**Abstract.** We collected ground-based and aircraft vertical profile measurements of meteorological parameters during a 2-week intensive campaign over the Valencia basin, in order to understand how mesoscale circulations develop over complex terrain and affect the atmospheric transport of tracers. A high-resolution version of the RAMS model was run to simulate the campaign and characterize the diurnal patterns of the flow regime: night-time katabatic drainage, morning sea-breeze development and its subsequent coupling with mountain up-slopes, and evening flow-veering under larger-scale interactions. An application of this mesoscale model to the transport of CO<sub>2</sub> is given in a companion paper. A careful evaluation of the model performances against diverse meteorological observations is carried out. Despite the complexity of the processes interacting with each other, and the uncertainties on modeled soil moisture boundary conditions and turbulence parameterizations, we show that it is possible to simulate faithfully the contrasted flow regimes during the course of one day, especially the inland progression and organization of the sea breeze. This gives confidence with respect to future applicability of mesoscale models to establish a reliable link between surface sources of tracers and their atmospheric concentration signals over complex terrain.

## 1 Introduction

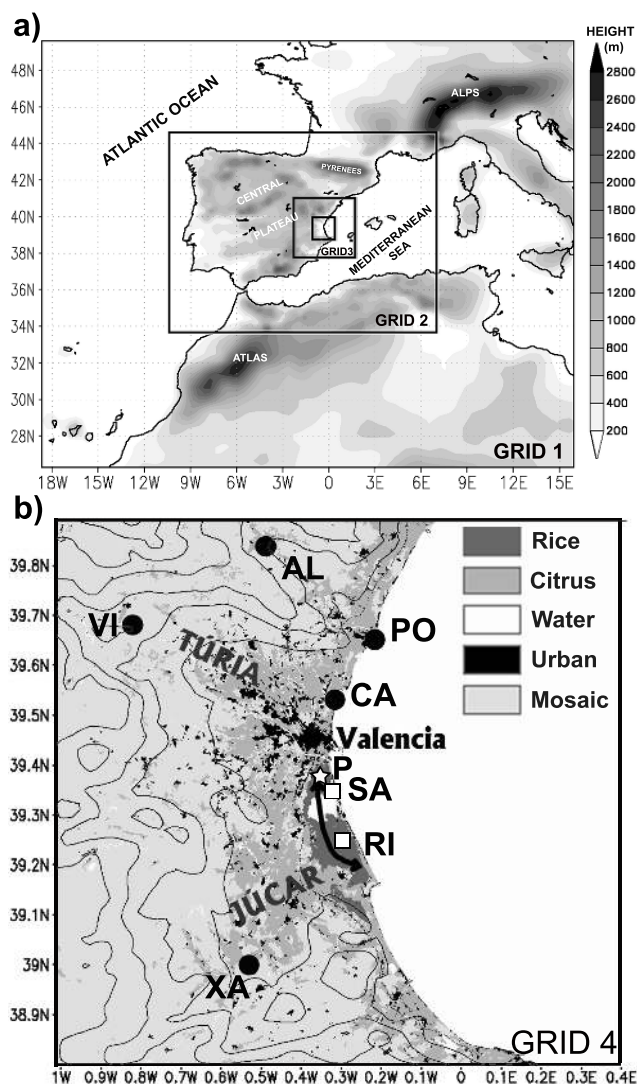

More than 75% of the Earth's population live near the sea (Michener et al., 1997), with many coastal cities being sur-

rounded by hills or mountains. In coastal regions with complex terrain, the various atmospheric gases and aerosols emitted at the surface will be transported by mesoscale circulations and injected into the atmosphere with very specific patterns. These patterns are not resolved in coarse-scale global transport models, and thus require further study to understand atmospheric transport processes at small scales. Solar heating frequently creates thermally induced mesoscale circulations that develop under clear sky conditions, with strong diurnal variations, and with patterns and intensities that depend on the regional surface energy budget and orography. The formation of pollution layers has been related to these mesoscale circulations, in particular to the interaction between the sea breeze and mountain circulations. This process has been observed at Athens (Lalas et al., 1987), Los Angeles (Lu and Turco, 1994), British Columbia, (McKendry et al., 1997), Tokyo (Chang et al., 1989), and over the Northern (Millán et al., 1984) and Eastern (Millán et al., 1992) coasts of Spain.

The Western Mediterranean Basin is surrounded by high mountains and during summer clear-sky conditions prevail. In total, 42 million people live in urban areas on the Western Mediterranean coast (Attane and Courbage, 2004). Former campaigns have shown that mesoscale processes dominate the meteorological regimes in this region (Millán et al., 1997). Regional circulations are diurnal and become self-organized from cells of a few tenths of a kilometer in their early development stages, up to circulations extending to the whole basin (hundreds of kilometers) later in the evening (Gangoiti et al., 2001). The presence of stacked layers of pollutants has been attributed to the mesoscale recirculation of airmasses in the Mediterranean basin (Millán et al., 1997).

**Fig. 1.** (a) Domain configuration and orography of the RAMS model showing the four nested domains with increasing horizontal resolution. The largest domain (GRID 1) has a grid length of 40.5 km, and the smallest (GRID 4) is of 1.5 km. (b) Characteristics of the smallest-domain simulated meteorological fields are compared to the campaign measurements. Black lines show the orography every 200 m. Grey-scaled colours show the different land cover types (see legend). The location of the meteorological stations (black circles), eddy-covariance flux towers (open squares), airborne horizontal transect (black arrow) and vertical profiles (stars) can be seen.

Joint use of mesoscale models and Lagrangian particle dispersion models was found useful in the description of transport patterns in this region (Gangoiti et al., 2001; Pérez-Landa et al., 2002).

The goal of this paper is to quantify and understand the atmospheric transport processes acting on scales ranging from 1 to 100 km in the Western Mediterranean Region. To meet

this goal, an intensive measurement campaign was carried out during the summer of 2001 in the Valencia region, a coastal basin with complex terrain located on the East coast of Spain. The campaign was part of the European project RECAB (Regional Assessment and Modelling of the Carbon Balance in Europe). Airborne vertical profiles and ground based continuous measurements of meteorological variables were collected at different locations (Gioli et al., 2004). We used a high-resolution mesoscale model to interpret these measurements in terms of atmospheric transport processes. The following sections describe the typical summertime mesoscale transport processes in the Western Mediterranean area (Sect. 2), the campaign (Sect. 3) and, the model simulations (Sect. 4). The model results are evaluated against observations (Sect. 5) and analyzed in the context of air masses recirculation and breeze effects (Sect. 6). A quantitative estimation of the model performances is made in Sect. 7. Carbon dioxide fluxes and concentrations were also measured during the campaign. In a follow-up paper (Pérez-Landa et al., 2007, this issue) we analyze the mesoscale transport of CO<sub>2</sub> using the same atmospheric mesoscale model.

## 2 Relevant features at regional and local scales

The terrain of the Western Mediterranean Basin (WMB) exerts a strong influence on its weather regimes by generating local and regional mesoscale circulations on diurnal time scales (Millán et al., 1997, 2002; Gangoiti et al., 2001). The main orographic features are illustrated in Fig. 1a. In summer, sea breezes combine with up-slope winds to transport wet air inland, where it can be injected at the front of the combined breeze into a return flow at typical heights of 2–3 km (Millán et al., 1997). During the day, the resulting generalized convergence of winds at ground level along the coast is compensated by an increased subsidence over the sea (Millán et al., 1997). During the night, these processes relax and gravity flows dominate along the coastal valleys, advecting inland air near the surface towards the sea (Millán et al., 1992). These processes create a marked diurnal cycle of the wind direction and pressure. They also enable a recirculation of air masses with a periodicity of a few days, as shown by tracer experiment results (Millán et al., 1992). Such mesoscale circulation cells involving vertical re-circulations and/or oscillations are also observed in the Central Mediterranean (Georgiadis et al., 1994; Orciari et al., 1998) and the Eastern Mediterranean basins (Kallos et al., 1998; Ziomas et al., 1998). Around the WMB mesoscale circulations can develop coherently at a scale that may encompass the whole basin (Millán et al., 1997; Gangoiti et al., 2001). This makes it necessary to consider mesoscale circulations around the WMB as a whole, in order to properly quantify and understand the transport patterns within a smaller region, here the Valencia basin.

