Minimizing Blocking Probability for MCRWA problem in WDM Networks: Exact Solutions and Heuristic Algorithms

Dinh Danh Le, Fen Zhou, and Miklós Molnár

Abstract— Given a sparse splitting WDM network, a set of available wavelengths, we investigate the problem of provisioning a set of multicast requests simultaneously with the objective of minimizing the blocking probability. Two blocking policies are taken into account: *full blocking probability* and *partial blocking probability*. As the problem is NP-hard, we propose an Integer Linear Programming (ILP) formulation with two variants (each for a blocking policy) to search for the optimal solution and several efficient *adaptive* heuristic algorithms to compute approximated solutions. Specially, instead of using light-trees, both ILP and heuristics use light-hierarchy, a recently optimal route under sparse splitting configurations. Extensive simulations reveal that our adaptive algorithms are able to compute near-optimal solution and they outperform *static* approaches under both blocking probability policies. The results also show that it is more advantageous to provision multiple multicast communications with light-hierarchies, since they are able to accommodate more requests and destinations compared with the light-tree solutions.

I. INTRODUCTION

Wavelength division multiplexing (WDM) is becoming a perfect core network infrastructure for communications with huge bandwidth capacity, data transparency and low latency. According to the Cisco traffic forecast report [1], the average global Internet traffic will increase threefold over the next five years between 2012 and 2017. Applications accounting for this growing mainly include video sharing between data centers, Internet Protocol Television (IPTV), Voice over Internet Protocol (VoIP), video conferences, etc., in which both bandwidth and quality of services (QoS) requirements are crucial regarding the members of multicast groups. Consequently, all-optical multicasting techniques are indispensable for accommodating aforementioned bandwidth-intensive and QoS-sensitive applications.

To support WDM multicasting efficiently, the networks should be equipped with multicast capable cross-connects (MC-OXC) that are capable of splitting an incoming signal to

multiple outgoing ports. However, they are costly in both fabrication and power consumption. Thus, it is common in current optical networks that not all but a subset of nodes are multicast capable, giving rise to the *sparse splitting* configuration [2]. The fact that a small percentage of MC-OXC mixed with multicast incapable cross-connects (MI-OXC) may suffice to support optical multicasting [3].

Traditionally, light-tree [4] was assumed to be a cost-effective route with the support of MC-OXC at the branching nodes. Recently, a new multicast structure called *light-hierarchy* was proposed in [5]. A light-hierarchy allows an MI-OXC to be crossed several times by using different input-output link pairs, and hence relaxes the constraint of tree structure required by the routing.

The routing and wavelength assignment (RWA) problem in all-optical networks consists in finding a route and assigning a wavelength for each connection request such that two routes cannot be assigned with the same wavelength if they share a common link. This constraint is known as the *distinct wavelength constraint* or *wavelength clash constraint* [6]. Moreover, in the absence of wavelength converters, another constraint namely *wavelength continuity constraint* must be satisfied: the same wavelength should be retained in all the links of the computed route. This problem was earlier posed just for unicast connections with the name Lightpath Establishment problem [7]. It was then extended to the case of multicast traffic for the names MCRWA [8] or MC-RWA [9]. For the sparse splitting networks, the MCRWA problem is subject to the *sparse splitting constraint*, i.e., only MC-OXC can be branching nodes in the computed routes (e.g., light-trees) while MI-OXC cannot.

The (MC)RWA problem can be either *static* or *dynamic*, depending on static or dynamic traffic patterns, respectively [10]. Among the two, the static (MC)RWA problem is more challenging since it has to deal with multiple requests simultaneously. The static routing and wavelength assignment is called *off-line* RWA since all the requests are known beforehand. The objective is mainly to minimize the resources (i.e., the number of wavelengths used, and/or the total link cost) provided that wavelength availability is sufficient to route all the requests; or to maximize the total number of requests provisioned, or equivalently, to minimize the blocking probability in the case of limited wavelengths.

Regarding blocking probability, two policies can be used: *full destination blocking probability (FB)* and *partial destination blocking probability (PB)* [8], [9]. Accordingly, under

FB policy, a multicast request is established if the source can reach to all the destinations. The appropriate metric to evaluate the solutions is session blocking probability (SBP). It is suitable for the applications that require all the multicast members receiving the data to take place, e.g., teleconferencing, distributed databases and distributed computing. On the other hand, in other applications such as video-on-demand, it may not be obligatory to reach all destinations at the same time. Rather, if some of the destinations are not reachable through the selected route, the connection is set-up between the source and the reachable destinations. This is the case where PB policy is supposed to use. Under PB policy, the metric of number of multicast sessions accepted (or SBP) is not suitable to evaluate the solutions. Instead, it is more appropriate to evaluate the maximum number of destinations served for all multicast sessions, i.e., the destination blocking probability (DBP).

In this paper, we deal with the static MCRWA problem in sparse splitting WDM networks (abbreviated as *MCRWA-SS*) where costly wavelength conversion is not available. We aim at minimizing the blocking probability of multicast demands for a given number of wavelengths. Two blocking models (FB and PB) with the corresponding metrics (SBP and DBP) are taken into account. To this end, we propose an Integer Linear Programming (ILP) formulation with two variants (each for a blocking policy) to search for the optimal solution. Since the ILPs are not able to run with large instances, we propose several scalable adaptive MCRWA strategies that integrate the routing and wavelength assignment tasks in one step. Specially, both exact solutions and heuristics compute light-hierarchies for each request instead of light-trees. Extensive simulations carried out on realistic optical networks reveal that our adaptive algorithms are able to compute near-optimal solution and they outperform the static (including fixed and fixed-alternate) MCRWA approaches. The results also show that light-hierarchies can help to reduce blocking probability better than light-trees.

The rest of the paper is organized as follows. The related work is reviewed in Section II. The problem of MCRWA is presented in Section III. Section IV gives a brief definition of hierarchies in graphs and light-hierarchy structure. The two ILP formulations for computing light-hierarchies are presented in Section V. In Section VI, after introducing the layered graph model, we present several adaptive heuristic algorithms. Numerical results are shown in Section VII to evaluate the performances of the proposed algorithms. The paper is concluded in Section VIII.

II. RELATED WORK AND MOTIVATION

The RWA problem was proved to be NP-hard [7]. The MCRWA problem is therefore NP-hard since it contains the RWA problem as a special case [3]. Solving the static (MC)RWA problem can be done either by integrating the routing (R) and wavelength assignment (WA) in one step (*coupled* approach), or by separating them into two separated steps (*decoupled* approach).

