SUMMARY

Unnotched $[\pm\theta/0/90]_s$ graphite/epoxy laminates, designed to delaminate at the edges under static and cyclic tensile loads, were tested and analyzed. The specimen stacking sequences were chosen so that the total strain-energy-release rate, G , for edge delamination was identical for all three layups. However, each layup had different percentages of crack-opening and shear-mode strain-energy-release rates, G_I and G_{II} , respectively. Results with composites made from T300 graphite fibers and 5208 epoxy, a brittle resin, indicated that only G_I contributed to delamination onset under static loading. However, results with composites made from C6000 fibers and H205 epoxy, a tougher resin, indicated that the total G governed the onset of edge delaminations under cyclic loads. In addition, for both materials, the threshold level of G for delamination onset in fatigue was significantly less than the critical G_c measured in static tests. Furthermore, although the C6000/H205 material had a much higher static G_c than T300/5208, its fatigue resistance was only slightly better. A series of mixed-mode tests, like the ones in this study, may be needed to evaluate toughened-resin composites developed for highly strained composite structures subjected to cyclic loads.

NR3-175-98 #

NOMENCLATURE

a	delamination size
Δa	incremental delamination size
$E_{[90]}$	stiffness of a 90° ply in axial (loading) direction
$E_{[\pm 45/0]}$	axial stiffness of a laminate containing $+45^\circ$, -45° , and 0° plies
E_{LAM}	axial laminate stiffness calculated from laminated plate theory
E^*	axial stiffness of a laminate completely delaminated along one or more interfaces
G	strain-energy-release rate associated with edge delamination
G_c	critical strain-energy-release rate for delamination onset
G_I, G_{II}, G_{III}	strain-energy-release rate components due to opening, interlaminar shear, and out-of-plane shear fracture modes
G_{Ic}	critical value of Mode I strain-energy-release rate for delamina- tion onset
h	ply thickness
N	number of fatigue cycles
n	number of plies
t	laminate thickness
ϵ	nominal tensile strain
ϵ_c	nominal tensile strain at delamination onset
ϵ_{MAX}	maximum cyclic strain level in fatigue
θ	fiber orientation angle in laminate plies

INTRODUCTION

One major obstacle to the application of advanced composite materials in primary aircraft structure is the tendency for these materials to delaminate. Delamination often results in loss of stiffness, strength, and fatigue life [1-4]. Delamination failure criteria are needed to predict the onset and growth of delaminations. One measure of delamination resistance under static loading is interlaminar fracture toughness. The interlaminar fracture toughness, G_c , of a composite laminate is the critical value of the strain-energy-release rate, G , required to cause a delamination to grow. Previously [1], the critical strain-energy-release rate measured at delamination onset in eleven-ply $[\pm 30/\pm 30/90/\overline{90}]_s^\dagger$, NARMCO T300/5208^{††} graphite/epoxy laminates was used to predict delamination onset in layups with other thicknesses and stacking sequences. Good agreement was found between measured and predicted delamination onset strains. However, before delamination criteria can be generated with confidence, the relative contributions of interlaminar tension and shear to the formation and growth of delaminations must be identified.

The primary goal of this investigation was to determine the effect of different mixed-mode (interlaminar tension and shear) strain-energy-release rate percentages on the formation of edge delaminations in unnotched laminates subjected to static and cyclic tensile loads. Unnotched graphite/epoxy laminates, designed to delaminate at specific interfaces, were analyzed and tested. A parametric study was performed to optimize laminate layups for G_c measurement (Appendix). A combination of stacking sequences was chosen so that the total

[†]The bar over the center 90° ply denotes one half of a ply thickness.

^{††}Use of trade names or manufacturers does not constitute an official endorsement, either expressed or implied, by the National Aeronautics and Space Administration or AVRADCOM.

strain-energy-release rates were the same, but the percentages of interlaminar tension, G_I , and interlaminar shear, G_{II} , were very different. A closed-form equation [1] was used to calculate total strain-energy-release rates. A quasi-three-dimensional finite-element analysis [5] was used to determine G_I and G_{II} percentages using the technique outlined previously [1].