The Valencia region is located on the East coast of the Iberian Peninsula. At the confluence of the Turia (North) and Jucar (South) river valleys, the region presents a coastal plain extending up to 50 km inland (Fig. 1b), surrounded by mountain ranges with an average elevation of 1000 m. The combination of fertile soils, proximity to the sea, mild temperatures and flat topography enables the large-scale cultivation of irrigated tree-crops (mainly citrus) and paddy rice along the coast. The city of Valencia, located at the mouth of the Turia river (Fig. 1b), contains 1.4 M people, including conurbations, and has no heavy industry.

### 3 Airborne and ground-based measurements during the campaign

We focus here on the campaign episode of 1–2 July 2001, during which many vertical aircraft profiles were collected near the coastline, specifically over rice fields (Fig. 1a). The weather conditions for this episode show a high pressure system centered over the Netherlands and a typical decrease in sea level pressure towards the East in the Mediterranean region (Fig. 2). There is a local pressure minimum over the center of the Iberian Peninsula at 12:00 UTC, where the temperature is locally warm at that time. Under such a typical summer weather pattern, mesoscale circulations are expected to develop in the Valencia basin.

The airborne measurements made on 2 July consist of vertical profiles and horizontal transects collected at selected intervals, using a Sky Arrow ERA light-weight aircraft (Table 1). Vertical profiles were taken between 15 m and 800 m above the rice fields. Eddy covariance flux measurements

were performed along each horizontal transect (Fig. 1b). The aircraft measured sensible and latent heat fluxes, temperature, relative humidity and wind, and CO<sub>2</sub> concentrations and fluxes (the latter analyzed in a companion paper). These measurements are described by Gioli et al. (2004).

Airborne vertical profiles are collocated with ground-based eddy covariance flux measurements. Eddy-covariance, fluxes of CO<sub>2</sub>, H<sub>2</sub>O and energy were measured on top of two towers (Fig. 1b). The first tower (12 m), called El Saler (SA), is permanently located over a Pine-dominated maquia forest. The second tower (2 m), called Rice (RI), was set up during the campaign over a rice field. Eddy covariance fluxes of sensible and latent heat (and CO<sub>2</sub> fluxes) are calculated at 30 min time steps from ultrasonic anemometer wind, H<sub>2</sub>O and temperature sensors 10 Hz data, following the guidelines of the Euroflux methodology (Aubinet et al., 2000). The measurements of wind speed and direction, temperature and relative humidity made on top of each flux tower were used to evaluate the results of the RAMS model (Sect. 5). Additional measurements come from five meteorological stations within the Valencia basin: Villar (VI) and Xátiva (XA) located inland, and Altura (AL), Port (PO) and Carraixet (CA), located in the North.

### 4 Mesoscale simulation: Model setup, initial and boundary conditions

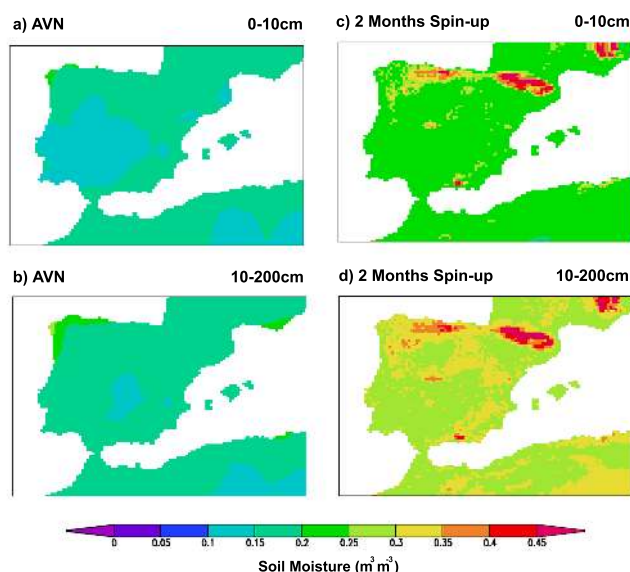

The Regional Atmospheric Modeling System (RAMS; Pielke et al., 1992) in its version 4.3.0 was used to simulate selected days of the RECAB campaign. The RAMS model was applied to four domains of decreasing size at increasing

**Fig. 2.** Temperature ( $^{\circ}\text{C}$ ) at 1000 hPa and Sea Level Pressure (hPa) fields from the AVN global model at 12:00 UTC on 2 July.

spatial resolution (Fig. 1a). A series of two-way interactive nested domains were configured at decreasing horizontal grid spacing of 40.5, 13.5, 4.5 and 1.5 km, respectively (Fig. 1a). The vertical discretization uses 45 levels with a 30 m spacing near the surface increasing gradually up to 1000 m near the model top at 17 000 m, and with 15 levels in the lower 1000 m. Our version of RAMS includes the Mellor and Yamada (1982) level 2.5 turbulence parameterization, a full-column two-stream single-band radiation scheme that accounts for clouds to calculate short-wave and long-wave radiation (Chen and Cotton, 1983), and a Kuo-modified parameterization of sub-grid scale convection processes in the coarse domain (Molinari, 1985). The cloud and precipitation microphysics scheme from Walko et al. (1995) was applied in all the domains. The LEAF-2 soil-vegetation surface scheme was used to calculate sensible and latent heat fluxes exchanged with the atmosphere, using prognostic equations for soil moisture and temperature (Walko et al., 2000).

Atmospheric boundary and initial conditions are derived from the analysis of the NCEP Aviation (AVN) run of the Global Spectral Model (Caplan et al., 1997), available every 6 h at  $\approx 100$  km resolution globally. A Four-Dimensional Data Assimilation (FDDA) technique is used to define the forcing at the lateral boundaries of the outermost eight grid cells of the largest domain. Surface boundary conditions also include land cover information. We use here the USGS land cover (Anderson et al., 1976) modified to include detailed land use information from CORINE (CEC, 1995) over the Iberian Peninsula, and from PELCOM (Mucher et al., 2000) over the rest of Europe. The various land cover types are reclassified into the 30 distinct LEAF-2 vegetation classes with an original resolution of  $0.0083^{\circ}$  (Baklanov et al., 2004). Over the ocean, we prescribe SST values at  $0.5^{\circ}$  resolution by means of direct processing of NOAA-AVHRR raw satellite data during the days of the campaign following the