In the coupled approach, the routes are decided and then assigned wavelengths depending on the network status. Since

the network state changes dynamically during the route computation, this approach belongs to dynamic (or adaptive) RWA. Typical work of this approach include [6], [11]–[13]. In the decoupled (MC)RWA approach, a predetermined set of routes are computed in the physical topology as possible candidate routes for each connection request. Therefore, the routes cannot be changed during the wavelength assignment and this approach belongs to static RWA. The predetermined route set contains either a single route (in *fixed* routing) or multiple ones (in *fixed-alternate* routing) [14]. When a request is considered in the RWA process, these fixed routes are examined one by one until one is accepted. The request is blocked if all the routes are attempted without success. Most of the previous work employed the decoupled approach: [14]–[19].

Among the static (MC)RWA problems, the one for unicast traffic was extensively studied in the literature. Typical work can be found in [6], [18], [20], [21]. In [18], several static RWA strategies resulted from possible combinations of static routing and First-Fit wavelength assignment [14] are proposed to minimize the blocking probability. The authors in [6] studied the routing and wavelength assignment of static lightpath requests with the objective to minimize the number of wavelengths used. They proposed several adaptive heuristic algorithms by applying classical bin-packing algorithms. By taking both the ideas of bin-packing method and edge-disjoint paths, the authors in [21] proposed an GA-based algorithm to solve the static RWA problem. This algorithm outperforms the bin-packing based algorithms with a high computational time complexity. In [20], two static and three dynamic algorithms to reduce the blocking probability were also proposed. These algorithms resulted from the combination of fixed and fixed-alternate routes with First-Fit, Random, Most-Used and Least-Used [14] wavelength assignment schemes.

Besides, lots of published work in the literature [2], [5], [22]–[25] search for better solutions for the MCRWA problem under sparse splitting networks. However, they just focus on one multicast request, which do not fully reflect the nature of the MCRWA problem.

Few studies, however, tackled static MCRWA for multiple multicast requests [8], [9], [13], [19]. The static MCRWA problem was first studied in [8] and [9] targeting to the objective of minimizing the blocking probability. The work [19] focused on minimizing the number of wavelength converters (WCs) that are required to support the entire group of static multicast requests. However, these studies assumed to work on the networks wherein nodes are equipped with full splitting capability and/or wavelength converters, which does not closely reflect the currently sparse splitting network configurations. In [13], the authors studied the MCRWA problem under sparse splitting and sparse wavelength conversion networks. They proposed several heuristic algorithms based on "quasi-Prim" and "quasi-Kruskal" heuristics. Although the multi- λ -light-trees are used instead of light-trees, they do not make use of possible arcs as the light-hierarchies.

Recently, the multicast-related resource allocation in spectrum elastic optical networks (EONs) has been received lots of attention in the literature in order to better utilize fiber's bandwidth. The typical works [26], [27] tried to minimize the

blocking probability of multicast requests in EONs. However, only full blocking probability policy was taken into account, and the multicasting in EONs is not considered in our current work.

From the above analysis, there are two issues making the static MCRWA-SS problem challenging: multiple requests present together, and the sparse splitting constraint without wavelength conversion. This challenge builds up our motivation to tackle the problem.

III. MCRWA-SS PROBLEM DEFINITION

For simplicity, we assume that the MC-OXCs are realized by nonblocking Splitter-and-Delivery (SaD) switches [28] that can split an incoming light signal to as many outgoing ports as possible. Besides, we suppose that every MI-OXC supports Tap-and-Continue (TaC) [29]. A TaC-OXC can tap a small portion of power to the local station (when passing by a destination) and forward the remaining to one of the outgoing ports. Finally, no wavelength converter is available in the network.

A WDM network topology is represented by a digraph $G = (V, E)$ where V is a set of OXCs. Under sparse splitting, $V = MC \cup MI$, in which MC is the set of MC-OXCs, MI is the set of MI-OXCs. A link between two adjacent OXCs u and v consists of two optical fibers (u, v) and (v, u) in charge of the communications for two opposite directions. All the optical fibers constitute the arc set E , in which each arc $(u, v) \in E$ is associated with a cost c_{uv} . We suppose that all optical fibers support the same set of wavelengths $W = \{\lambda_1, \lambda_2, \dots, \lambda_{|W|}\}$. A set of multicast requests R are known beforehand, $R = \{r_i, i \in \mathcal{I}\}$, in which $r_i = (s_i, D_i) : s_i \in V, D_i \subseteq V \setminus \{s_i\}, \mathcal{I} = \{1, 2, \dots, |R|\}$. For each request, a set of light-structures LS (e.g., light-trees or light-hierarchies) is computed to delivery the multicast message from the source s_i to the set of destinations D_i while satisfying all the three constraints mentioned in Section I.

To evaluate the solutions, we define two quantitative metrics: session blocking probability (SBP) and destination blocking probability (DBP). The SBP corresponds to the full blocking policy, and the DBP corresponds to the partial blocking policy. Let B_i, B_i^d be two set of binary variables such that: $B_i = 1$ if request r_i is accepted, 0 otherwise; and $B_i^d = 1$ if destination d of request r_i is accepted, 0 otherwise. SBP and DBP are defined as follows:

$$SBP = 1 - \frac{\sum_{i \in \mathcal{I}} B_i}{|R|}$$

$$DBP = 1 - \frac{\sum_{i \in \mathcal{I}} \sum_{d \in D_i} B_i^d}{\sum_{i \in \mathcal{I}} |D_i|}$$

Formally, the MCRWA-SS problem can be defined as follows.

- **Input:** An WDM network $G = (V, E)$, a set of wavelengths W and a set of multicast requests $R = \{r_i, i \in \mathcal{I}\}$
- **Output:** A set of light-structures satisfying the three constraints

- **Objective:** Minimize SBP under FB policy or minimize DBP under PB policy

IV. LIGHT-HIERARCHY TO SOLVE THE MCRWA PROBLEM

In all-optical WDM networks, light-trees have been proposed for MCRWA problem. However, the tree structure restricts the network links to be passed no more than once, even though there is another (opposite) direction on the same link available to use. (Recall that in our study, we suppose that there are two (opposite) directed fibers in order to provide both directions in each link.) To make use of the possible directions in each link, the concept *hierarchy* is proposed in [30] to replace the traditional solutions (e.g., path, tree, etc.).

