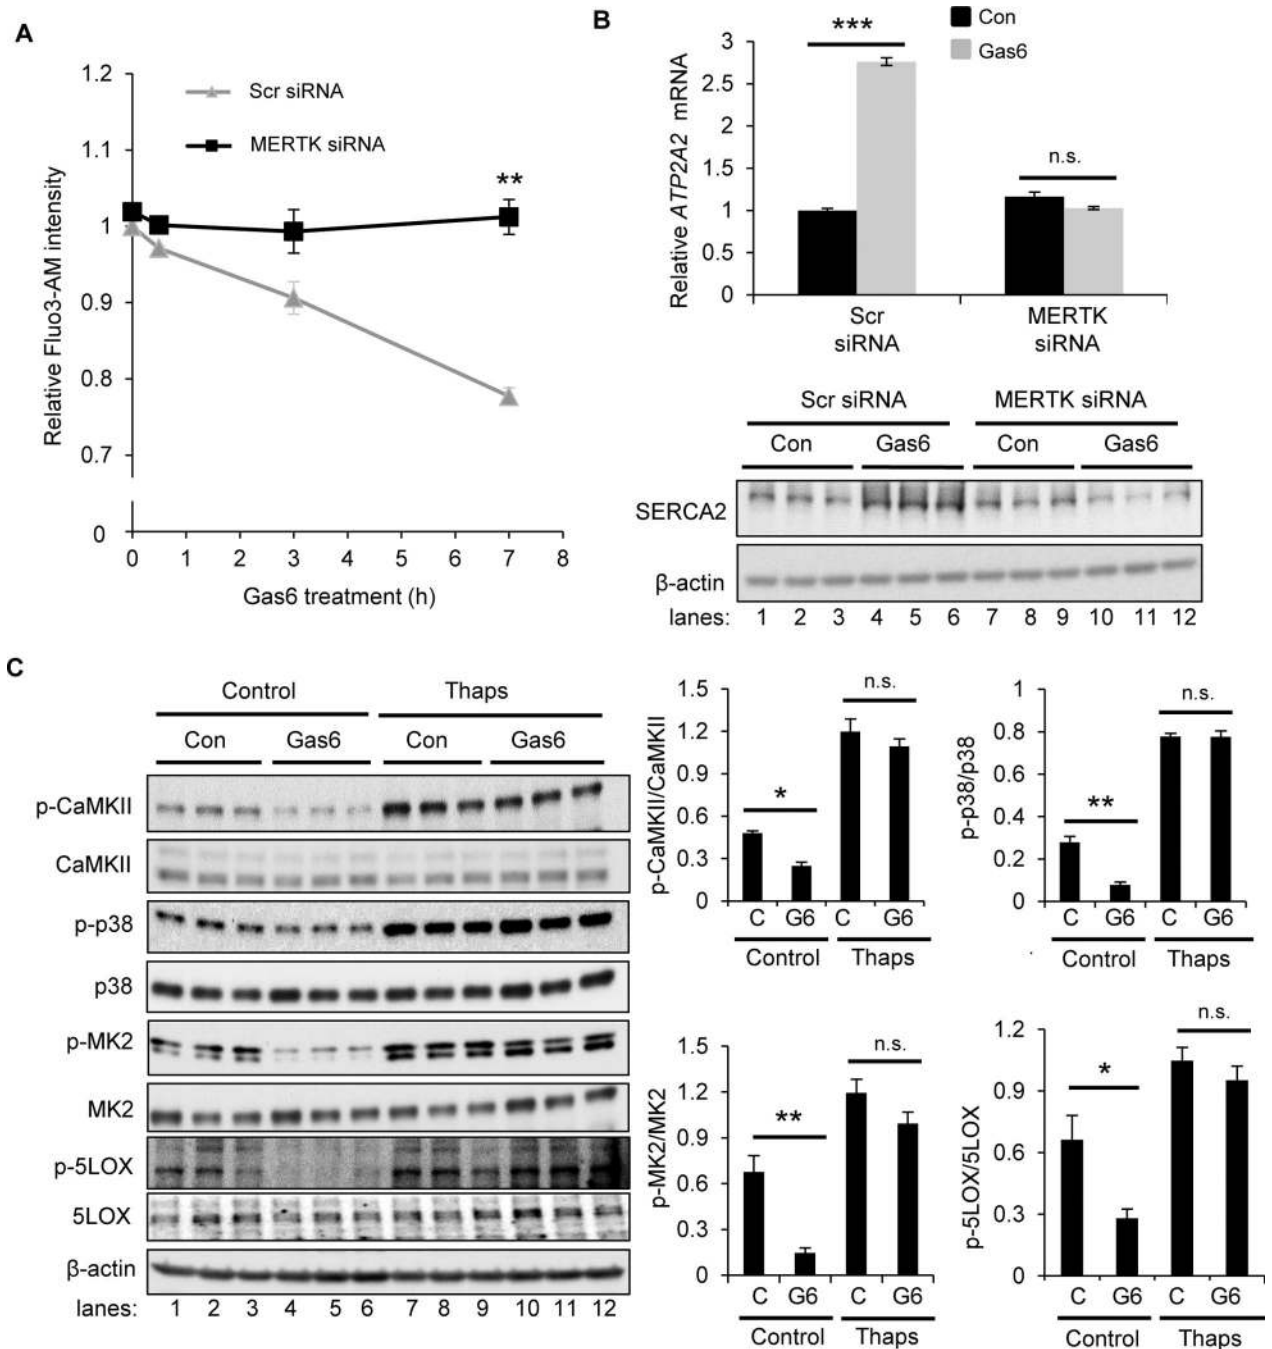

Fig. 2. Gas6 inactivates CaMKII by inducing the expression of *ATP2A2* mRNA and *SERCA2* protein and reducing the concentration of cytosolic Ca^{2+} .

(A) Human macrophages were transfected with scrambled siRNA or MERTK-specific siRNA and were incubated with control or Gas6-conditioned medium for the indicated times. The cells were then loaded with the Ca^{2+} probe Fluo3-AM, and the cytosolic Ca^{2+} concentration was determined by flow cytometry. Data are means \pm SEM of three different donors. $**P < 0.01$ vs. scrambled siRNA by unpaired *t*-test. (B) Macrophages transfected with scrambled RNA or MERTK siRNA were incubated with control or Gas6-conditioned

medium for 7 hours. The relative abundances of *ATP2A2* mRNA (top) and SERCA2 protein (bottom) were assayed by real-time qPCR and Western blotting analysis, respectively. (C) Macrophages were pre-treated with 2 μ M thapsigargin (Thaps) for 5 min and then incubated with control or Gas6-conditioned medium for 7 hours. Left: Cells were lysed and analyzed by Western blotting with antibodies specific for phosphorylated (p-) and total CaMKII, p38, MK2, and 5-LOX; β -actin served as the loading control. Blots show samples from three different donors. Right: Bar graphs show the ratio of the amounts of phosphorylated protein to total protein, which was quantified by densitometry with ImageJ software. Data in the bar graphs in (B) and (C) are means \pm SEM of three different donors. * $P < 0.05$, ** $P < 0.01$, *** $P < 0.001$ vs. control medium by one-way ANOVA with post-hoc t-tests for group comparisons; n.s., not significant.

