

Monitoring effects of anthropogenic climate change on ecosystems: A role for systematic ecological observation?

Guy F. Midgley^{a*}, Steven L. Chown^b and Barney S. Kgope^a

WE CONSIDER HERE THE OPPORTUNITIES and challenges for South Africa in long-term ecological research (LTER) to detect the impacts of anthropogenic climate change on biota (as one of several competing objectives of long-term monitoring). The LTER approach has high potential for this purpose in South Africa because of a wealth of historical climate data relative to much of the African continent, and good representation of many African ecosystem types. However, there are substantial challenges to the identification and attribution of climate change impacts on African ecosystems. These are posed by climate variability at a range of time scales, the importance of rainfall rather than temperature as an ecological driver, and the significance of fire as a stochastic disturbance. An awareness of environmental and climate history will be crucial to interpreting data on trends, and sites with established historical data should be preferred for this reason. The placement of LTER sites to provide representativity of ecosystem types may unintentionally limit the detectability of climate change impacts, because change might best be detected in ecotonal or azonal environments. This could be overcome by additional experimental manipulations at LTER sites to 'force' anticipated changes and characterize species and ecosystem responses. A focus on the detection of climate change would sharpen an LTER programme's emphasis over time and provide policy advice, and science training rationales for the long term. It should especially interpret key information to decision-makers as a priority.

Introduction

At the heart of the UN Framework Convention on Climate Change, Article 2 describes its objective as 'stabilization of greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system', and goes further to define this as a level that would not

compromise food production, would allow sustainable economic development, and should be 'achieved within a time-frame sufficient to allow ecosystems to adapt naturally to climate change' (see <http://unfccc.int/resource/docs/convkp/conveng.pdf>). It is not surprising, therefore, that some of the most powerful data that have influenced policy debate in the climate change arena derive from longitudinal studies of wild organisms and ecosystems that reveal their responses to climate trends.¹⁻³ Indeed, in the development of reports of the Intergovernmental Panel on Climate Change (IPCC, the premier policy-relevant compendium of climate change information), the first powerful compilation of such recorded responses was carried out for the Third Assessment Report.⁴ The success and influence of this contribution has ensured that, in the Fourth Assessment Report, an entire chapter has been devoted to this topic (Working Group 2, Chapter 1, Assessment of Observed Changes and Responses in Natural and Managed Systems; see <http://www.ipcc.ch/activity/wg2outlines.pdf>).

Systematic environmental monitoring has long been recognized as a key support

for rational policy-making, and an important early-warning mechanism.⁵ It is interesting to note that the publication of reports relating to climate change and long-term ecological research (LTER) seems to have been stimulated by the release of IPCC reports (Fig. 1), possibly indicating a growing appreciation of the policy value of such studies, and prompting further publication of data sets and conceptual designs for more efficient and policy-relevant monitoring systems.⁶ We briefly review here the results and influence of some key LTER studies for their relevance to interpreting climate change impacts, which is arguably one of the most significant roles for the South African Environmental Observation Network (SAEON) initiative in South Africa.⁶

Studies using systematic site-based observation

The longest-running records of systematic observation most often are of phenological phenomena (the timing of growth and development events), generally of plants, e.g. ref. 7. Many such studies were summarized by Hughes⁸ in one of the first attempts at a comprehensive assessment. It is clear from this and subsequent studies that reliable, long-running biological response data sets are concentrated in the northern hemisphere.⁹ A main reason for the successful extraction of trends from these data sets is that growth stages monitored (e.g. bud-break, leafing-out, flowering) are generally limited by low temperatures, and may show a threshold-type response.¹⁰ It comes as no surprise, therefore, that a large majority of studies successfully identifying climate change impacts on these processes¹¹ are situated in parts of