A. Hierarchies in graphs

Hierarchy is a graph related structure obtained by a homomorphism of a tree in a graph which is defined as follows. Let $Q = (W, F)$ and $G = (V, E)$ be two graphs. A hierarchy H is obtained by an application $h : W \rightarrow V$ mapping a vertex in W to each vertex in V under two conditions: (1) Q is a tree and (2) h is a homomorphism. Recall that h is a homomorphism if the mapping preserves the adjacency: $(u, v) \in F \Rightarrow (h(u), h(v)) \in E$. Fig. 1 gives an example of a mapping h from a tree Q to a graph G for a hierarchy H . Each vertex of tree Q is associated with a unique vertex of G . In the reverse direction, some vertices of G are mapped from several vertices in Q (vertices d and e). We label the vertex (vertices) in Q associated to the same vertex v in G as v^1, v^2, \dots, v^k . Especially, when the mapping h is injective, the hierarchy corresponds to a tree. The reader is encouraged to refer to [30] for a full definition with detail properties and possible applications of hierarchies.

Fig. 1: Mapping of vertices for a hierarchy

B. Light-hierarchy versus Light-tree

A *light-hierarchy* is a directed partial spanning hierarchy realized by using a single wavelength respecting the optical constraints. Equivalently, a light-hierarchy is a hierarchy that has no duplicated arc but is free of repetition of nodes. Thus, light-hierarchy is a general case of light-tree.

An example showing the advantages of light-hierarchy over light-tree can be seen in Fig. 2. The network topology is in solid line; all the nodes are MI-OXC except node 1, an arrival multicast request $(s, \{d_1, d_2\})$. The optimal light-tree solution is shown in the dash-dotted line in Fig. 2(a) with the total cost of 7 (supposed that all links have identical cost). However, a light-hierarchy can be found by using different ingress-egress fibers crossing node 3 as shown in Fig. 2(b) with the total cost of 6. The solution can still be improved by another light-hierarchy that utilizes the links in both directions as shown in Fig. 2(c) with the total cost of 5. Obviously, the light-hierarchy solution outperforms the light-tree solution.

Fig. 2: Light-hierarchy solution versus light-tree solution

V. LIGHT-HIERARCHY BASED ILP FORMULATIONS WITH FULL BLOCKING AND PARTIAL BLOCKING POLICY

With light-hierarchy structure, the sparse splitting constraint could be relaxed to some extent. Consequently, more destinations may be served in one light-hierarchy. This is why the light-hierarchy structure can be the optimal solution. In this section, the integer linear programming (ILP) method is applied to search for the optimal light-hierarchy solution under each of aforementioned blocking probability (FB and PB) policies. In general, the two ILP formulations are similar to each other. They differ from one another in the objective function and some related constraints.

To formulate, some notations mentioned in Section III are reused, including G, V, E, W, R . Besides, several additional notations are predefined in Table I and four ILP variable vectors $L_{uv}^{i\lambda} \in \{0, 1\}^{|R| \times |W| \times |E|}$, $F_{uv}^{i\lambda} \in \mathbb{N}^{|R| \times |W| \times |V|}$, $B_i \in \{0, 1\}^{|R|}$, and $B_i^d \in \{0, 1\}^{|R| \times |D_i|}$ as in Table II.

A. ILP with Full Blocking Policy (ILP-FB)

For ease of presentation, let $LH^{i\lambda}$ be a light-hierarchy on wavelength λ , which is used for the request r_i . The binary variable $L_{uv}^{i\lambda}$ denotes whether the arc (u, v) is used by $LH^{i\lambda}$, integer variable $F_{uv}^{i\lambda}$ represents the number of destination

TABLE I: Network Parameters

λ	: A wavelength, $\lambda \in W$.
$N^+(v)$: Extremities of the outgoing arcs from OXC v .
$N^-(v)$: Extremities of the incoming arcs to OXC v .
Deg	: The maximum nodal degree in G .
(u, v)	: The arc from OXC u to v .
c_{uv}	: The cost of the arc from OXC u to v .
Δ	: An integer big enough such that $\Delta > W \times \sum_{(u,v) \in E} c_{uv}$.
MC	: The set of MC-OXCs in G .
MI	: The set of MI-OXCs in G .
$i \in \mathcal{I}$: The index i / The index set \mathcal{I} of R .
f_i	: The importance of multicast request r_i .

TABLE II: ILP Variables

$L_{uv}^{i\lambda} \in \{0, 1\}$: Equals 1 if multicast request r_i uses wavelength λ on link (u, v) , equals 0 otherwise.
$F_{uv}^{i\lambda} \in [D_i]$: Commodity flow. Denotes the number of destinations in request r_i receiving a flow from s_i via arc (u, v) on λ .
$B_i \in \{0, 1\}$: Equals 1 if request r_i is accepted, 0 otherwise.
$B_i^d \in \{0, 1\}$: Equals 1 if destination d of request r_i is accepted, 0 otherwise.

OXCs in the request r_i receiving a flow from s_i via arc (u, v) on λ , and binary variable B_i decides whether the request r_i is accepted. As we suppose that the wavelength availability is limited, the original objective of our problem is to minimize the session blocking probability (SBP), or equivalently to maximize the number of accepted requests. To provide a flexible solution, we introduce a variable f_i for the importance of the request r_i , and objective is now to maximize the overall importance of all accepted multicast requests, i.e., $\sum_{i \in \mathcal{I}} f_i \cdot B_i$. Secondly, we also try to minimize wavelength channel cost. To this end, a big enough integer Δ should be introduced such that the contribution of $\Delta \times \sum_{i \in \mathcal{I}} f_i \cdot B_i$ in the overall objective function should be much bigger than the wavelength channel cost times $|W|$, i.e. $\Delta > |W| \times \sum_{(u,v) \in E} c_{uv}$.

Hence the general objective function can be expressed as follows:

$$\text{Maximize} : \Delta \cdot \sum_{i \in \mathcal{I}} f_i \cdot B_i - \sum_{i \in \mathcal{I}} \sum_{\lambda \in W} \sum_{(u,v) \in E} c_{uv} \cdot L_{uv}^{i\lambda} \quad (1)$$

subject to the light-hierarchy constrains (2)-(8) and the connectivity constraints (9)-(15). In the following, we use $\forall i, \forall d, \forall \lambda$, and $\forall (u, v)$ to imply $\forall i \in \mathcal{I}, \forall d \in D_i, \forall \lambda \in W$, and $\forall (u, v) \in E$ respectively.