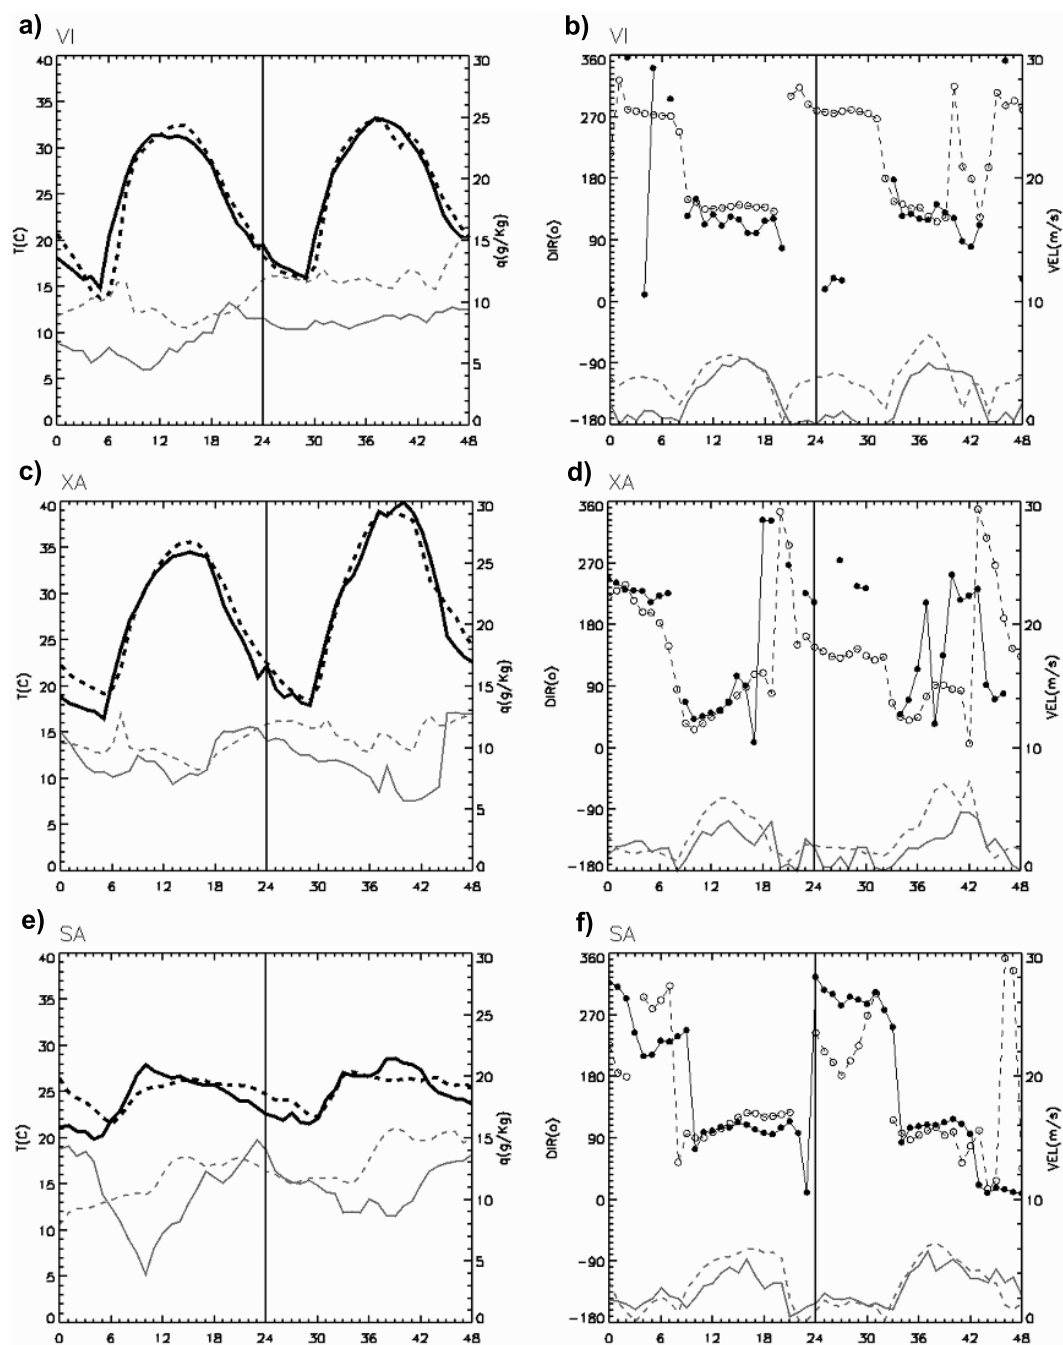

**Fig. 3.** Soil moisture for the 1st of July at 00:00 GMT: interpolated from the (a) 0–10 cm and (b) 10–200 layers of the AVN global model into RAMS domain 2; output of the 2 months spin up simulation over RAMS domain 2, vertically averaged (c) between 0 and 10 cm and (d) between 10 and 200 cm.

scheme by Badenas et al. (1997). In areas where processed data was not available (some peripheral areas located outside GRID 2) data from weekly means global data (Reynolds, 1994) were used.

Soil-moisture plays a central role in controlling the development of mesoscale circulations, via its influence on the surface energy budget (Ookouchi et al., 1984; Lanicci et al., 1987; Jacobson 1999). Soil moisture is usually estimated in global models by using atmospheric variables as forcing data (Mahfouf, 1991). This procedure provides soil moisture gridded fields, which are otherwise impossible to obtain from direct observations. When soil moisture and temperature from the AVN fields were used to initialize RAMS, however, the simulated meteorological fields showed important differences against the measurements. The simulation was too dry (Table 2) and the morning vertical profiles of temperature during the morning were poorly captured (not shown).

We thus initialized soil moisture and soil temperature during the campaign by running RAMS coupled to LEAF-2 over the two largest domains (Fig. 1a) for two months preceding the campaign, guided by a smooth data assimilation (FDDA) of the AVN fields. For simplicity, we prescribed LEAF-2 with a homogeneous soil texture of the clay-loam type. The soil column at each grid point is subdivided into 11 layers down to a depth of 2 m. The soil moisture was initialized with a uniform profile at a value of  $0.38 \text{ m}^3/\text{m}^3$ . The initial soil temperature profile is obtained by subtracting from the surface air temperature a value of  $2.3^{\circ}\text{C}$  in the top soil, which linearly decreases down to a decrease of  $1^{\circ}\text{C}$

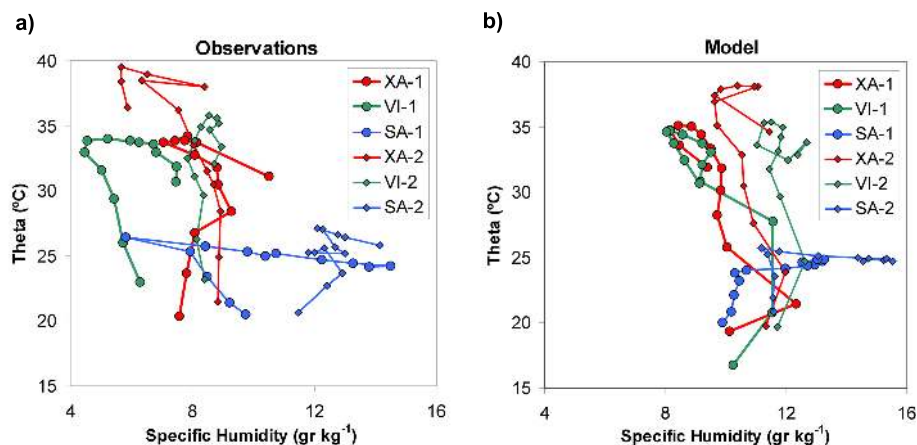

**Fig. 4.** Measured (continuous line) and simulated (discontinuous line) time series on 1 and 2 July 2001 in VI, XA and SA (see Fig. 1b). On the left: temperature (black) and  $q$  (grey). On the right: wind speed (grey) and wind direction (black). When the observed or simulated wind speed was less or equal to  $0.5 \text{ m s}^{-1}$ , the wind direction was not drawn.

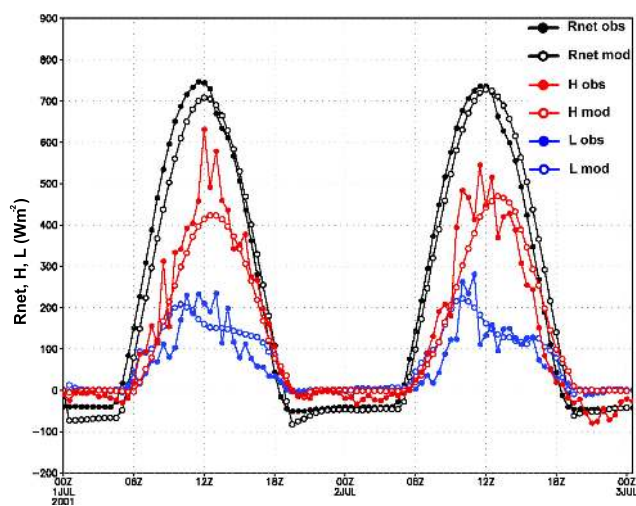

in the bottom soil. The soil variables obtained in RAMS for 1 July 2001 were compared to the AVN global analysis data. Soil temperatures were similar in both simulations, except for those regions where differences in model orography are important (not shown). Soil moisture from AVN was drier than in RAMS for the 0–10 cm layer, and for 10–200 cm (Fig. 3). The RAMS results show their highest mois-

ture values in mountainous regions, probably due to the effect of convective precipitation which the global AVN model could not resolve. Other differences in AVN vs. RAMS soil moisture fields must also be attributed to their different land surface schemes, which may induce different soil moisture dynamic ranges (see e.g., Koster and Milly, 1997).