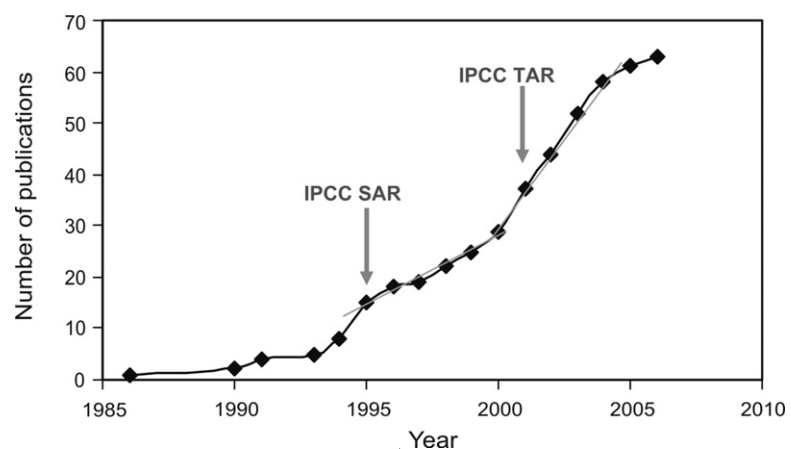

Fig. 1. Annual number of papers published in the international literature as obtained with the search ('LTER' and 'climate change') on www.scholar.google.com. The trend shows two strong inflections, both of them in the year of publication of two previous IPCC reports (SAR = Second Assessment Report, TAR = Third Assessment Report), suggesting increasing interest in this field, stimulated by their preparation and publication (data point for 2006 publications is based on an incomplete sample of the current calendar year)

the world where ecological processes are limited by low temperatures,¹² enabling detection of consistent trends even in marine environments.¹³ This is not to say that temperature responses are always simple to interpret, as evidenced, for example, by complex changes in bird populations as a function of brood activity.¹⁴

Studies involving changes in low-temperature limitations have also identified consistent shifts in species' range, such as in altitude¹⁵ or tree-lines¹⁶ and even in shifts in geographic range polewards over large regions.^{9,11} Significant range shifts have emerged generally in vagile organisms such as butterflies,¹ with a few exceptions.¹⁷ Incipient range shifts in plants may be detected as changes in population growth rate, especially in long-lived plants such as the kokerboom (*Aloe dichotoma*)¹⁸ or in forest trees.¹⁹ Studies of range shifts most positively identify such changes through records of new appearances, indicating range expansion.²⁰ Range contraction²¹ is more difficult to demonstrate directly. Local species extinction and even global extinction such as recorded for the Costa Rican golden toad²² indicate a range loss. Attributing such an effect to local climatic changes may be complex, however, and requires explanations that tease apart ancillary and synergistic stresses, such as the impact of disease on climate-stressed populations.²³

Complex multi-species studies that provide insight into ecosystem characteristics and processes such as community composition and biomass production²⁴ have been carried out by re-analysing long-term data sets from studies that were originally established for reasons not related to climate change at all. Some studies (unfortunately, often of shorter duration) have identified strong predator–host relationships that operate either independently of or in addition to climate regimes.²⁵ Such studies underline the importance of flexible, integrated and sufficiently complete sampling regimes that are robust enough to allow trends to be detected or positively refuted.

As the policy imperative for LTER has grown, e.g. ref. 26, a need for an integrated view of anthropogenic impacts on natural ecosystems and biogeochemical cycling has emerged. The first major studies to monitor the global biogeochemical cycles were those of the carbon cycle, established in the late 1950s on Mauna Loa, Hawaii,²⁷ and these remain relevant.²⁸ Today, large spatial scale studies involving cooperative groups and consortia have

been initiated, e.g. ref. 29, and these now involve established long-term monitoring sites for both changes in ecosystem composition and productivity, e.g. ref. 30, and measurement of ecosystem-level physiological characteristics, e.g. ref. 31.

Significant concerns have been expressed, however, about blocks between monitoring efforts and policy making. For example, despite the annual investment of hundreds of millions of dollars in the United States in environmental monitoring, access to data and information for policy and decision makers has been lacking. This limits the extent to which policies may be updated in order to meet desired objectives, and suggests careful attention to the production of annual statistical reports and interpretational summaries from LTER efforts.³² This is a significant challenge for LTER projects that might be addressed, for example, by clear linkages with national programmes such as State of the Environment reporting (<http://www.ngo.grida.no/soesa/nsoer/>).

In the southern hemisphere, LTER research has a narrower scope and a shorter history than north of the equator. Indeed, recent reviews have highlighted the comparative dearth of long-term research in the southern hemisphere.^{3,9} In the south, LTER efforts to detect climate change impacts may be complicated by the hemispheric difference in environmental controls of ecosystem processes,³³ namely energy-related factors in the north in contrast to water-related factors in the south. Nonetheless, significant effects related to climate change have been detected through LTER, such as in marine communities,³⁴ and in studies of island environments of the southern oceans.³⁵ Long-term monitoring of seabird populations has been a critical policy input for marine resource management.³⁶