1) *Light-hierarchy Constraints:*

$$\sum_{v \in N^-(s_i)} L_{vs_i}^{i\lambda} = 0, \quad \forall i, \forall \lambda \quad (2)$$

$$\sum_{u \in N^-(v)} L_{uv}^{i\lambda} \leq B_i, \quad \forall i, \forall \lambda, \forall v \in MC \setminus \{s_i\} \quad (3)$$

$$\sum_{u \in N^+(v)} L_{vu}^{i\lambda} \leq \sum_{u \in N^-(v)} L_{uv}^{i\lambda} \cdot Deg, \quad \forall i, \forall \lambda, \forall v \in MC \setminus \{s_i\} \quad (4)$$

$$\sum_{u \in N^+(v)} L_{vu}^{i\lambda} \leq \sum_{u \in N^-(v)} L_{uv}^{i\lambda}, \quad \forall i, \forall \lambda, \forall v \in MI \setminus \{s_i\} \quad (5)$$

$$\sum_{u \in N^+(v)} L_{vu}^{i\lambda} \geq \sum_{u \in N^-(v)} L_{uv}^{i\lambda}, \quad \forall i, \forall \lambda, \forall v \notin D_i \quad (6)$$

$$\sum_{i \in \mathcal{I}} L_{vu}^{i\lambda} \leq 1, \quad \forall \lambda, \forall (v, u) \quad (7)$$

$$L_{vu}^{i\lambda} \leq B_i, \quad \forall i, \forall \lambda, \forall (v, u) \quad (8)$$

For any $i \in \mathcal{I}$ and $\lambda \in W$, constraint (2) ensures that the light-hierarchies for a multicast request r_i are rooted at the source node s_i . Constraint (3) guarantees that each MC-OXC has at most one input arc in each light-hierarchy $LH^{i\lambda}$, while constraint (4) indicates that each MC-OXC is able to split the light signal. Constraints (4) and (5) make sure that no OXC in V can be the root of $LH^{i\lambda}$ except the source node s_i . Constraint (5) together with constraint (6) indicates an intermediate MI-OXC may have multiple input links and multiple output links with the help of cross pair switching, but the number of input links must be equal to the number of output links. Constraint (6) determines that only the destinations in D_i can be leaf nodes of a light-hierarchy $LH^{i\lambda}$. For all $i \in \mathcal{I}$, constraint (7) corresponds to the distinct wavelength constraint, which forbids two light-hierarchies to share a link using the same wavelength. Constraint (8) indicates that there is no link used for the blocked request.

With the above the light-hierarchy structure constraints, we can not guarantee the connectivity of the light-hierarchy. Thus, we propose a commodity flow method to impose supplementary constraints on variables $L_{uv}^{i\lambda}$ so that the connectivity of the resultant light-hierarchy could be guaranteed.

2) *Connectivity Constraints:* To establish a multicast request, several light-hierarchies may be required. And the same destination may be spanned by several light-hierarchies. However, a destination can only be served in one light-hierarchy to consume the light signal (i.e. receive the multicast messages), while it is spanned in the other light-hierarchies to uniquely forward the light signal to the successor node.

$$\sum_{\lambda \in W} \sum_{v \in N^+(s_i)} F_{s_iv}^{i\lambda} = |D_i| \cdot B_i, \quad \forall i \quad (9)$$

$$\sum_{\lambda \in W} \sum_{v \in N^-(d)} F_{vd}^{i\lambda} = \sum_{\lambda \in W} \sum_{v \in N^+(d)} F_{dv}^{i\lambda} + B_i, \quad \forall i, \forall d \quad (10)$$

$$\sum_{v \in N^-(d)} F_{vd}^{i\lambda} - B_i \leq \sum_{v \in N^+(d)} F_{dv}^{i\lambda}, \quad \forall i, \forall d, \forall \lambda \quad (11)$$

$$\sum_{v \in N^-(d)} F_{vd}^{i\lambda} \geq \sum_{v \in N^+(d)} F_{dv}^{i\lambda}, \quad \forall i, \forall d, \forall \lambda \quad (12)$$

$$\sum_{u \in N^-(v)} F_{uv}^{i\lambda} = \sum_{u' \in N^+(v)} F_{vu'}^{i\lambda}, \quad \forall i, \forall \lambda, \forall v \notin D_i \quad (13)$$

$$F_{uv}^{i\lambda} \geq L_{uv}^{i\lambda}, \quad \forall i, \forall (u, v), \forall \lambda \quad (14)$$

$$F_{uv}^{i\lambda} \leq |D_i| \times L_{uv}^{i\lambda}, \quad \forall i, \forall (u, v), \forall \lambda \quad (15)$$

If multicast request r_i is accepted, i.e., $B_i = 1$, constraint (9) indicates that s_i should generate $|D_i|$ commodity flow so that each destination of this multicast request can be served once. Constraints (10) and (11) ensure that each destination of request r_i must consume one and only one commodity flow generated by s_i in all the light-hierarchies built for this request. In other words, they guarantee each destination is reachable from the source s_i in all light-hierarchies. Constraint (13) guarantees that the flow does not drop after passing a non-member node. Relationship between $L_{uv}^{i\lambda}$ and $F_{uv}^{i\lambda}$ is expressed by constraints (14) and (15). They assure that a link should carry non-zero flow if it is used in a light-hierarchy, and the value of this flow should not beyond the total flow emitted by the source node.

B. *ILP with Partial Blocking Policy (ILP-PB)*

The ILP-PB is formulated based on the previous ILP-FB with some changes. With the partial blocking policy (PB), some destinations in a request may be rejected while the other destinations in the same request are served. Under the PB policy, the metric of number of multicast request accepted (or *SBP*) is not suitable for this scenario to evaluate the algorithm performance. Instead, it is more interesting to evaluate the maximum number of destinations served for all multicast requests (equivalently, to minimize the *DBP*). Thus, we use the ILP variable B_i^d instead of B_i , and several constraints should be changed accordingly. Also, the link usage (resource) should be minimum. Accordingly, the new objective function can be expressed as:

$$\text{Maximize} : \Delta \cdot \sum_{i \in \mathcal{I}} \sum_{d \in D_i} B_i^d - \sum_{i \in \mathcal{I}} \sum_{\lambda \in W} \sum_{(u,v) \in E} c_{uv} \cdot L_{uv}^{i\lambda} \quad (16)$$

To adjust the previous ILP-FB model for the partial blocking policy, we replace constraints (9)-(11) by constraints (19)-(21).

Besides, the constraints (3) and (8) are changed as follows:

$$\sum_{u \in N^-(v)} L_{uv}^{i\lambda} \leq 1, \quad \forall i, \forall \lambda, \forall v \in MC \setminus \{s_i\} \quad (17)$$

$$L_{vu}^{i\lambda} \leq \sum_{d \in D_i} B_i^d, \quad \forall i, \forall \lambda, \forall (v, u) \quad (18)$$

Constraint (17) makes sure the unique input link coming to any MC-OXCs. Constraint (18) guarantees that there is no link used for a request if all of its destinations are blocked.