Static tests were performed on T300/5208 laminates. Measured delamination onset strains and corresponding strain-energy-release rates were compared for the layups with the same total G but with different G_I and G_{II} percentages. Results were also compared to G_{Ic} measurements from double cantilever beam tests.

Static and fatigue tests were performed on Hexcel C6000/H205^{††} graphite/epoxy laminates. The number of cycles to delamination onset at prescribed maximum cyclic strains (and corresponding strain-energy-release rates) were compared for two layups with the same total G but again with different G_I and G_{II} percentages.

The secondary goal of this investigation was to determine if these static and fatigue tests could be used to establish the relative delamination resistance of different composite materials. Therefore, static and fatigue results for T300/5208 and C6000/H205 were compared.

STATIC BEHAVIOR

Delamination Onset Prediction

Previously, the onset of 0/90 interface edge delaminations in $[+45_n / -45_n / 0_n / 90_n]_s$ ($n = 1, 2, 3$) T300/5208 graphite/epoxy laminates were predicted from a closed-form equation for the total strain-energy-release rate, G , for edge delamination [1]. This equation

$$G = \frac{\varepsilon_c^2 t}{2} (E_{LAM} - E^*) \quad (1)$$

is independent of delamination size. The stiffness quantities, E_{LAM} and E^* , were calculated from laminated plate theory and the rule of mixtures [1,2]. To predict delamination onset, the critical value, G_c , was calculated from equation (1) using the critical strain, ε_c , measured at the onset of -30/90 interface edge delamination in tension tests on $[\pm 30 / \pm 30 / 90 / 90]_s$ laminates. Then, equation (1) was rearranged, and this G_c was used to predict ε_c in the $[+45_n / -45_n / 0_n / 90_n]_s$ laminates. The predictions [1] agreed closely with the data reported [6]. In this study, additional 8-ply and 16-ply specimens were tested to verify these results. Figure 1 shows that the predicted and newly measured values of ε_c also agreed well. The arrow in the stacking sequence shown in figure 1 indicates that delaminations were modeled in the 0/90 interfaces. Figure 2 shows a micrograph of the specimen edge showing the delamination location through the thickness for the 8-ply laminates. Delaminations formed at, and wandered between, the 0/90 interfaces where they were assumed to occur. This same detail was observed for the 16-ply laminates.

Because these results verify the thickness dependence of delamination onset observed in the data and show good quantitative agreement with predicted delamination onset strains, the strain-energy-release rate appears to be a viable

parameter for predicting delamination behavior. However, G , as calculated using equation (1), is a total strain-energy-release rate consisting of both G_I and G_{II} . As previously mentioned, to evaluate the relative contributions of the two fracture modes to edge delamination, three different quasi-isotropic layups, each with the same total G but different percentages of G_I and G_{II} , were analyzed and tested. The total G was calculated from equation (1), and the relative percentages of G_I and G_{II} were calculated by a finite-element analysis [5] using the technique outlined previously [1].

Analysis

Three different quasi-isotropic layups were analyzed. Laminate A was $[\pm 45/0/90]_s$, laminate B was $[0/\pm 45/90]_s$, and laminate C was $[45/0/-45/90]_s$. All three have 90° plies in the center to create high interlaminar tensile stresses at the $\theta/90$ interfaces, where θ is either 0° or -45° . Delaminations were modeled at the $0/90$ interfaces for laminate A, and at the $-45/90$ interfaces for laminates B and C.

Because these layups are all quasi-isotropic, their initial laminate stiffnesses, E_{LAM} , are identical. The rule of mixtures equation for stiffness after the $\theta/90$ interfaces are completely delaminated is

$$E^* = \frac{6E_{[\pm 45/0]} + 2E_{[90]}}{8} \quad (2)$$

The stiffness of a $[\pm 45/0]_s$ laminate, calculated from laminated plate theory, is identical for all three permutations of $+45^\circ$, -45° , and 0° plies in layups A, B, and C. Hence, E^* is also identical for the three layups. Therefore, the total strain-energy-release rate calculated from equation (1), for a given nominal strain, ϵ , and laminate thickness, t , will be identical for laminates A, B, and C.