Some terrestrial monitoring studies have also detected trends in the southern hemisphere, such as in forest trees of the South American tropics, where significant increases in individual plant turnover and biomass have been documented.³⁰ In South Africa, game counts and other forms of wildlife monitoring in terrestrial ecosystems have provided early insights into the potential influence of climate change on wildlife populations, such as in the Kruger National Park.³⁷

Looking to the future – SAEON-based opportunities and potential limitations

Many modelling studies based on empirical correlations of species relationships with climate (the so-called bioclimatic

niche approach) suggest that species ranges and abundance should be sensitive to climate change.^{8,38–41} Systematic observations could therefore provide a sensitive test of these projections by monitoring species turnover in time, with the added benefit of revealing the demographic processes that accompany range shifts. Recent developments in detecting climate change effects on ecosystems and wild species have begun to invoke the stringent requirement of 'joint attribution'⁴² – that is, a statistical match between modelled expectations of climate changes and their impacts on the ecosystem as predicted and observed. Early work of this type on *Aloe dichotoma* has achieved some success.¹⁸

The likelihood of future joint attribution in southern Africa remains slim, nonetheless, given the few studies in this area under way. A lack of credible evidence that climate change is affecting biodiversity and ecosystems, either positively or negatively, or that predicted effects are being realized, will ultimately undermine a key voice for climate policy and adaptation measures in South Africa. A pressing goal of SAEON should be the development of coupled modelling and empirical studies over a range of time scales that can further the achievement of joint attribution.

Given the wealth of biodiversity in southern Africa, and the wide array of plant and animal 'functional types', this region seems to offer excellent opportunities to use a national network of systematically observed sites for changes in abundance and/or species distributions that may confirm or refute expected responses to climate trends. The region has also developed a significant store of species distribution databases (though recognizing the considerable taxonomic bias thereof and the poor quality of invertebrate databases),⁴³ and fine-grained climate and substrate spatial information. Such resources have fuelled a productive effort in modelling the potential responses of many hundreds of species, including invasive aliens, to potential anthropogenic climate changes.^{38–41} This represents a powerful data set to guide focused monitoring efforts at the national scale, especially if combined with future modelling efforts that should develop projections for changes in ecosystem processes (such as fire and biological invasions), and range shifts for a broader range of vagile functional types such as birds and insects, under a broader set of climate change scenarios.

It is not only climate trends that may force ecosystem modifications—changes

in atmospheric CO₂ alone are believed to be able to alter the relative success of plant functional types by favouring, for example, woody plants coexisting with grasses in savanna-type ecosystems.⁴⁴ Long-term monitoring of permanent plots with controlled fire frequency in key sites around the country has been crucial in developing an early understanding of how this trend may alter southern African ecosystem structure and function.⁴⁵ More recent modelling of CO₂ fertilization effects suggest that even semi-desert regions may experience some increase in vegetation cover as CO₂ continues to rise and possibly ameliorate or counteract the potentially adverse effects of warming and increasing soil water stress.⁴⁶ Many large-scale experiments in the northern hemisphere have simulated this atmospheric change and discovered some ameliorating impacts,⁴⁷ but only one such experiment⁴⁸ has been conducted in the southern hemisphere.

While the potential role of LTER in detecting the effect of climate change is promising, significant barriers remain to establishing credible links between climate change trends and ecological responses in South Africa, and indeed in broader regions of the southern hemisphere. There are three main reasons for this:

- Species ranges and ecosystem function may be controlled by water availability and drought, rather than linear and/or threshold-type temperature effects.^{49,50} This implies that climates in South Africa are typical of parts of the world where few ecological changes have been attributed to climate change, and stochastic events may trigger changes in ecosystem states. Teasing apart water and temperature control on plant species composition is critical in projecting the effect of climate change on tree success in South African grasslands, for example, where frost has been proposed as a primary limiting factor.⁵¹ Several other factors may, however, be dominant drivers.⁴⁵
- Species occurrence and ecological success and ecosystem function are significantly affected by fire regime in many parts of the region,^{45,52} obscuring or complicating the attribution of climate change impacts.
- LTER sites are selected to represent 'typical' biomes or ecosystem types, a strategy that possibly limits the sensitivity of their component species to climate change, as sites may be positioned far from the 'edge' of biome and species ranges.

To counter these limitations, LTER efforts need careful strategizing to avoid obvious pitfalls.