Constraint (22) ensures that if d of request i is rejected, then d will not have any input link reserved for request i on any wavelength.

$$\sum_{\lambda \in W} \sum_{v \in N^+(s_i)} F_{s_i v}^{i\lambda} = \sum_{d \in D_i} B_i^d, \quad \forall i \quad (19)$$

$$\sum_{\lambda \in W} \sum_{v \in N^-(d)} F_{vd}^{i\lambda} = \sum_{\lambda \in W} \sum_{v \in N^+(d)} F_{dv}^{i\lambda} + B_i^d, \quad \forall i, \forall d \quad (20)$$

$$\sum_{v \in N^-(d)} F_{vd}^{i\lambda} - B_i^d \leq \sum_{v \in N^+(d)} F_{dv}^{i\lambda}, \quad \forall i, \forall d, \forall \lambda \quad (21)$$

$$L_{ud}^{i\lambda} \leq B_i^d, \quad \forall i, \forall d, \forall u \in N^-(d), \forall \lambda \quad (22)$$

In short, ILP-PB is subject to light-hierarchy constraints: (2), (4)-(7) and (17)-(18), and connectivity constraints: (12)-(15), and (19)-(22).

C. Comparison of two ILP models

In the proposed ILP-FB model, there are $|W| \times (2|R| \times |E| + 1)$ variables and $|R| \times |W| \times (3|V| + 3|E| + |MC|) + (2 + |R|) \times |W| \times |E| + \sum_{i \in \mathcal{I}} |D_i| + |R| + |W|$ constraints. Regarding the ILP-PB model, there are $\sum_{i \in \mathcal{I}} |D_i|$ more variables and $|W| \times \sum_{i \in \mathcal{I}} \sum_{d \in D_i} |N^-(d)|$ more constraints.

The two ILP formulations above are run to search the exact solutions for the two problems corresponding to the two blocking policies. The results are used as the references to evaluate the proposed heuristics presented in the next sections.

VI. HEURISTIC SOLUTIONS

In this section, we first present our implementation for existing static routing approaches, known as *fixed* and *fixed-alternate* strategies. In order to design adaptive strategies, a layered graph model is introduced. We then describe the Arc Removal Light-Hierarchy (ARLH) algorithm which plays a core role in our proposed adaptive strategies presented afterwards.

A. Existing Static Strategies

For static strategies, we employ Member-Only (MO) algorithm [2] for routing and First-Fit scheme [14] for wavelength assignment. Note that due to the sparse splitting constraint, a single light-tree may not sufficient to accommodate a request. So a set of light-trees (i.e., a light-forest) may need to be computed. For the *fixed* strategy, the light-trees for each request are computed one-by-one for each request on the physical topology. Each light-tree is tried to assign an available wavelength (employing First-Fit) complying the distinct wavelength constraint until the wavelength pool is exhausted. Under full blocking (FB) policy, the requests having at least one unreachable destination are blocked. Thus, whenever a light-tree (say, for request r) is not accepted, the algorithm blocks r by excluding it from the request set, freeing the wavelengths that have been assigned for the previous light-trees for r , and continuing with the next request. On the other

hand, if partial blocking (PB) policy is applied, all the light-trees for r are considered even though some of them may not be accepted. If request r is not accepted, the reachable destinations are still adopted.

In *fixed-alternate* strategy, for a request we computed two arc-disjoint trees for each light-tree in the light-forest. If the first light-tree is not accepted, the alternate tree is tried. The request is blocked if none of the two light-trees is accepted. The two blocking policies are also applied in the same way as mentioned with fixed routing scheme above. In the simulations, we name MO-FIX for MO with fixed routing scheme and MO-ALT for MO with fixed-alternate routing scheme, respectively.

B. Layered graph model

In order to design coupled (adaptive) strategies for the considered MCRWA-SS problem, we modify the layered graph model that was first proposed in [11] to solve RWA with unicast traffic and then was used in [13] for the MCRWA problem. The proposed algorithms are operated on the layered graph instead of the physical topology. In this model, the physical topology is replicated into $|W|$ *directed* wavelength graphs $G_\lambda, \lambda = 1, 2, \dots, |W|$ or *layers*, each layer corresponds to a distinct wavelength. Since we assume that no wavelength converter is available in the network, there is no interconnection between the layers. With the assumption that all the fibers have the same set of wavelengths, all the wavelength graphs (layers) are identical at the beginning. However, during the network operation, it is continuously changed to immediately reflect the current network state. Given a physical topology modelling a network with three wavelengths ($\lambda_1, \lambda_2, \lambda_3$) as shown in Fig. 3(a), a constructed layered graph is shown in Fig. 3(b). Note that, the physical topology appears as an undirected graph, but its layered graph is a collection of bidirected graphs because we assume that each network link has two directed fibers (cf. Section III).

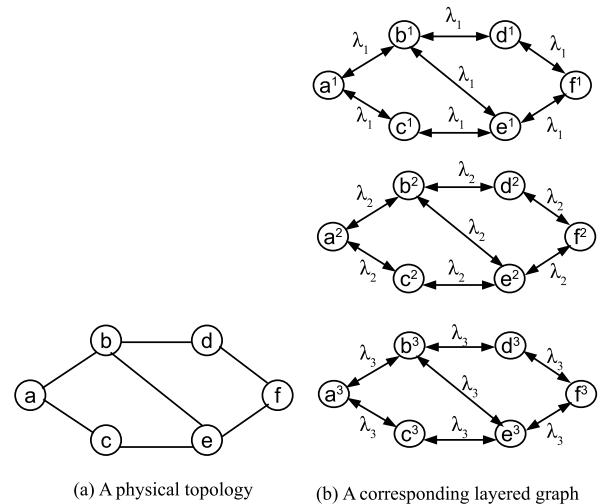

Fig. 3: An example of a layered graph

Many interesting properties can be obtained from the layered graph model, which the physical topology model does

not have, including [13]:

- 1) Solving MCRWA in one step. Wavelength assignment is accomplished when routing.
- 2) Low computational complexity and high performance. Any algorithm running on each wavelength graph generally takes no more computational time than running on physical topology graph. Moreover, since the wavelength assignment is done when routing, the time complexity of the WA subproblem is eliminated.
- 3) Immediately updating the latest network state. Whenever a wavelength is assigned, the corresponding arc is removed from the wavelength graph. Thus the layered graph keeps track of and reflects the updated status of the network.

C. Arc Removal Light-Hierarchy Algorithm (ARLH)

The Arc Removal Light-Hierarchy Algorithm is designed to compute a light-hierarchy for a multicast request r on wavelength graph G_λ . As discussed in the previous part, an MI-OXC could be visited more than once in a light-hierarchy, while the arc already used in a sub light-hierarchy cannot be used any longer in the same light-hierarchy. As a result, the used arc in a sub light-hierarchy is useless for the expansion of the light-hierarchy to the remaining destinations of the considered request. From this point, an Arc Removal Light-hierarchy algorithm is designed to compute the light-hierarchies, such that the used arc is removed from the wavelength graph whenever it is used. ARLH employs the basic idea of the Minimum Path Heuristic [31].