Figure 3 shows the finite element meshes used to calculate strain energy release rates. Delaminations were modeled in the $\theta/90$ interfaces previously specified. The virtual crack extension technique outlined in reference 1 was used to compute strain-energy-release rates from nodal forces and displacements calculated before and after an incremental delamination extension, respectively. Figure 4 shows G calculated with the coarse finite element mesh and a remote strain of 0.004, plotted as a function of delamination size normalized by ply thickness. As was previously observed for other layups [7-10], G_I , and total G are independent of delamination size, once the delamination has grown one to two ply thicknesses in from the specimen edge. As indicated in figure 4, the total G calculated from finite element analysis by summing G_I and G_{II} agrees closely with the total G calculated independently from equation (1). Figure 4 also shows the percentage of the total G attributed to the opening mode, G_I . The opening mode, G_I , was 85 percent, 57 percent, and 28 percent of the total G for laminates A, C, and B respectively. The interlaminar shear mode, G_{II} , constituted the remainder. The out-of-plane shear mode, G_{III} , was negligible for all three layups.

Refinement of the coarse finite element mesh from one to three elements through a ply thickness had a negligibly small effect on the G_I percentages, as shown in figure 4 for $a/h = 3.7$. The G curves in figure 4 were generated assuming material properties in table 1 [6]. In addition, a three-dimensional set of material properties were used, based on the work of Kriz [11], to account for the different in-plane and through thickness moduli and Poisson's ratios. These modified properties had only a small influence on the G_I percentages, as shown in figure 4 for $a/h = 9.3$.

Experiments

Two 305 mm by 305 mm panels were made for each of the three layups using the same roll of T300/5208 graphite/epoxy prepreg. Each panel was cured in an autoclave using the manufacturer's prescribed curing cycle. Five 254 mm by 38 mm (10-by-1.5 inch) coupons were then cut from each panel and tested in tension using apparatus and procedures described in references 1 and 2. A pair of LVDT's were mounted on either side of the specimens to measure nominal strain over a 102 mm (4 in.) gage length. Dye-penetrant-enhanced radiographs were taken to confirm the onset of edge delamination, which was indicated by a deviation from a linear stress-strain curve. Photomicrographs of specimen edges shown in figures 2 and 5 indicated that delaminations formed only in the interfaces that were assumed to delaminate in the analysis.

Results and Discussion

Laminates A, B, and C all have the same total G . Therefore, if total G_c governs the onset of edge delamination, ϵ_c would be identical for all three layups. However, if only G_I governs delamination onset, then ϵ_c would be lowest for the layup with the highest G_I percentage. Hence, ϵ_c would be lowest for A, highest for B, with C somewhere in between. Figure 6 shows the measured ϵ_c values. The symbols represent the mean of ten tests, and the brackets show the scatter. The mean values of ϵ_c were lowest for layup A and highest for layup B, with C in between. Hence, G_I , and not the total G , appears to control the onset of edge delamination for static loading.

Figure 7 shows the critical values of strain-energy-release rate, G_c , calculated from equation (1) with the ϵ_c data for the three layups. The open symbols and brackets represent the mean values and scatter bands, respectively. The solid symbols represent corresponding values of G_{Ic} calculated from the percentage of G_c that was due to G_I . For laminates A and C, these G_{Ic} values

agree fairly well with G_{I_c} data from unidirectional double cantilever beam (DCB) flexure tests [12]. However, for laminate B, which had the lowest G_I percentage, the estimated G_{I_c} was well below G_{I_c} measured by the DCB tests.

Both laminates B and C exhibited large scatter in G_c data and, hence, in G_{I_c} values. Figure 8 shows that both of these laminates developed many 90° ply cracks before the onset of delamination, as seen in sequential dye-penetrant-enhanced radiographs taken at load increments throughout the tests. Previously, Talug and Reifsnider [13,14], and more recently Crossman, Wang, and Law [8,9], showed that interlaminar tensile stresses can develop at ply interfaces at matrix crack tips. Perhaps, the interaction of these stresses with the interlaminar edge stresses due to Poisson's mismatch led to the large G_c scatter observed in layups B and C which developed many cracks before delamination onset. Furthermore, in layups like B where the G_I percentage is low, these stresses may have a significant effect on the apparent mean values of G_{I_c} . Hence, care should be taken to avoid extensive 90° ply cracking before delamination onset in layups where the edge delamination test is used to measure interlaminar fracture toughness. Matrix ply cracking can be reduced by optimizing specimen layups to minimize the ϵ_c required to measure a given G_c . A $[\pm 35/0/90]_s$ family of layups appears to be optimal (see Appendix). Layups from this family were used to study delamination resistance in fatigue in the next section. In addition, concern about 90° ply cracking influencing G_c measurements is diminished for tougher resin composites where 90° ply cracking is suppressed [7]. For this reason, C6000/H205 graphite/epoxy composites were analyzed and tested to study mixed-mode effects in fatigue.