**Fig. 5.** Scatter plot of virtual potential temperature vs. specific humidity hourly data at weather stations XA (red), VI (green) and SA (blue) observed (a) and modeled (b), for the daytime period of 06:00 to 18:00 UTC on 1 July (–1) and 2 July (–2).

**Fig. 6.** Observed (closed circles) and modeled (open circles) net radiation (black), sensible (red) and latent (blue) heat fluxes at SA surface station during 1 and 2 July 2001.

The use of a 2-month model spin-up to initialize our high-resolution simulation could be disputed, when compared with other more complex schemes employed in mesoscale models (e.g. Smith et al. 1994). However, initialized in this way, RAMS showed good skills in simulating wind and temperature fields during the campaign (Sect. 5 and Pérez-Landa et al., this issue).

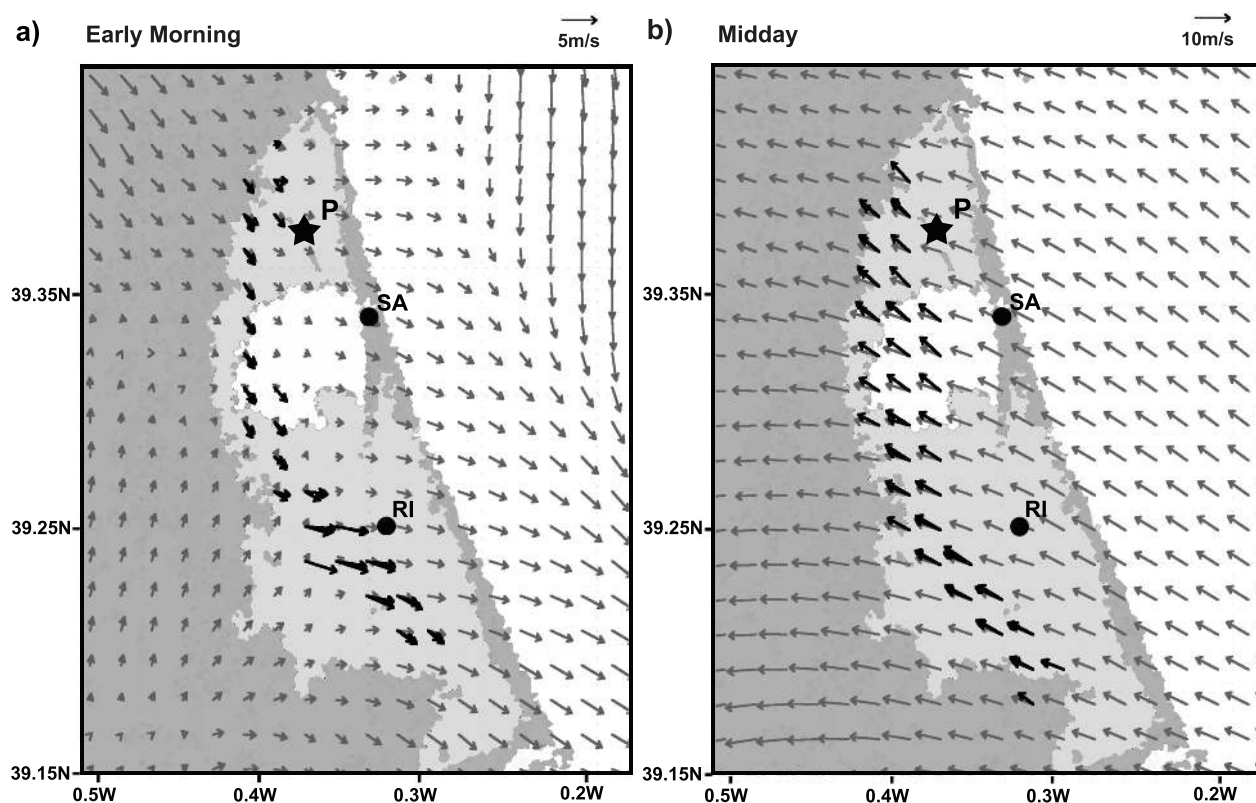

## 5 Results: modeled and observed meteorological quantities

### 5.1 Model comparison with surface weather stations

We focus here on time series from three stations shown in Fig. 1b, SA (El Saler, coastal), VI (Villar, inland in the Jucar river valley) and XA (Xàtiva, inland in the Turia river valley). The two inland stations show a larger diurnal temperature cycle ( $15^{\circ}\text{C}$ ) than the coastal station ( $8^{\circ}\text{C}$ ), as seen in Fig. 4. The model captures quite well the diurnal temperature range at each station (see Sect. 6), as well as the gradient between the coastal station SA and the inland ones XA and VI. The warming trend observed at all three sites between 1 and 2 July, reaching up  $+5^{\circ}\text{C}$  in one day at XA, is well reproduced. However, there is a noticeable under-prediction of the SA diurnal temperature range, by up to  $3^{\circ}\text{C}$ , with overly high minimum and overly low maximum values (Fig. 4e).

The air specific humidity shows a rather complex diurnal variation, different between the three stations and between 1 July and 2 July (Fig. 4). The observed humidity is on average higher near the coast at SA, although the first day shows a dry spell in the morning. The XA station experiences a daytime drying which intensifies on 2 July, whereas the VI station has an opposite trend. Generally, the model is too wet compared to the observations at all three sites (Fig. 4), but it does reproduce the observed trend towards increasing humidity between 1 July and 2 July.

In the hourly wind speed and direction data shown in Fig. 4, we can observe a strong diurnal oscillation, characterized by the daytime development of the sea-breeze advecting air from sea to land at a speed of up to  $6\text{ m s}^{-1}$ , followed by night time surface drainage winds oriented from land to sea. Thermal circulations develop during the day, stabilizing a flow pattern advecting air from sea to land. The wind blows inland from the East, but it is occasionally variable and

**Fig. 7.** (a) Early morning horizontal wind vectors at 50 m above ground. Thick black arrows: observed winds during the airborne transects at 06:50 UTC on 2 July. Thin grey arrows: modeled winds at the same time. Grey regions correspond to the same land cover types as in Fig. 1. (b) Same fields but for midday conditions, at 12:10 UTC. Note that corresponding wind scales are drawn at the top right of each panel.

its direction also varies between sites. At SA, winds blowing from the East were observed on 1 July, but they were seen to come from the North-East on the evening of 2 July (Fig. 4e). In XA, the winds blew initially from the North-East, changed to the North-West by the evening of 1 July and to the South-West by the evening of 2 July. Gravity-driven drainage circulations develop during the night. The drainage winds follow the main axis of the valleys (Fig. 4 and Fig. 1b). Nocturnal winds blowing from the South-West along the Jucar valley (Fig. 4d) were observed at XA. At VI, calm conditions within a stable stratified surface layer prevailed, with no representative wind direction. At SA near the coast, the wind blew from the South-West during the night of 2 July, and from the North-West during the night of 3 July. This station is located at the confluence of the Jucar and Turia valleys (Fig. 1b) so that the main nocturnal wind direction depends on which of the two drainage flows prevails.