Normally, ARLH computes one rooted light-hierarchy (LH) at a time. However, it may produce no LH due to the sparse splitting and/or lack of wavelengths on the wavelength graph. Also, the computed LH may or may not cover all the destinations of the considered request. If the request is not entirely provisioned, the remaining of it will be reconsidered in the next runs. Initially, the LH consists only the source of the multicast request (cf. Algorithm 1). ARLH then extends LH by iteratively adding destinations one by one by the shortest paths. At each iteration, the algorithm finds the nearest destination d from the MC_SET^1 of the current LH . Then the corresponding shortest path $SP(c, d)$ in wavelength graph G_λ is added to LH (c is the nearest node in MC_SET to d). Then the arcs in the shortest path $SP(c, d)$ are removed from the wavelength graph G_λ and MC_SET is updated. In the next iteration, the nearest destination and the shortest path are computed in the updated wavelength graph of G_λ . The algorithm terminates when there is no destination remaining, or the computed LH cannot be extended. It is definitely true that the light-hierarchies computed respect the splitting constraint.

D. Adaptive strategies for MCRWA-SS problem

In what follows we describe several strategies for the MCRWA-SS problem. In these strategies the routing is performed by applying ARLH algorithm on the layered graph to

¹ MC_SET includes the MC-OXCs and the leaf MI-OXCs in the current computed light-hierarchy.

Algorithm 1 Arc Removal Light-Hierarchy Algorithm

Input: A wavelength graph G_λ , a multicast request $r_i = (s_i, D_i)$.
Output: A light-hierarchy LH_i^λ on wavelength λ for r_i .

- 1: $MC_SET \leftarrow \{s_i\}$
- 2: $LH_i^\lambda \leftarrow \{s_i\}$
- 3: **while** (D is reachable from MC_SET in LH_i^λ) **do**
- 4: **for all** ($c \in MC_SET$) and ($d \in D_i$) **do**
- 5: Compute the shortest path $SP(c, d)$ in G_λ
- 6: **end for**
- 7: Find the shortest path $SP(\mathbf{c}, \mathbf{d})$, with the corresponding nearest destination \mathbf{d} and MC_SET node \mathbf{c}
- 8: $LH_i^\lambda \leftarrow LH_i^\lambda \cup SP(\mathbf{c}, \mathbf{d})$
- 9: $MC_SET \leftarrow MC_SET \cup \{\text{MC in } SP(\mathbf{c}, \mathbf{d})\} \cup \{\mathbf{d}\}$
- 10: **if** (\mathbf{c} is an MI-OXC) **then**
- 11: $MC_SET \leftarrow MC_SET \setminus \{\mathbf{c}\}$
- 12: **end if**
- 13: $D_i \leftarrow D_i \setminus \{d\}$
- 14: $G_\lambda \leftarrow G_\lambda \setminus \{\text{arcs in } SP(\mathbf{c}, \mathbf{d})\}$
- 15: **end while**

compute the light-hierarchies for the requests, then the light-hierarchies are assigned with the corresponding wavelengths straightforward. By this way, we integrate the routing and wavelength assignment tasks in one step.

1) *Sequential Request (seqR)*: For each request r_i to be considered (selected according to the indexed order $r_1, r_2, \dots, r_{|R|}$), compute the light-hierarchies employing ARLH on the layers (wavelength graphs) $\lambda_1, \lambda_2, \dots, \lambda_{|W|}$ one by one (according to the indexed order). Whenever a light-hierarchy is computed in certain layer, it is directly assigned the corresponding wavelength. Then the affected layers are updated in such a way that the arcs used for wavelength assignment are removed from the wavelength graphs. Repeat the operations until all the requests are attempted. The pseudo code of *SeqR* algorithm is shown in Algorithm 2.

Note that we use both aforementioned blocking policies and apply them for all the proposed algorithms described below. Under FB policy, a request is considered to be accepted if all of its destinations are accepted. If not, the request is blocked, the algorithm frees the wavelengths (restore the status for the used arcs) that have been assigned for the light-hierarchies computed for it. In contrast, when PB policy is used, if the request is not totally accepted, the accepted destinations are still served.

This strategy is natural and relatively straightforward. It does not need the global information of all the requests. Thus it can be applied for the dynamic traffic case.

2) *Smallest Request First (SRF)*: It is similar to *seqR*, for each iteration, except that it selects the smallest request (in terms of number of destinations or group size) to consider first. To this end, the requests are sorted beforehand according to the *non-descending* order of group size. After that it follows the same operations as *seqR* for all the requests considered. The idea of this strategy (choosing the smallest request first) based on the observation that more number of small items can be put into a bin with limited capacity than putting larger items

first. *SRF* can help to increase the total number of requests accepted, and hence can achieve lower the session blocking probability (SBP).

3) *Largest Request First (LRF)*: It is somewhat contrary to *SRF*, instead of provisioning the smallest request, it chooses the largest one first. By choosing the largest request sooner, more destinations might be adopted, hence *LRF* can increase the total number of destinations served or increase the destination blocking probability (DBP). However, it can also increase the probability that small requests will easily be blocked, leading high SBP compared with *SRF*.

Algorithm 2 Sequential Request Algorithm

Input: A layered graph $LG = \{G_\lambda, \lambda = 1, 2, \dots, |W|\}$, a set of multicast requests R .

Output: A set of light-hierarchy LHs

- 1: **for all** $r_i \in R, i = 1, 2, \dots, |R|$ **do**
 - 2: **for all** $\lambda \in W, \lambda = 1, 2, \dots, |W|$ **do**
 - 3: compute light-hierarchy LH_i^λ on G_λ using $ARLH(G_\lambda, r_i)$
 - 4: assign λ to LH_i^λ
 - 5: **end for**
 - 6: **end for**
 - 7: calculate blocking probability metrics (i.e., SBP and DBP under FB policy or BP policy).
-

E. Computational Complexity

Theorem 1: Let n be the number of destinations accepted for all the requests. The time complexity of the three adaptive algorithms (*SeqR*, *SRF* and *LRF*) are $O(n \times (|V| \log |V| + |E|))$.