FATIGUE BEHAVIOR

Analysis

Cyclic loading may cause extensive delamination in graphite/epoxy laminates, even for stacking sequences that do not delaminate under static loads. Therefore, it is necessary to characterize delamination resistance in fatigue as well as in static loading. To this end, two layups with the same total strain-energy-release rate, but relatively high and low G_I percentages, were analyzed and tested. Specifically, these layups were $[\pm 35/0/90]_s$ and $[0/\pm 35/90]_s$. The 35° angle was chosen from a parametric study to optimize the layup for the edge delamination test for measuring interlaminar fracture toughness (see Appendix). Both laminates have 90° plies in the center to create high interlaminar tensile stresses.

Figure 9 compares G and G_I , calculated at a remote strain of 0.004, for two $[\pm\theta/0/90]_s$ families. Results for both $[\pm\theta/0/90]_s$ families were calculated using the T300/5208 material properties in table 1 [6]. The quasi-isotropic results were replotted from figure 4. As indicated by the arrows in figure 9, delaminations were modeled in the 0/90 and -35/90 interfaces for the $[\pm 35/0/90]_s$ and $[0/\pm 35/90]_s$ layups, respectively. The open symbols show the total strain-energy-release rates, calculated by summing G_I and G_{II} . The solid symbol shows that these total G 's agree well with values calculated independently from equation (1). Also shown in figure 9 are the G_I calculations from finite-element analyses.

Figure 9 illustrates that changing θ from 45° to 35° will result in a higher total G at the same remote strain, and a wider range of Mode I

percentages for the three different stacking sequence permutations. Furthermore, as was previously noted [7], G_I percentages are controlled by the stacking sequence and are very insensitive to large changes in the matrix-dominated lamina properties, as long as the fiber-dominated moduli are relatively unchanged. Table 2 shows the influence of material properties on G_I percentages for the $[\pm 35/0/90]_s$ family of layups. The range of Mode I percentages was slightly greater for T300/5208 than C6000/H205, due primarily to the lower E_{11} value for the C6000/H205 composite (table 1).

Experiments

Static and constant-amplitude, strain-controlled ($R = 0.2$, $f = 10$ Hz) cyclic tests were performed on $[\pm 35/0/90]_s$ and $[0/\pm 35/90]_s$ layups made of C6000/H205 graphite/epoxy. The H205 epoxy was chosen because, as a composite matrix, it has significantly greater interlaminar fracture toughness than the 5208 epoxy [7,15]. Furthermore, 90° ply cracking was greatly suppressed in C6000/H205 $[\pm 30/\pm 30/90/\overline{90}]_s$ laminates used to measure interlaminar fracture toughness [7]. Hence, the tougher H205 matrix was expected to suppress 90° ply cracking before delamination in the $[0/\pm 35/90]_s$ layup that has a low G_I percentage.

Tests were run until the first indication of delamination onset. Indications involved a combination of visual detection, audible detection, and measured stiffness loss indicated by a discontinuous jump in the load deflection plot during static tests or a drop in cyclic load during the strain-controlled fatigue tests. At the first sign of delamination, loading was stopped and a dye-penetrant-enhanced radiograph was taken to verify the presence of delamination.

Figure 10 shows typical dye-penetrant-enhanced radiographs for the C6000/H205 laminates taken just after delamination onset in fatigue. Figure 11 shows that delaminations formed in the 0/90 interfaces of $[\pm 35/0/90]_s$ and in the -35/90 interfaces of the $[0/\pm 35/90]_s$ layups as modeled. The delaminations wandered through the 90° plies to the symmetric $\theta/90$ interfaces. There was no evidence of significant 90° ply cracking before delamination during either the static or cyclic loading.