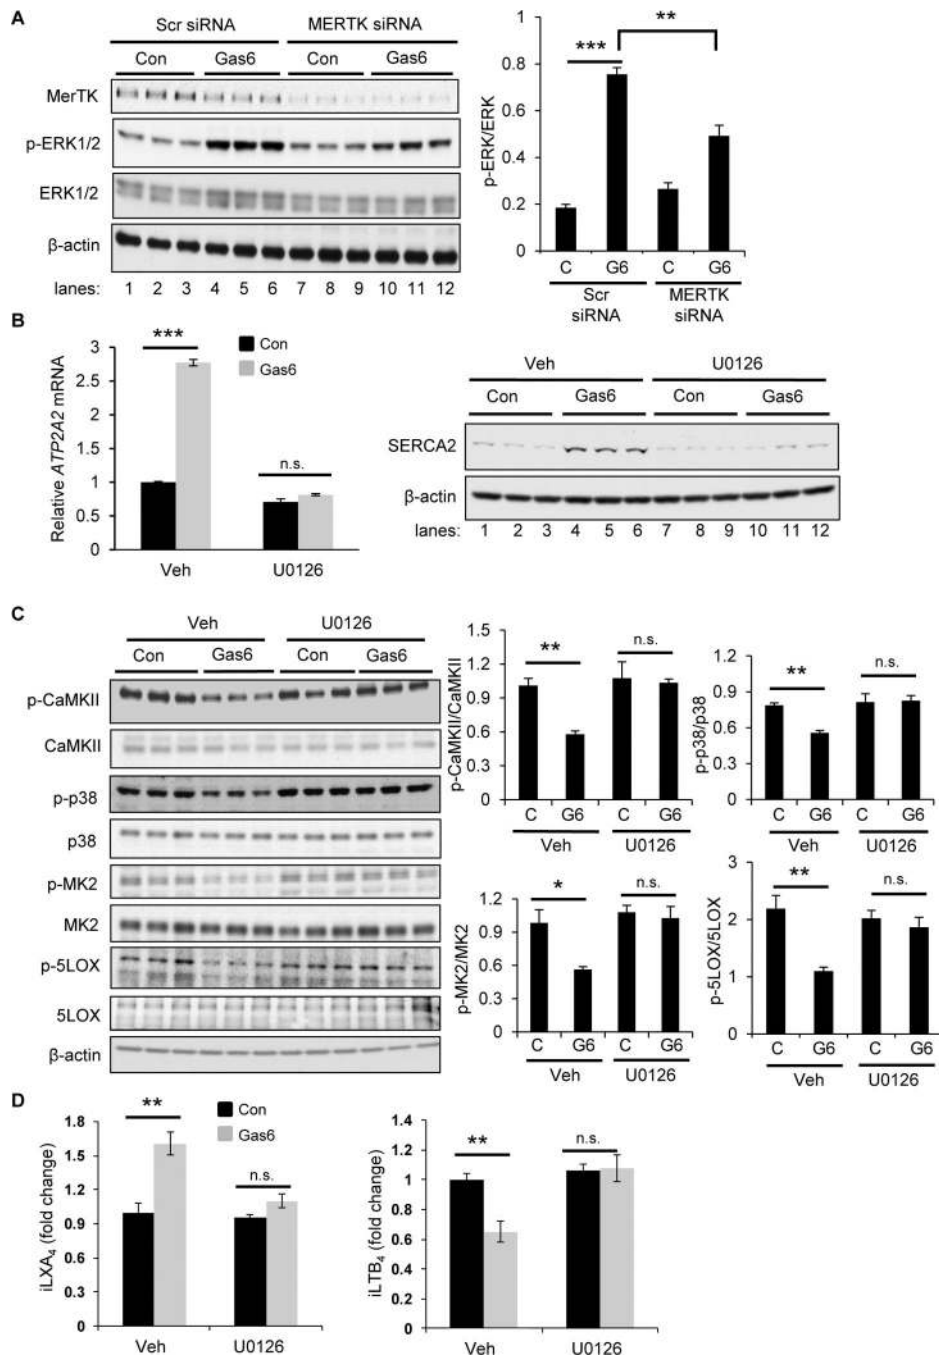

Fig. 3. Gas6-MerTK signaling induces the expression of *ATP2A2* mRNA and SERCA2 protein in human macrophages by activating ERK.

(A) Human macrophages transfected with scrambled siRNA or MERTK-specific siRNA were incubated with control or Gas6-conditioned medium for 30 min, lysed, and then analyzed by Western blotting with antibodies specific for MerTK, p-ERK1/2, ERK1/2, and β -actin (loading control). Left: Western blots show samples from three different donors. Right: Densitometric analysis of the ratio of the abundances of p-ERK1/2 to total ERK1/2.

(B) Macrophages were pre-treated with vehicle or 10 μ M U0126 for 30 min and then

incubated with control or Gas6-conditioned medium for 7 hours. The cells were then analyzed by real-time qPCR and Western blotting analysis, respectively, to determine the relative abundances of *ATP2A2* mRNA (left) and SERCA2 protein (right). Western blots show samples from three different donors. (C) Macrophages were treated as described in (B) and then were analyzed by Western blotting with antibodies specific for phosphorylated (p-) and total CaMKII, p38, MK2, and 5-LOX. β -actin served as the loading control. Left: Western blots show samples from three different donors. Right: Bar graphs show the ratio of the indicated phosphorylated protein to total protein, which was quantified by densitometry with ImageJ software. (D) Macrophages were treated as described in (B), after which the culture medium were subjected to ELISA assays to quantify iLXA₄ or iLTB₄. For the macrophages used for the iLTB₄ assay, 10 μ M arachidonic acid was added to the medium during the last hour of Gas6 treatment. For all bar graphs, data are means \pm SEM of three different donors. * $P < 0.05$, ** $P < 0.01$, *** $P < 0.001$ by one-way ANOVA with post-hoc t-tests for group comparisons; n.s., not significant.