Proof: We analyse the time complexity of *SeqR* only, it is then deduced for the other two. Let us take a look in the Algorithm 2, the most expensive operation is in line 3 where *ARLH* is called. Since W is limited, we suppose that n_i is number of destinations of request r_i that are reached ($0 \leq n_i \leq |D_i|$). To find the nearest destination in D_i from the MC_SET in any wavelength graph G_λ , Dijkstra's algorithm should be used once. Because, the connector nodes in MC_SET could be virtually gathered and viewed together as a virtual source (e.g., set their distances to the source as 0) and it is sufficient to find the nearest destination and the distances by constructing a single shortest path tree in G_λ from the source to all the destinations. Since n_i destinations are reached, n_i steps are required. Thus the Dijkstra's algorithm should be used n_i times during the construction of light-hierarchies for request r_i . The time complexity of Dijkstra's algorithm implemented by a Fibonacci heap is $O(|V| \log |V| + |E|)$ [32]. So, the time complexity of the proposed *SeqR* algorithm is

$$\sum_{i=1}^{|R|} n_i \times O(Dijkstra) = n \times O(|V| \log |V| + |E|)$$

Since *SRF* and *LRF* have one complement step of sorting the requests before calling *SeqR*, and this step needs much less time compared to the active operation (in line 3) of the Algorithm 2, we can state that all the three algorithms have the same complexity. ■

VII. PERFORMANCE EVALUATION

We divide the simulations into two parts. The first part is to evaluate the proposed heuristics with the exact solutions obtained from corresponding ILP formulations with small instances. The second part presents the comparison among heuristics with larger realistic configurations.

A. Heuristics versus ILP results

Due to the exponential complexity of ILP formulations, only small instances can be possible. We use the 14-node NSF network (cf. Fig. 4(a)). To simulate with sparse splitting capacity, the ratio of MC-OXCs is set to 0/14 and 3/14. Given S MC-OXCs ($S = |MC|$), 10 multicast requests are randomly generated in a manner that the source and destinations are distributed randomly and uniformly in the networks. The number of wavelengths varies from 1 to 3. The ILP were solved with CPLEX 12.5. Both ILPs and heuristics were run on a machine with Intel Core i3, 2.20GHz processor and 4GB of RAM. We ran ILPs for maximum of one-hour each run. If the solver cannot find the optimal solution within one hour, the quasi-optimal solution with the gap of 1% to the optimal is accepted. Otherwise, the instance is considered failed and our program directs the ILP to run on another instance. The simulation results are shown in Table III. Each value on the table is the average of 20 successful individual runs. For simplicity, we suppose that all requests have the same importance, i.e., $f_i = 1, \forall i \in \mathcal{I}$.

TABLE III: Performance comparison of heuristics to ILP solutions.

	Algos	W =1		W =2		W =3		Avg Ratio	
		S=0	S=3	S=0	S=3	S=0	S=3	S=0	S=3
SBP (%)	MO-FIX	80	73	64	63	43	50	2.2	2.4
	MO-ALT	79	72	61	59	37	47	2.1	2.3
	SeqR	74	65	46	36	21	14	1.7	1.5
	SRF	62	60	40	36	17	13	1.4	1.4
	LRF	79	77	53	46	23	21	1.8	1.8
	ILP	58	52	24	22	2	4	1.0	1.0
DBP (%)	MO-FIX	80.5	80.7	65.9	65.2	44.1	54.3	2.6	2.8
	MO-ALT	77.1	78.4	61.3	63	38.5	46.7	2.4	2.6
	SeqR	61.9	60.5	33.5	31.1	11.1	5.9	1.4	1.4
	SRF	68.7	68.5	38.8	35.2	10.1	4.1	1.6	1.5
	LRF	58.9	56.9	28.5	24	6.7	4.3	1.3	1.2
	ILP	54	54.3	19.1	15.2	1.2	1.7	1.0	1.0

The table presents the session blocking probability (SBP) under full blocking (FB) policy and the destination blocking probability (DBP) under partial blocking (PB) policy. As it is shown, the two static strategies (*MO-FIX* and *MO-ALT*) suffer from high SBP as well as high DBP compared to the adaptive ones. Among the adaptive heuristics, *SRF* achieves the lowest ratio (1.4, on average) compared to the optimal solution on SBP, but suffers from a relatively high DBP (1.55, on average). In contrast, *LRF* heuristic obtains the lowest ratio (1.25, on average) compared to the optimal solution on DBP, but with a quite high SBP (1.8, on average). *SeqR* performs more steadily, providing a good tradeoff between the other two.

B. Comparison of heuristics

1) *Simulation settings:* In this part, we use the realistic US Longhaul network (28 nodes, 45 links) (cf. Fig. 4(b)) as the

Fig. 4: Testbeds for simulations

platform for our simulations. We conduct the simulations by setting up three contexts:

- 1) Given a number of requests $|R|$, the number of MC-OXC S , evaluate the solutions versus the number of wavelengths $|W|$. In particular, $|R| = 200$, $S = 6$, $|W|$ varies in the list (10,20,...,100) (cf. Fig. 5).
- 2) Given $|R|$ requests, $|W|$ wavelengths, evaluate the solutions versus S (the sparse splitting level). In particular, $|R| = 200$, $|W| = 50$, S varies in the list (0,3,...,21) (cf. Fig. 6).
- 3) Given $|W|$ wavelengths, S MC-OXC, evaluate the solutions versus $|R|$. In particular, $|W| = 50$, $S = 6$, $|R|$ varies in the list (50,150,...,300) (cf. Fig. 7).

In our simulations: MC-OXC are randomly selected throughout the network such that only nodes with degree larger than two are possibly selected for MC-OXC²; multicast requests are randomly generated such that their group sizes are randomly selected in the range of $(1, |V| - 1)$; and 100 simulations are conducted for a given triplet $(|W|, S, |R|)$. Hence, the value of each point in the graphs is the average of 100 samples. Both session blocking probability (SBP) and destination blocking probability (DBP) are calculated to evaluate the solutions under each blocking probability policy. For the reason mentioned in Section II, we just show SBP under full blocking probability (FB) policy and DBP under partial blocking probability (PB) policy.

2) *Adaptive Strategies versus Static Strategies:* Since all the described adaptive strategies compute light-hierarchies for their solutions. To be fair, the two approaches should be compared on the same light-structure. To this end, we make a little modification in the *ARLH* algorithm to compute light-trees.

²In 28 node-Longhaul topology, there are 7 nodes with degree of 2, that is why we set up to 21 nodes to be MC-OXC.

The modified version is basically the same *ARLH*, except that whenever a destination is added, all the intermediate MI-OXC and their adjacent arcs are removed from the wavelength graph (to retain the tree structure). In particular, we develop a light-tree version based on Sequential Request algorithm and call it Sequential Request with Light-trees (*seqR-LT*).