Results and Discussion

Figure 12 shows the delamination onset strains as a function of fatigue cycles for the two C6000/H205 layups chosen from the $[\pm 35/0/90]_s$ family. Delamination onset strains for static loading are shown at $N = 0$ in this figure. Delaminations formed at the edge of $[\pm 35/0/90]_s$ layups before failure. However, the $[0/\pm 35/90]_s$ layups fractured into two pieces before delaminations formed at the edge. These layups have the same total G , but did not delaminate at the same strain. Hence, total G_c does not control delamination onset for static loading. Because the $[\pm 35/0/90]_s$ layup that did delaminate has a very high G_I percentage, then G_I probably plays the dominant role under static loading as was observed earlier for T300/5208. However, quantitative verification would require performing static tests on composites with higher fiber failure strains (see Appendix).

The fatigue data in figure 12 show the number of cycles applied at the onset of edge delamination for a range of maximum cyclic strains. Fatigue cycles are plotted on a linear scale to show the steep reduction in the maximum cyclic strain for delamination onset with increasing fatigue cycles. Eventually, a plateau is reached that is tantamount to an endurance limit for delamination onset. Below this level, no delaminations formed. Data points

with arrows indicate runouts at 10^6 cycles. Figure 12 demonstrates that delaminations form at different strains in the two layups under static loading. However, delaminations form at nearly identical numbers of fatigue cycles at the same maximum cyclic strains in the two layups.

Static and constant-amplitude fatigue data for $[\pm 45/0/90]_s$ T300/5208 laminates are also shown in figure 12. These fatigue data were generated in load-controlled tests [3]. However, these data can easily be transferred to maximum cyclic strains since no significant stiffness loss occurs before delamination onset [1,2]. The endurance limit for delamination onset, i.e., the maximum cyclic strain at which no delamination occurs at 10^6 cycles, is higher for C6000/H205 than for T300/5208. However, because strain endurance limits will decrease with increasing laminate thickness [3], comparisons of the fatigue delamination resistance of materials should be presented in terms of strain-energy-release rates.

Figure 13 shows critical G_c values for delamination onset, calculated from equation (1), as a function of fatigue cycles. For static tests ($N = 0$), G_c values were calculated from the ϵ_c data shown in figure 12. For fatigue tests ($N > 0$), G_c values were calculated from the ϵ_{MAX} data shown in figure 12. The G_c values for the $[\pm 35/0/90]_s$ and $[0/\pm 35/90]_s$ layups under static loading are obviously different; however, the G_c values under cyclic loading for the two layups are nearly identical. Hence, although G_I may govern delamination onset under static loading for the C6000/H205 composite, the total G appears to govern the threshold for delamination onset in fatigue. Obviously, the interlaminar shear that is present may not contribute to delamination under static loading, but contributes fully to delamination under cyclic loading. Of course, the difference in static versus fatigue behavior is not simply a matter of

adding the interlaminar shear contribution, because the threshold value of G for fatigue is much less than the static G_c . Furthermore, if we were to consider the H205 matrix material as a toughened resin alternative to 5208, figure 13 shows a significant improvement in the static G_c , yet the magnitude of this improvement for the G_c threshold in fatigue is much less. Hence, a series of mixed-mode static and cyclic tests, like those performed in this study, may be needed to evaluate toughened resin composites developed for highly strained composite structures subjected to cyclic loads.