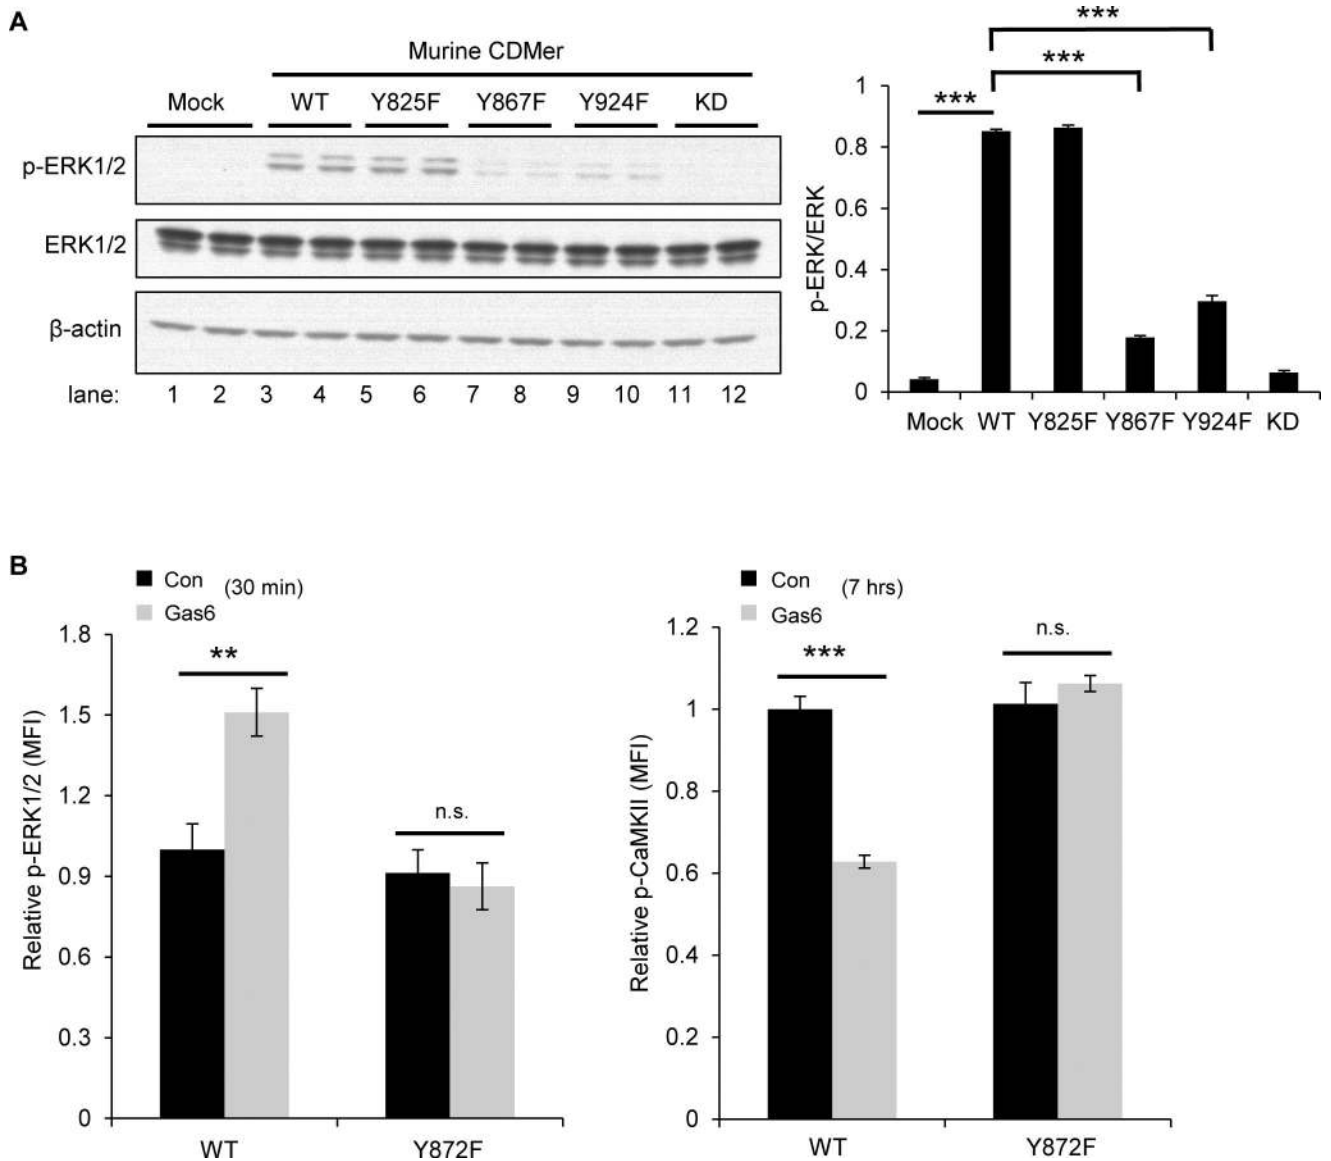

Fig. 4. Specific tyrosine residues in the cytoplasmic tail of MerTK are required for the activation of ERK and CaMKII.

(A) HEK 293 cells were transfected with various CDMer plasmids encoding WT MerTK, the Y825F, Y867F, and Y924F mutants, and the kinase-deficient (KD) mutant. Forty-eight hours later, the cells subjected to the transfection procedure without plasmids served as control (“Mock”). The cells were lysed and analyzed by Western blotting with antibodies specific for p-ERK1/2, ERK1/2, and β -actin. Bar graphs show the ratio of phosphorylated ERK1/2 to total ERK1/2, which was quantified by densitometry with ImageJ software. Data are means \pm SEM of three independent experiments. *** $P < 0.001$ vs. WT by oneway ANOVA with post-hoc t-tests for group comparisons. (B) Bone marrow-derived macrophages from *Mertk*^{-/-} mice were transduced with pMSCV-human *MERTK* (WT) or pMSCV-human *MERTK* Y872F. Seventy-two hours later, the cells were then incubated with control or Gas6-conditioned medium for 30 min (left) or 7 hours (right), which was followed by flow cytometric quantification of p-ERK1/2 or p-CaMKII, respectively. Data means \pm