Let us focus on *seqR-LT* and the two static algorithms (namely, *MO-FIX* and *MO-ALT*). It is easy to realize the dominance of *seqR-LT* to the other two in all the simulation contexts shown in the figures. In particular, as shown in Fig. 5(a) on SBP, the gap between *seqR-LT* and the two achieves maximum in both SBP and DBP at $|W| = 70$ wavelengths: 33% improvement compared with *MO-FIX*, and 25% improvement compared with *MO-ALT*. Similarly, as shown in Fig. 5(b) on DBP, also at $|W| = 70$ wavelengths, *seqR-LT* blocks 42% fewer destinations than *MO-FIX*, and blocks 29% fewer destinations than *MO-ALT*.

We also analyse the performances of considered strategies versus sparse splitting level of the networks (e.g., the number of MC-OXC). As it is shown in Fig. 6, all the algorithms get lower blocking probability with denser MC-OXC. Comparing *seqR-LT* with static strategies, the average gap on SBP is 23% and 17% compared with *MO-FIX* and *MO-ALT*, respectively (cf. Fig. 6(a)); the average gap on DBP is 36% and 26%, respectively (cf. Fig. 6(b)).

The results presented above is reasonable, because adaptive strategies try to route as many requests as possible by making use of the available wavelengths on the layered graph, resulting in lower blocking probability. Meanwhile, fixed strategies just compute light-trees in the physical topology neglecting the current state of network, giving high blocked probability. Fixed-alternate strategy has more choices compared with fixed strategy, it still suffers from high blocking probability due to the inherent shortcoming of static routing.

3) *Light-hierarchy versus Light-tree:* To show the difference between the light-hierarchy solution and the light-tree solution, we compare the performance of *seqR* (for light-hierarchy solution) and *seqR-LT* (for light-tree solution). As we can see from the figures, *seqR* outperforms *seqR-LT* in both metrics used in all the studied contexts. The advantage of *seqR* can be seen most clearly in Fig. 6 at very sparse splitting level. Specifically, the performance gap between the two algorithms gets pick at zero MC-OXC: as shown in Figs. 6(a) and 6(b), *seqR* achieves 5.5% on SBP and 4.6% on DBP improvement over *seqR-LT*. On average, *seqR* achieves 2.8% on SBP and 2.4% on DBP better than its counterpart *seqR-LT*.

In short, the light-hierarchy based solutions are better than the light-tree counterparts in both blocking metrics, especially at very sparse splitting level. This is because light-hierarchies allow to exploit all the available wavelengths in current network state by taking advantage of using all possible directions (arcs) on every link and cross connects in MI-OXC. Since there are more selections to route the requests, light-hierarchies allow to reduce blocking probability better than light-trees.

4) *Comparison of adaptive light-hierarchy based strategies:* As we can see from all the overall results, among three proposed adaptive strategies based on light-hierarchy, *SRF* does best on SBP but worst on DBP, *LRF* works best on DBP

but worst on SBP, and *seqR* ranks at the middle between the other two in both metrics.

The results are predictable. Indeed, since it is easier for small requests to be totally accepted, giving high priority to them probably results in lower SBP. However, when most of small requests has been adopted, the availability of wavelengths become exhausted and the incoming (larger) requests will be blocked, causing high DBP. In contrast, provisioning the larger requests first would allow more destinations to be served, or lower DBP, however larger requests often need much of the network resources, in turn, the network resources rapidly become over-utilized and reject the incoming requests (including many small requests), causing high SBP.

In short, giving higher priority on smaller or larger requests produces own gain and loss. Choosing which one depends on the the types and objectives of applications. The applications which require the presences of all the attendants should be suitable with *SRF* to get higher probability to take place. On the other hand, the less-restrictive applications should use *LRF* to maximize the receivers to fulfil their communication objective. Moreover, *seqR* is a pretty choice, because it provides a tradeoff solution between the other two. Besides, *seqR* does not need a global information about the considered requests, it can be applied for the case of dynamic traffic where the incoming requests are unknown until they arrive.

VIII. CONCLUSION AND FUTURE WORK

This paper investigated the problem of provisioning multiple static multicast requests in sparse splitting WDM networks (MCRWA-SS). We aim at minimizing the blocking probability considering two models: full blocking probability and partial blocking probability. To this end, we employed the layered graph model and used light-hierarchies to design several adaptive algorithms to solve the problem. The contributions of this study include:

- 1) Provided an ILP formulation with two variants using light-hierarchies to find the exact solution for the MCRWA-SS problem.
- 2) Proposed three adaptive heuristic algorithms to compute the approximated solutions, in which: Smallest Request First works best under FB policy, Largest Request First achieves close optimal solution under PB policy, and Sequential Request can be used for the case of dynamic traffic (i.e., the dynamic MCRWA).
- 3) Showed that under sparse splitting configurations, light-hierarchy is better than light-tree for the MCRWA-SS problem in terms of blocking probability.

Note that this study supposes that all the considered requests are treated the same, meaning that the precedences of the requests are not taken into account. In some network domains, the requests are categorized into different classes according to their precedences to support various types of applications, users and specific business requirements. If it is taken into account, the proposed algorithms should be modified in such a way that the more important requests should be served first. The ILPs are also able to adapt this property by setting higher importances to the requests with higher precedences.

Moreover, many recent issues accompanied with MCRWA, including dynamic traffic, traffic grooming, QoS-aware RWA, power-aware RWA, etc., are not investigated in this work. Especially, the recent advances on multicast-related resource allocation in flexible-grid elastic optical networks (EONs) have attracted intensive research interests recently, and been treated as a potential replacement of the fixed-grid WDM networks [26], [27]. They are of our main concerns in our next study.

ACKNOWLEDGMENT

This work is realized at the LIRMM of University Montpellier 2, France. Dinh Danh Le is now a Ph.D student in Computer Science Department at laboratory LIRMM, University Montpellier 2, France. He was graduated at the Information Technology Faculty of Hong Duc University, Vietnam in 2004 and received a master degree in Computer Science at Information Technology Faculty of Vietnam National University, Hanoi in 2007. His main research topics and interests include network evaluation, multicast routing, optical networks, and combinatorial optimization.

Fen Zhou is an Associate Professor at the computer science lab LIA of the University of Avignon, France. He obtained the Ph.D. degree from INSA Rennes in 2010. His research interests include combinatorial optimization for routing and resource allocation in optical networks, content delivery networks (CDN) and vehicular ad-hoc networks (VANETs).

Miklós Molnár is with the University Montpellier 2, laboratory LIRMM and he is a full professor in Computer Science. He was graduated at the Faculty of Electrical Engineering, University BME of Budapest in 1976 and received the Ph.D. degree in Computer Science from the University of Rennes 1 in 1992 and the French HDR degree in 2008. His main research activity is in combinatorial optimization to solve network related problems. His results are related to NP-hard optimization problems, constrained spanning and Steiner problems, routing algorithms for unicast, in-cast and multicast communications in optical and in wireless networks, dependable communications, energy aware protocols and optimization.