It is very encouraging to see that the mesoscale model is able to capture quite realistically both the timing and the intensity of breezes and drainage winds (Fig. 4). At VI, the modeled wind speed and direction match the data during the day, except for the change in the evening of 2 July (Fig. 4). At XA, the model predicts a change in wind direction from

North-East to East by mid-day on 2 July, whereas the data show a variable wind direction. A second change in wind direction by the evening of 2 July is simulated, with winds from the North, while the observed winds are from the South-West. At SA, on the coast, the daytime sea breeze development is well-reproduced, especially for 2 July (Fig. 4). More discrepancies with the station data are observed during the night under stable conditions. At VI, the modeled drainage wind speed is overestimated by  $1.5 \text{ m s}^{-1}$ , probably due to the presence of a ground inversion not resolved in the model, while at XA and SA the modeled winds are occasionally in the wrong direction.

The link between the mesoscale circulations and the thermodynamic cycle can be analyzed with the help of conserved variable plots (Betts and Ball, 1995). Figure 5 shows the heating of airmasses observed during the early morning and, in general, coupled to drying processes. A sharp decrease in heating and an increase in specific humidity can then be observed in the six cycles analyzed. The moistening occurs with the set-up of the mesoscale circulations which advects humidity inland until the end of the daytime cycle. The only exceptions are XA and SA on the second day, which show a second stage of drying and heating processes. This could

**Fig. 8.** Experimental (left) and modeled (right) vertical profiles of horizontal winds over the rice paddy fields at the aircraft campaign location (marked with P in Fig. 1b) at different times on 2 July.

indicate some entrainment of dry and warm air from a layer aloft in the mixing layer.

The model results represented in Fig. 5 show important differences when compared with observations. The model presents moister values and less variability during the diurnal cycle than measurements show (see also above). The model captures the moistening due to advection in SA, although it cannot see the strong heating and drying measured on the first day. This could be due to the early development of the simulated breeze circulation at SA compared to observations (Fig. 4f). The model does not solve clearly the role advection plays in moistening the air mass at the inland stations, although the presence of moister air before the arrival of the breeze could have decreased this effect. It is clear that the drying processes during the early stages of the cycle are very different from those observed, which could be due to the effect of our simple soil moisture initialization scheme. The model shows less variability than the aircraft data, suggesting that the spatial gradients in specific humidity are too small. The second stage of the drying and heating processes observed at XA and SA stations is not captured by the model. This could be due to the limitations of the PBL schemes simulating the effect of the entrainment processes.

Figure 6 shows good agreement between simulated and observed net radiation and heat and moisture fluxes at SA. However, the singular location of this site as well as the heterogeneous character of the region limits the representativity of this result. Thus, as our previous analysis on moisture suggests, more bias in the fluxes is expected throughout the domain.

## 5.2 Comparison between model and aircraft measurements

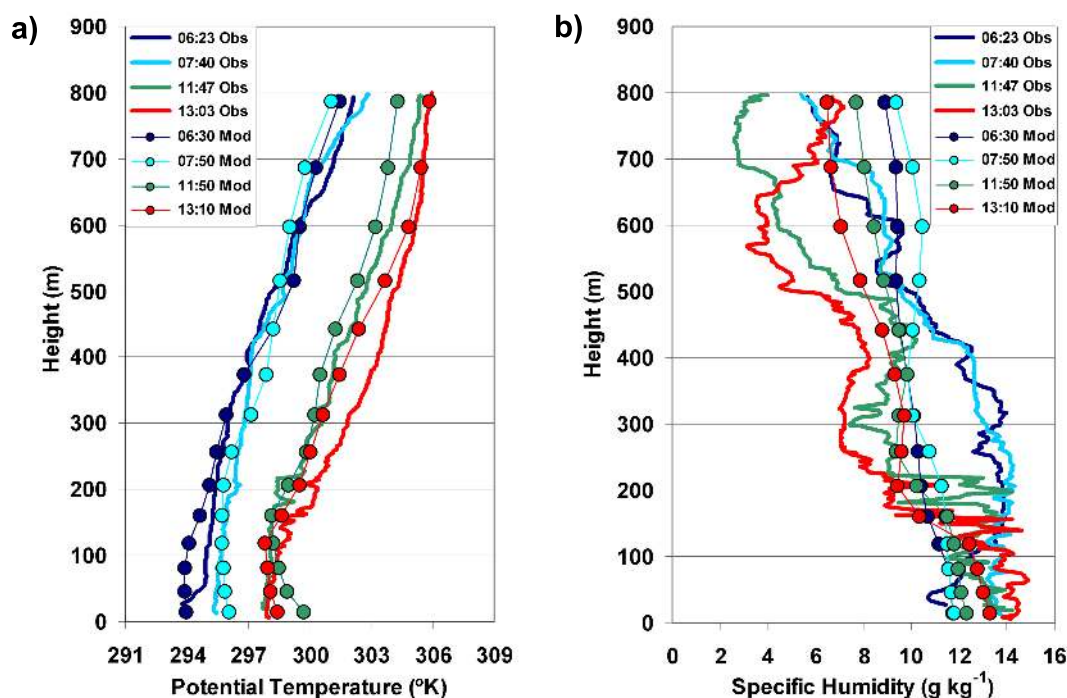

The horizontal winds measured at 50 m above ground during the aircraft transects are shown in Fig. 7. During the early morning (Fig. 7a), the drainage winds flow towards the sea. In the northern basin (Turia), the wind speed is low and the wind comes from the North-West, while in the southern basin (Jucar), the wind turns to the West and increases in speed. At the confluence of the Jucar and Turia valleys, the wind acquires a different direction and speed. There is good agreement between model and data, except for an underestimation of the drainage winds in the southern basin (Fig. 7a). In contrast with the complex early-morning drainage wind fields (driven by orography and gravity), the mid-day wind field is more uniform, with a South-East origin and higher speeds than in the morning near the coast. This daytime breeze flow is nicely reproduced by RAMS (Fig. 7b).

Figure 8 shows the wind vertical profiles measured on 2 July. The early morning data (06:23 UTC) indicate that the drainage winds are confined below  $\approx 200$  m. The next morning profile (07:40 UTC) shows a transition period between drainage and sea breeze regimes, with low speeds at every altitude. Later in the day, the sea breeze develops and blows from the South-East at a speed of  $5 \text{ m s}^{-1}$  by 11:47 UTC, increasing up to  $7 \text{ m s}^{-1}$  by 13:03 UTC. This breeze cell remains confined below 400 m throughout the day.

The changing shapes of the wind profiles are well captured by the model (Fig. 8). At 06:30 UTC, however the model underestimates the drainage wind intensity in the lowermost layers, while aloft there is overestimation. At 07:50 UTC, the model reproduces the drop in wind speed at the transition between drainage and breeze. At 11:50 UTC and 13:10 UTC, the model captures well the persistent breeze regime (see also Fig. 10), including the wind shear above  $\approx 400$  m.

Vertical profiles of potential temperature show the transition between the drainage and breeze regimes (Fig. 9). Heating occurs in the lower 200 m because of convective mixing, and between 200 and 800 m because of the sinking of air in the compensatory subsidence capping the sea breeze (Milan et al, 1997). The model reproduces the observed temperature profiles and rate of change well, suggesting that the mesoscale dynamics of the basin (also governing the  $\text{CO}_2$  dispersion) is realistic. Nevertheless, some discrepancies with the data can still be found in the lowest levels. The model cannot solve for the inversion present in the 06:37 profile near the ground, and at 11:50 UTC and 13:10 UTC while observed profiles are slightly stable, the model shows unstable profiles in the lowest 100 m. Both features could have a significant impact in the simulation of the atmospheric transport of any tracer. Additionally, the model is too wet in altitude, a bias also seen at surface stations, and it does not resolve explicitly the fine scale structure of the humidity profiles (Fig. 9), owing to its coarse resolution.