CONCLUSIONS

Unnotched composite laminates, designed to delaminate at the edge under static and cyclic tensile loads, were analyzed and tested. The specimen stacking sequences were chosen so that the total strain-energy-release rate, G , for edge delamination was identical for all three layups. However, each layup had different percentages of crack opening and shear mode strain-energy-release rates, G_I and G_{II} , respectively. Static and fatigue tests were conducted on T300/5208 and C6000/H205 graphite/epoxy laminates. Based on the analysis and experiments conducted, the following conclusions have been reached:

- (1) The interlaminar crack opening mode strain-energy-release rate, G_I , controls the onset of edge delamination under static loading.
- (2) The total mixed-mode (interlaminar tension and shear) strain-energy-release rate controls the onset of edge delamination under cyclic loads.
- (3) The threshold value of strain-energy-release rate for delamination onset in fatigue is significantly less than the corresponding value measured in a static test.
- (4) Based on a comparison of T300/5208 and C6000/H205 laminates, the improved delamination resistance provided by the toughened resin (H205) composite was much larger for static loading than fatigue loading.
- (5) A series of mixed-mode static and cyclic tests, like those performed in this study, may be needed to evaluate toughened resin composites developed for highly strained composite structures subjected to cyclic loads.

APPENDIX - Layup Optimization for G_c Measurements

Background

Recently, the edge delamination test was used to measure the interlaminar fracture toughness of toughened resin composites in reference 7. In that study, eleven-ply $[\pm 30/\pm 30/90/\overline{90}]_s$ laminates, with C6000 graphite fibers reinforcing Hexel 205 and rubber-toughened F185 resins, were tested to determine critical values of mixed-mode interlaminar fracture toughness, G_c . These edge delamination tests were successful in discriminating the improved toughness of the different matrices. However, in order to achieve a better quantitative comparison of interlaminar fracture toughness, layups with a wide range of mixed-mode percentages are needed. In addition, fiber-dominated layups, containing zero degree plies, may be needed for testing composites with toughened resins (like the rubber-toughened F185 resin) that exhibit material nonlinearity in the individual plies of the $[\pm 30/\pm 30/90/\overline{90}]_s$ layup before delamination onset [7]. Therefore, a parametric study was undertaken to develop optimal layups for the edge delamination test for measuring interlaminar fracture toughness.

The ideal layup for the edge delamination test would be one that requires the fewest number of plies yet delaminates at the lowest possible strain for a given interlaminar fracture toughness. Minimizing the number of plies will help conserve the amount of constituent material needed to make the composite specimen. This is of particular concern when only small quantities of resin are available. Minimizing ϵ_c for measuring a given G_c will help insure that edge delamination precedes extensive 90° ply cracking and/or fiber and, hence, laminate failure. Some 90° plies must be kept in the center of the laminate to insure a high Poisson's mismatch [16].

$[\pm\theta/90]_s$ Family Optimization

Perhaps the simplest layup would be a $[\pm\theta/\overline{90}]_s$ five-ply laminate with delaminations occurring in the $-\theta/\overline{90}$ interfaces. As θ varies, the $(E_{LAM} - E^*)$ term in equation (1) will change. Figure 14 shows the variation in delamination onset strains, ϵ_c , required for various $[\pm\theta/\overline{90}]_s$ laminates to measure an interlaminar fracture toughness of 0.15 kJ/m^2 . As shown in figure 14, the lowest ϵ_c occurs in the vicinity of 30° .

Furthermore, by noting that ϵ_c is proportional to $1/\sqrt{t}$, increasing the laminate thickness, t , will also lower the ϵ_c required to measure a given G_c . This may be accomplished in two ways: first, by increasing the number of angle plies, i.e., $[(\pm\theta)_n/\overline{90}]_s$, or second, by increasing the number of 90° plies, i.e., $[\pm\theta/\overline{90}_n]_s$, where $n = 1, 2, 3, \dots$. Figure 15 shows the effect of both techniques on the ϵ_c required to measure a given G_c . For a given number of 90° plies, n , the $[(\pm 30)_2/\overline{90}_n]_s$ layup requires a lower ϵ_c than the $[\pm 30/\overline{90}_n]_s$ layup to measure the same G_c . However, increasing the number of angle plies has the disadvantage of rapidly increasing the laminate thickness and, hence, the amount of material needed to make the specimen. Increasing $\pm\theta$ plies requires adding four new plies each time. As shown in figure 15, increasing the number of 90° plies will also lower the ϵ_c required to measure a given G_c . However, increasing the number of 90° plies has the disadvantage, when taken to extremes, of increasing the contribution of the 90° ply cracks to laminate stiffness loss. Such a significant contribution would have to be included in the E^* calculation [1]. In addition, if the number of 90° plies grouped in the center is large enough, delaminations can form due to the interlaminar stress fields that develop in the interface at the 90° ply crack tips and not due to the large Poisson's mismatch [8,9,17]. However, both these concerns about increasing 90° ply thickness are diminished by the tendency for 90° ply cracking to be suppressed in composites with toughened-resin matrices [7].