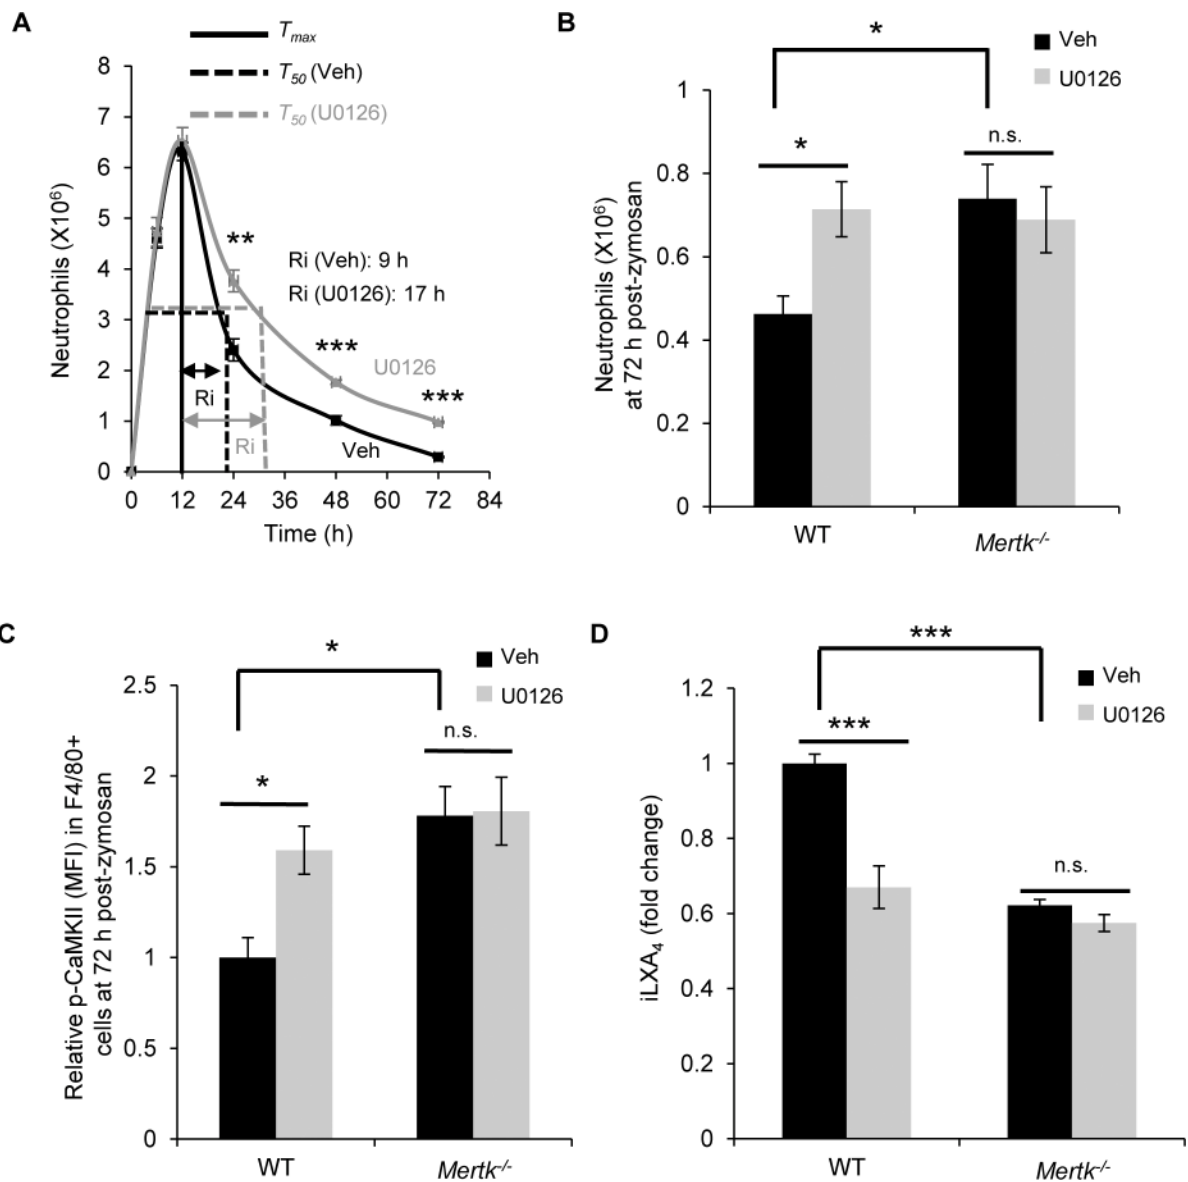

SEM of three different mice. ** $P < 0.01$, *** $P < 0.001$ vs. control medium by one-way ANOVA with post-hoc t-tests for group comparisons; n.s., not significant.

ERK inhibition suppresses inflammation resolution in zymosan-induced peritonitis in mice.

(A) WT mice were co-injected intraperitoneally with 0.1 mg of zymosan and either 25 μ g/kg U0126 or an equal volume of DMSO as the vehicle control. Peritoneal exudates were collected by lavage with 3 ml of cold PBS at the indicated times, and leukocytes and exudate fluid were separated by centrifugation at 500g- for 10 min. Total leukocyte number in the exudate was counted with a hemocytometer, and the percentage of Ly6G⁺ neutrophils was determined by flow cytometry. Neutrophil number was calculated as total leukocytes \times % neutrophils. Resolution intervals (Ri) were calculated as previously described (30). Data are means \pm SEM of four mice per group. ** $P < 0.01$, *** $P < 0.001$ vs. vehicle-treated mice by unpaired *t*-test. (B to D) WT or *Mertk*^{-/-} mice were injected intraperitoneally with zymosan, which was followed 64 hours later by intraperitoneal injection with U0126 or DMSO. After an additional 8 hours, peritoneal exudates were collected. (B) Neutrophil number was calculated as described in (A). (C) Peritoneal leukocytes were stained with PE-conjugated

anti-F4/80 antibody, which was followed by fixation and permeabilization. Permeabilized cells were stained with anti-p-CaMKII antibody and then an Alexa Fluor 647-conjugated secondary antibody. The mean fluorescence intensity (MFI) of p-CaMKII in the macrophages was quantified by flow cytometry. (D) Exudate iLXA₄ was assayed by ELISA. For (B) to (D), data are means \pm SEM of four mice per group. * $P < 0.05$, *** $P < 0.001$ vs. vehicle-treated WT mice by one-way ANOVA with post-hoc t-tests for group comparisons); n.s., not significant.