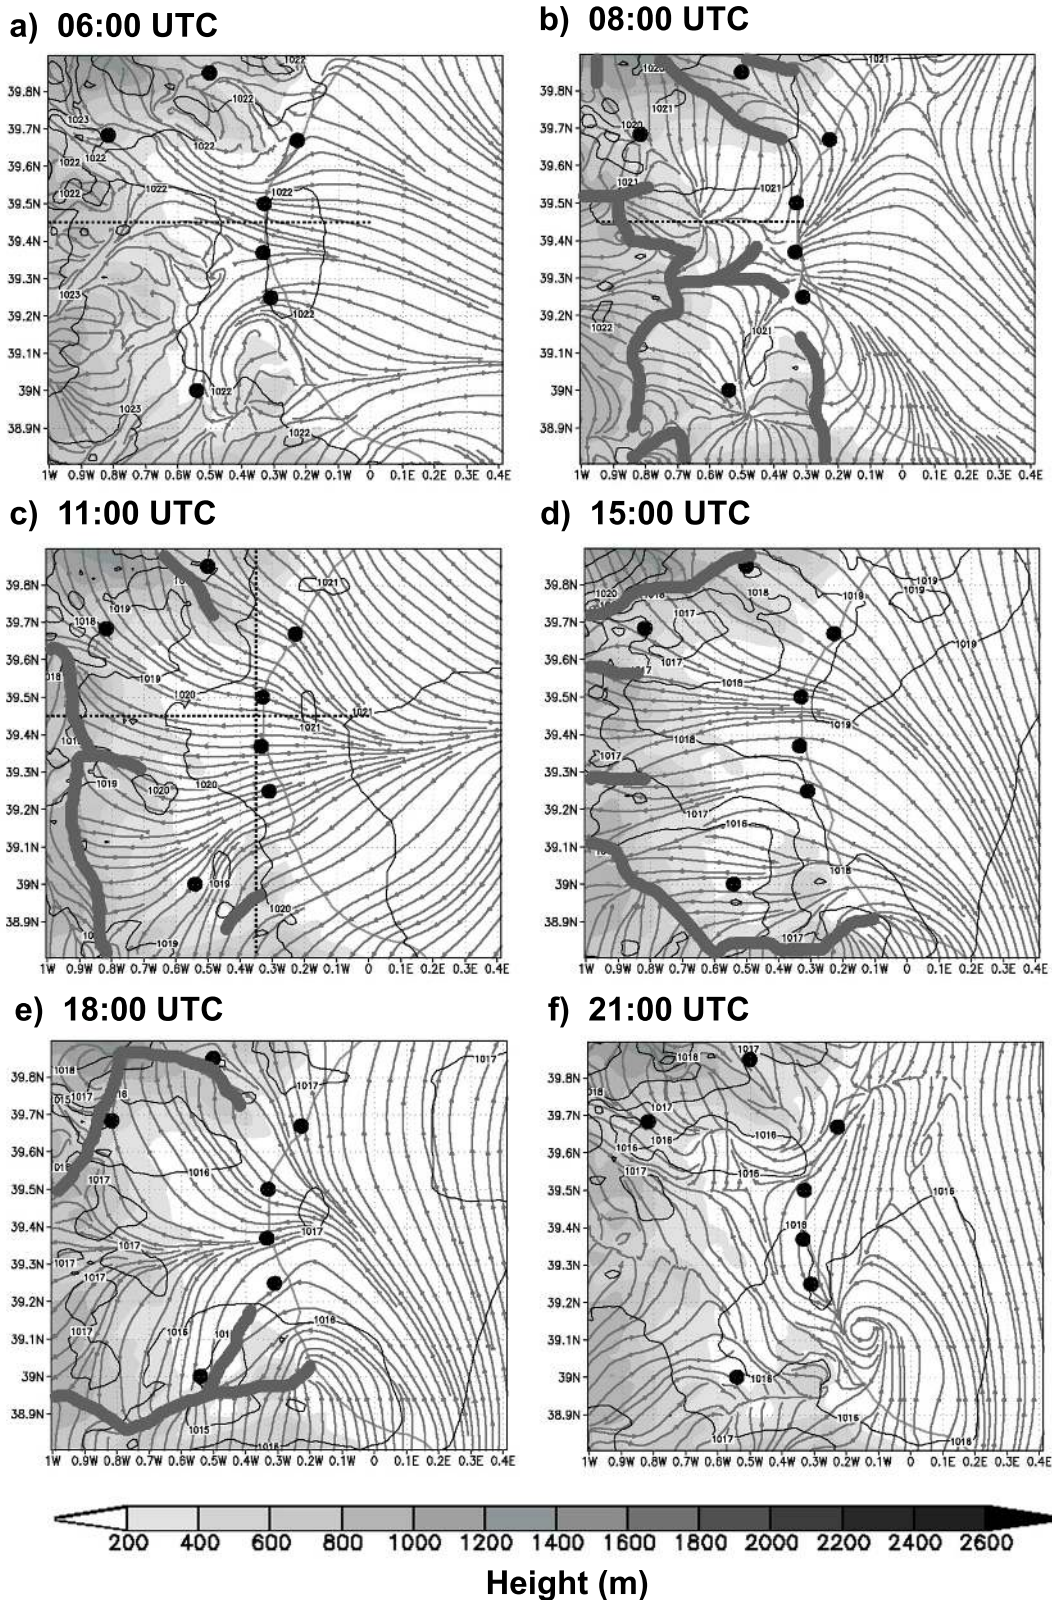

**Fig. 9.** Observed (Obs) and modeled (Mod) vertical profiles of potential temperature (left) and  $q$  (right) over the rice paddy fields at the aircraft campaign location (marked with P in Fig. 1b) at different times on 2 July.