Based on this parametric study, the eleven-ply $[\pm 30/\pm 30/90/\overline{90}]_s$ layup (shown on figure 15 as $[(\pm 30)_2/90]_n$ where $n = 3/2$) previously used in reference 7 is a good candidate layup to measure interlaminar fracture toughness. However, because material nonlinearity may appear before delamination for composites with toughened matrix resins [7], an alternate layup was sought for the edge delamination test.

$[\pm\theta/0/90]_s$ Family Optimization

The $[\pm\theta/0/90]_s$ family of layups was considered because including the 0° ply, i.e., having a fiber-dominated layup, would suppress the material nonlinearity. Figure 14 shows the variation in delamination onset strain, ϵ_c , for various $[\pm\theta/0/\overline{90}]_s$ layups required to measure an interlaminar fracture toughness of 0.15 kJ/m^2 . The lowest ϵ_c occurs in the vicinity of 35° . Figure 15 shows the effect on ϵ_c of increasing 90° ply thickness for $[\pm 35/0/90]_n$ laminates. The same concerns mentioned earlier about increasing 90° ply thickness would also apply to this layup, but would be diminished by the tendency for 90° ply cracking to be suppressed in toughened resin matrices [7]. As shown in figure 15, the largest reduction in ϵ_c results between $n = 1/2$ and $n = 1$. Hence, the 8-ply $[\pm 35/0/90]_s$ laminate is a good candidate for the edge delamination test.

Furthermore, the finite-element analysis performed in this study (table 2) shows that the three permutations of the $+35^\circ$, -35° , and 90° plies will result in three 8-ply layups with the same total G but a wide range of G_I and G_{II} percentages. Hence, the $[\pm 35/0/90]_s$ family of layups should be very useful for evaluating mixed-mode effects in toughened resin composites. One potential disadvantage with these layups, however, is that the range of toughness measurements that can be made is limited by the ultimate tensile strain of the

fiber, which controls the nominal failure strain of a fiber-dominated laminate [2]. However, the new high failure strain (> 1.4 percent) graphite fibers currently on the market will increase the range of G_c measurements possible beyond the 1 percent limitation illustrated in figures 14 and 15.

Summary

As a result of this parametric study, the eleven-ply $[\pm 30/\pm 30/90/\overline{90}]_s$ and the 8-ply $[\pm 35/0/90]_s$ layups appear to be good candidates for the edge delamination test for measuring interlaminar fracture toughness. Furthermore, the three permutations of the 8-ply layup, i.e., $[\pm 35/0/90]_s$, $[+35/0/-35/90]_s$, and $[0/\pm 35/90]_s$, all have the same total G but a wide range of G_I and G_{II} percentages. Hence, these three layups are good candidates for studying mixed-mode effects in toughened resin composites.

16. Abstract Unnotched [$\pm 0/0/90$] _s graphite/epoxy laminates, designed to delaminate at the edges under static and cyclic tensile loads, were tested and analyzed. The specimen stacking sequences were chosen so that the total strain-energy-release rate, G , for edge delamination was identical for all three layups. However, each layup had different percentages of crack-opening and shear-mode strain-energy-release rates, G_I and G_{II} , respectively. Results with composites made from T300 graphite fibers and 5208 epoxy, a brittle resin, indicated that only G_I contributed to delamination onset under static loading. However, results with composites made from C6000 fibers and H205 epoxy, a tougher resin, indicated that the total G governed the onset of edge delaminations under cyclic loads. In addition, for both materials, the threshold level of G for delamination onset in fatigue was significantly less than the critical G_c measured in static tests. Furthermore, although the C6000/H205 material had a much higher static G_c than T300/5208, its fatigue resistance was only slightly better. A series of mixed-mode tests, like the ones in this study, may be needed to evaluate toughened-resin composites developed for highly strained composite structures subjected to cyclic loads.