Extreme events: It will be important to account carefully for inherently variable southern African rainfall,⁵³ due especially to an apparent quasi-cyclical pattern on roughly decadal time scales,⁵⁴ often associated with remote changes in sea-surface temperatures and global oscillations such as the El Niño–Southern Oscillation.⁵⁵ An awareness of environmental and climate history will be crucial to interpreting data on trends – observations beginning after the severe drought of 1925–1934 would likely yield rather different trends from observations started after the good rainfall seasons of the 1970s. Sites with already established historical data should be preferred for this reason. Importantly, LTER efforts should avoid poor integration between observations made on different aspects of the environments at different sites that may result from a narrow focus of individual projects. The independent monitoring of different environmental features has previously been noted as an unintended weakness in LTER.⁶

Many challenges are associated with long-term monitoring of extreme climatic events, and the maintenance of consistency of observational methods is key.⁵⁶ In order to define an event statistically, the use of multiple variables to define events is advisable, and should facilitate the identification of trends, especially if events can be monitored over spatial scales broader than that of a single site. Appropriate statistical methods for defining extreme events should also be carefully considered.⁵⁷ Given that there are substantial difficulties associated even with identifying extreme climate events and detecting their trends,⁵⁶ there will be an even greater onus on careful and reproducible observations of biota. Indeed, such transient-type responses have been suggested as the key to understanding long-term ecological change.⁵² Investigations of the changing variance in systems may likewise provide a key indicator of the likely imminence of ecological transition.^{58,59}

Fire impacts: While fire is widely recognized as a driver of ecosystem structure, function and species composition, most work in this arena has focused on plant species, vegetation and ecosystem nutrient cycling. Rather little is known about the effects of fire on fauna, e.g. ref. 60. Unfortunately, fire frequency and intensity are functions of climatic factors, and may therefore be expected to change as

climate alters,⁶¹ as has been observed in temperate ecosystems.⁶² A key decision on LTER sites will centre on fire management – the maintenance of a range of fire regimes in fire-prone environments will be desirable, while the possible introduction of fire as a novel ecosystem disturbance in non-fire-prone sites will increasingly become relevant if warming trends continue. This is an issue that needs careful deliberation.

Site representivity: In LTER focused on the detection of climate change effects, placement of observation sites can be optimized to increase the probability of detecting trends. This may be carried out in one way by assessing where climate changes themselves may be more likely, or by positioning sites at points where change may be inherently more detectable. The importance of ecotonal vegetation types as areas that may be sensitive to changes in environmental conditions has long been recognized, and they may therefore be useful in change detection. For example, Stohlgren⁶³ described the arrangement of forty-two 1000-m² plots in characteristic forest types and intervening ecotones, on 14 vegetation transects. Permanent monitoring transects such as these should be designed and implemented to detect species compositional change over time, and especially to detect increasing prevalence of alien organisms, e.g. ref. 64.

What is clear is that a strategy of selecting representative ecosystem types for long-term monitoring may result in site placement well within the geographical borders of target biomes or ecosystem types. Such a strategy reduces the chances of detecting species and ecosystem responses to climate changes, as these 'typical' sites may be far from ecotonal regions where component species are more likely to experience limiting climatic drivers. This shortcoming might be overcome by using experimental treatments that drive climatic conditions to more extreme levels,^{65,66} or simulate anticipated human impacts such as eutrophication, e.g. ref. 67. In addition, altitudinal transects, and transects which span the boundaries of one or more biomes, may be of particular significance for detecting the effects of change, especially where such change is predicted to be rapid, as is the case in some areas of the Grassland/Savanna, Succulent Karoo and Fynbos biomes.^{45,64,68}

Taken together, the use of altitudinal transects and experimental treatments (such as drought, warming or CO₂ fertilization) to 'force' responses or control disturbance regimes would be a useful

addition to LTER and would help to address all three challenges identified above. Such treatments may also provide insights into anticipated responses in biota⁶⁹ that may guide ongoing detection of change by the LTER programme.

In summary, while the detection of the effects of climate change is only one of several primary objectives, SAEON provides a rare opportunity to coordinate this important objective countrywide, to maximize the chance for ecological work to guide policy. The cost of coordinating observations, as suggested above, is not likely to be much higher than that of programmes of independent observations. The cost of implementing experimental treatments replicated between SAEON sites will be high, however, but will provide useful opportunities to train and employ ecologists in a policy-relevant field that is urgently needed in this country. A focus on detecting climate change through SAEON would likely both sharpen the emphasis of monitoring protocols over time, and provide a rationale for maintaining funding inputs, science training and capacity building for the long haul, especially if the information generated were interpreted for the benefit of policy-making.