## 6 Modeled 3-D circulation patterns

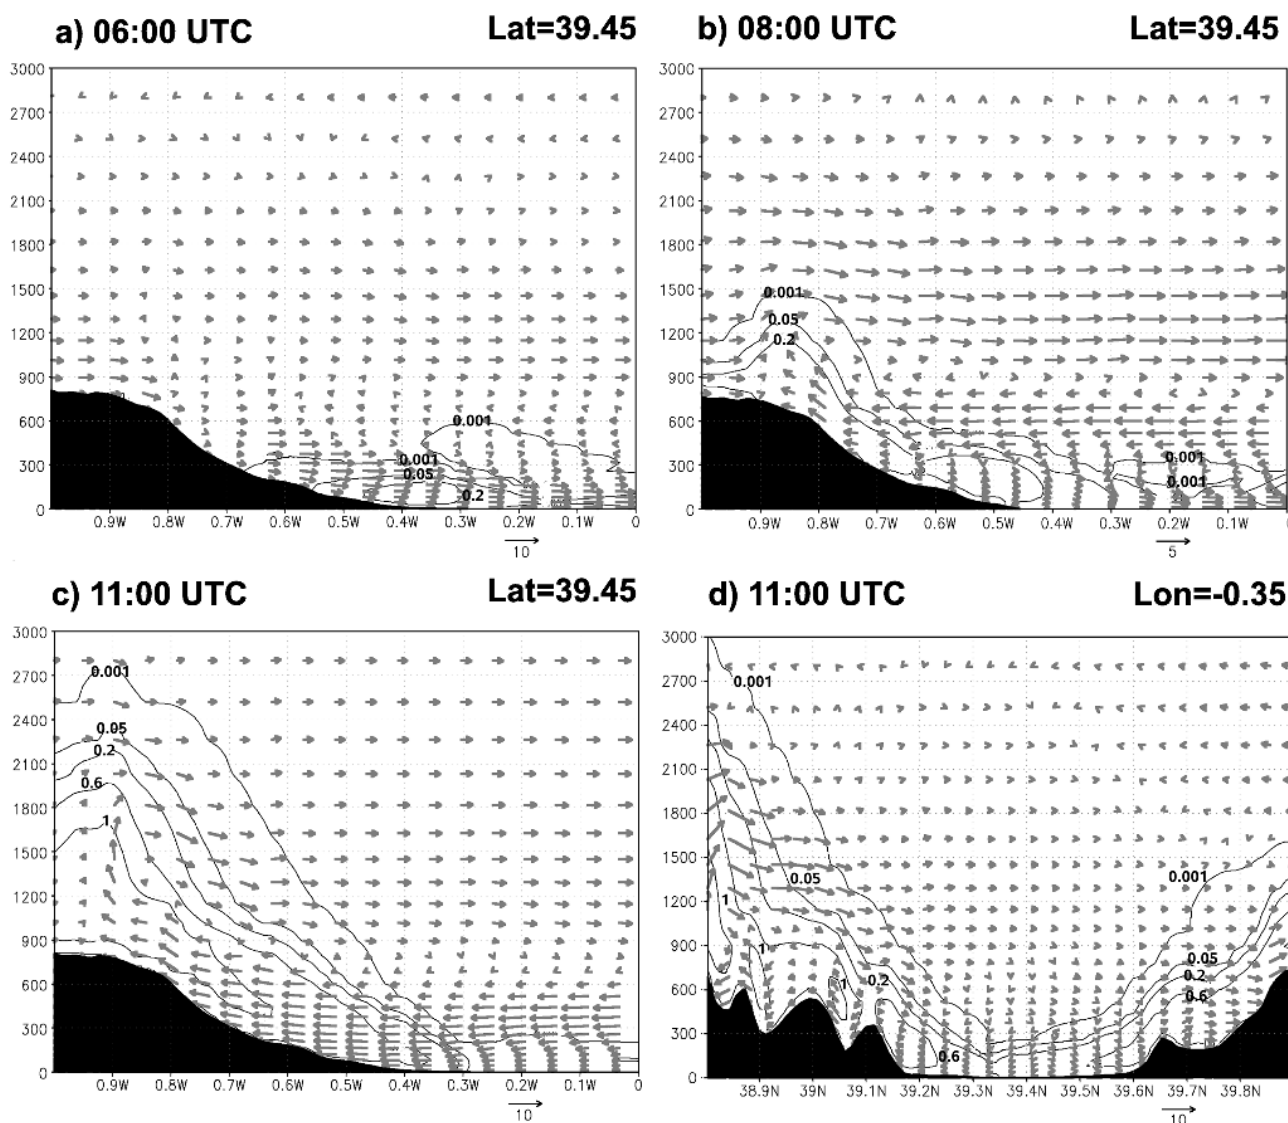

In this section, we use the model as a tool which helps to understand the 3-D character of the complex terrain circulations identified in the previous data analysis. Figure 10 shows the surface horizontal streamlines and pressure fields during the course of 2 July. During the night, the drainage winds follow the direction of each valley (Fig. 10a). Vertical cross-sections show the thickness and extension of this drainage flow, which penetrates over the sea (Fig. 11a). After dawn, at 08:00 UTC, heating of the slopes oriented toward the sun allows the development of up-slope winds, while in some areas close to the coast, nocturnal drainage persists (Fig. 10b). The gray lines in Fig. 10b show that vertical injection occurs at some well-defined convergence zones. In these convergence zones, positive vertical transport and upward advection of TKE occur (see, for instance, at longitude  $-0.87$  W in Fig. 11b). At the same time, there is a divergence zone at around  $-0.63$  W, where vertical winds become negative in the lower 200 m and sinking of TKE is modeled (Fig. 11b). Higher than 400 m above the sea, the wind coming from the East is connected to the up-valley injection. The return flow can be observed above 1200 m. A similar divergence center was modeled in the southern Jucar valley,  $38.95$  N,  $-0.48$  W, surrounded by convergence lines (Fig. 10b). The horizontal gradient of the Sea Level Pressure is small at this stage of the morning. This circulation consists of a complex pattern of horizontal and vertical winds, and the scales of the processes are related to the size of each valley.

At 11:00 UTC, the valley breezes have merged into a combined breeze extending from the sea (where horizontal winds are diverging) to a convergence line over the mountain range parallel to the coast (Figs. 10c and 11c). The vertical injection at this time of the day is stronger than it was earlier, reaching above 2000 m in height (Fig. 11c). The breeze cell stays confined to the first 400 m (Fig. 8), but it connects the coast with the mountain convergence and its return aloft. There is a continuous Sea Level Pressure decrease of 1–2 hPa within 60 km from the coast to the interior. The cross-section parallel to the coast (Fig. 11d) shows that the compensatory subsidence above the center of the valley limits the vertical mixing to the lower 300 m of the atmosphere.

At 15:00 UTC, the wind veers to the South-East over the sea, while inland the mountain convergence lines move perpendicular to the coast (Fig. 10d). The negative pressure gradient between the valleys and the coast has further increased. Three hours later, at 18:00 UTC, while the wind direction over the sea continues to be from the South-East, the wind inland has changed to North-East in the southern basin and to South-East in the northern basin (Fig. 10e). The development of this circulation partly compensates for the negative pressure gradient between the coast and the valleys. At 21:00 UTC, the cooling of the surface starts to organize drainage winds towards the sea, while part of the flow reflects previous processes (Fig. 10f). The spatial variability of the pressure decreases, except in the higher north-east valleys.

**Fig. 10.** Horizontal streamlines and Sea Level Pressure simulations near the surface (at  $\approx 15$  m) at different intervals on 2 July: (a) at 06:00, (b) at 08:00 UTC, (c) at 11:00 UTC, (d) at 15:00 UTC, (e) at 18:00 UTC, and (f) at 21:00. The thick grey solid lines represent convergence lines of the horizontal wind. The black dotted lines indicate the location of the cross-sections drawn in Fig. 11. Closed circles represent the location of ground stations (Fig. 1b).

**Fig. 11.** Vertical cross-sections of simulated TKE ( $\text{m}^2 \text{s}^{-2}$ ) and wind ( $\text{m s}^{-1}$ ). Contour lines represent TKE and vectors represent the wind component projected in the direction of the cross-section and with the vertical wind multiplied by 10. Each plot corresponds to the cross-sections drawn in Fig. 10 at constant latitude at the respective times, except for case (d) which represents a cross-section at constant longitude at 11:00 according to Fig. 10c. Note the different wind scaling in (b).

## 7 Quantitative estimates of the model performances

The ability of the RAMS model to reproduce mesoscale circulations over the complex terrain of the Valencia region deserves a further, quantitative assessment. Table 2 gives a detailed statistical comparison between modeled and observed temperatures, specific humidities and winds. The meteorological stations are grouped into a coastal group (PO, CA, SA, RI) and an inland group (AL, XA, VI). Hourly outputs of the model were spatially interpolated to the location of each station and compared to the data. We calculated the Mean Error (ME) and the Root Mean Square Error (RMSE)

for temperature and humidity. For winds, we calculated the RMSE of the Vector Wind Difference (see Stauffer and Seaman 1990 and Table 2 caption), which takes into account both wind speed and direction errors, an important advantage in the presence of wind reversals. We also calculated the wind speed Index Of Agreement (IOA), which measures the degree to which a model's prediction is free of error (Willmott, 1981; a value of 0 means complete disagreement and a value of 1, perfect agreement).

**Table 2.** Model skills against surface observations. The seven surface stations are grouped by location into Coastal (PO, CA, SA and RI) and Inland (AL, VI and XA). N represents the number of observations included in the calculation of Mean Error, Root Mean Square Error, Index of Agreement and Vector Wind Difference for the respective variables. P represents the simulated value and  $P_o$  observation, while  $M_o$  is the average observed wind speed for N values in the corresponding formulas:

$$\text{ME} = \frac{1}{N} \sum_{i=1}^N (P - P_o)$$

$$\text{IOA} = 1 - \frac{N(\text{RMSE})^2}{\sum_{i=1}^N (|P - M_o| + |P_o - M_o|)^2}$$

$$\text{VWD} = \sqrt{(u - u_o)^2 + (v - v_o)^2}$$

$$\text{RMSE} = \sqrt{\frac{1}{N} \sum_{i=1}^N (P - P_o)^2}$$

1–2 July 2001		Wind vector ( $\text{ms}^{-1}$ )					Temp. ( $^{\circ}\text{C}$ )			q ( $\text{g kg}^{-1}$ )

	Night	0.92	1.51	0.59	2.07	45	0.81	1.34	45	1.62	2.52	45

## 7.1 Temperature and humidity

The temperature RMSE for all stations is  $1.49^{\circ}\text{C}$ , with a ME of  $0.04^{\circ}\text{C}$  (i.e., no bias). The model performances for temperature are very good, if one compares the small value of the model-data misfit (Table 2) with either the large diurnal cycle amplitude of  $15^{\circ}\text{C}$  (Fig. 4) or the coast minus inland temperature difference of  $4^{\circ}\text{C}$ . When only the coastal stations are considered, the model shows no bias ( $\text{ME}=0.03^{\circ}\text{C}$ ) and performs equally well for daytime as for night time. For inland stations, the model has a slight negative bias during the day ( $\text{ME}=-0.24^{\circ}\text{C}$ ) and a slight positive one during the night ( $\text{ME}=0.81^{\circ}\text{C}$ ). This overestimate of the diurnal temperature cycle does not degrade the model-data comparison, the RMSE values for the inland stations being similar to those of the coastal sites. For specific humidity, the value of the ME for all stations is small ( $0.33 \text{ g kg}^{-1}$ ), indicating a slight wet bias in the model. The model simulates specific humidity less well than it does temperature, as illustrated by an RMSE value of  $3.5 \text{ g kg}^{-1}$  (see also Fig. 4). One can further see from Table 2 that the model is too dry near the coast ( $\text{ME}=-2.7 \text{ g kg}^{-1}$ ) and too wet inland ( $\text{ME}=2.4 \text{ g kg}^{-1}$ ). The dry bias at the coastal stations is more pronounced during the night, while the wet bias at the inland stations is higher during the day.

## 7.2 Winds

The model shows a slight positive bias for winds ( $\text{ME}=0.36 \text{ m s}^{-1}$ ). Averaged for all the weather stations, we simulated typical nocturnal wind values of  $1 \text{ m s}^{-1}$ , and daytime values of  $6 \text{ m s}^{-1}$ , giving a diurnal amplitude  $5 \text{ m s}^{-1}$  (see Fig. 4). The simulated wind has an RMSE of  $1.54 \text{ m s}^{-1}$ , which suggests good model performances, given the amplitude of the signal. The wind speed IOA is 0.79, which is good, given the complexity of the flow and the fact that the seven stations represent contrasted wind regimes. The modeled wind speed at the coastal stations is accurate ( $\text{ME}=0.04$ ), but at the inland stations it is too high ( $\text{ME}=0.79 \text{ m s}^{-1}$ ). In both cases, the mean bias remains lower than the RMSE. At inland sites, the wind speed RMSE is similar between day and night (Table 2). Considering that nocturnal winds are four times weaker than diurnal ones, this suggests worse model skills inland at night. At coastal sites, a positive bias is found during the day ( $\text{ME}=+0.36 \text{ m s}^{-1}$ ), and a negative one during the night ( $\text{ME}=-0.56$ ). The model performances are again worse during the night. Overall, during the night, the model is too windy inland and not windy enough on the coast.

For all stations, the RMSE of Vector Wind Difference (RMSE-VWD) varies between 1.2 and  $2.5 \text{ m s}^{-1}$ , with a peak at  $4 \text{ m s}^{-1}$  (Fig. 12). It is clear from Fig. 12 that

the model simulates the wind vector worse for inland sites (VWD=7 m s<sup>-1</sup>) than for coastal sites. For the coastal sites, maximum RMSE-VWD occurs at 20:00 UTC and probably corresponds to the period of transition from the evening breeze to the nocturnal drainage. Except for evening transitions, the VWD values remain between 1 and 3 m s<sup>-1</sup> with no differences between coastal and inland locations. Minimum values of 1 m s<sup>-1</sup> are observed when the wind speed is weaker, e.g., during the night of 1 July.

## 8 Concluding remarks

By combining measurements and models, we were able to identify three characteristic mesoscale circulation regimes over the Valencia basin: 1) a nocturnal drainage flow with katabatic winds channeled by the valleys, 2) a combined breeze regime during which the sea breeze merges with convective uplift over the mountain ranges followed by a subsiding flow over the sea, and 3) an evening regime where a large inland pressure minimum can interact with the combined breeze and change the flow pattern. Such regimes commonly develop in the Valencia region under summertime conditions.

Soil moisture and soil temperature in the RAMS model were initialized by a 2-months spin-up. This simple initialization procedure improved the model results for the atmospheric fields as compared to prescribing global AVN soil moisture fields (Table 2). Yet, the initial soil moisture fields seem to cause a wet bias of the atmospheric model inland, and a dry bias near the coast (Figs. 4 and 5). Despite this, the model statistical skills and the model evaluation in terms of processes controlling temperature and wind diurnal variations, are both in good agreement with the data. In fact, our statistical scores were comparable to those of other similar simulation studies (Seaman and Michelson, 2000; Hanna and Yang 2001; Zhong and Fast 2003) and the model's ability to solve processes was similar to other studies in complex terrain (Zhong and Fast, 2003; De Wekker et al., 2005).

One of the most interesting processes captured here is the combined breeze circulation cell, in particular its subsidence branch towards the sea which increases the temperature inversion and confines mixing to the lowermost 200 m despite solar heating rates higher than 700 Wm<sup>-2</sup>. A second important process solved by the model is the evening circulation generated when solar warming diminishes to compensate the spatial pressure gradient formed after heat distribution during the daytime mesoscale processes development (Fig. 10e).

Finally, the main processes and spatial flow patterns during the nocturnal regime are captured with high accuracy, although the comparison with station observations (Fig. 4), and consequently the statistical evaluation (Table 2), show some discrepancies. It seems that the model results are horizontally more homogeneous than reality, and that the stable boundary layer parameterization of RAMS does not repro-

**Fig. 12.** Time series of VWD averaged for the seven surface stations (Solid) and grouped by location as Coast: PO, CA, SA and RI (dots) and Inland: AL, VI and XA (dashed).

duce the high spatial variability of the wind in the area. Additionally, the early morning temperature profile solved by the model shows some vertical mixing while the observed profile remains stable (Fig. 9). Both results could indicate that during the nocturnal regime the model produces too much mixing through interactions with orography and thus homogenizes the flow in excess. Although more experimental data would be desirable to confirm this hypothesis, our results are consistent with those of Zhong and Fast (2003), who, when evaluating different mesoscale models in complex terrain, found stronger vertical mixing and diffusion than the observed values during the nocturnal regime.

It is well known that landscape and terrain heterogeneities induce spatially varying surface turbulent fluxes, resulting in heterogeneous boundary layers (Pielke, 2002). Our model study area combines the difficulties of land-sea contrasts, mountainous terrain and larger-scale mesoscale circulations. The measurements available during the campaign allowed us to characterize the breeze development in the lower atmosphere near the coast, although vertical profiles to a higher altitude and further inland would also have been very useful. It is very encouraging to note that, despite the inherent complexity of the system studied and the limitations from unknown initial soil moisture distribution, the RAMS model could reproduce faithfully the main mesoscale flow patterns. However, it is important to keep in mind that turbulence parameterizations of mesoscale models are derived from theories and data for horizontally homogeneous steady-state boundary layers (Pielke, 2002). Thus, it is likely that the simulated turbulence fields (usually provided for dispersion models) could have been conditioned by this limitation. New data over complex terrain could be useful to test mesoscale models beyond their range of normal applicability, with the aim of eventually improving them.
