In meiotic prophase, synaptonemal complexes (SCs) closely appose homologous chromosomes (homologs) along their length. SCs are assembled from two axial elements (AEs), one along each homolog, which are connected by numerous transverse filaments (TFs). We disrupted the mouse gene encoding TF protein Sycp1 to analyze the role of TFs in meiotic chromosome behavior and recombination. *Sycp1*^{-/-} mice are infertile, but otherwise healthy. *Sycp1*^{-/-} spermatocytes form normal AEs, which align homologously, but do not synapse. Most *Sycp1*^{-/-} spermatocytes arrest in pachynema, whereas a small proportion reaches diplonema, or, exceptionally, metaphase I. In leptotene *Sycp1*^{-/-} spermatocytes, γ H2AX (indicative of DNA damage, including double-strand breaks) appears normal. In pachynema, *Sycp1*^{-/-} spermatocytes display a number of discrete γ H2AX domains along each chromosome, whereas γ H2AX disappears from autosomes in wild-type spermatocytes. RAD51/DMC1, RPA, and MSH4 foci (which mark early and intermediate steps in pairing/recombination) appear in similar numbers as in wild type, but do not all disappear, and MLH1 and MLH3 foci (which mark late steps in crossing over) are not formed. Crossovers were rare in metaphase I of *Sycp1*^{-/-} mice. We propose that SYCP1 has a coordinating role, and ensures formation of crossovers. Unexpectedly, *Sycp1*^{-/-} spermatocytes did not form XY bodies.

In meiosis, two rounds of chromosome segregation follow one round of replication. The first segregation, meiosis I, is reductional, as homologous chromosomes (homologs) move to opposite poles, whereas meiosis II is equational, because sister chromatids disjoin. The disjunction of homologs is prepared during the prophase of meiosis I, when homologs pair and nonsister chromatids of homologs recombine (for review, see Zickler and Kleckner 1999). The resulting crossovers and cohesion between the sister chromatids connect the homologs and ensure their proper disjunction at meiosis I. In most analyzed eukaryotes, meiotic recombination is accompanied by the close apposition of homologs by a zipper-like proteinaceous structure, the synaptonemal complex (SC). After premeiotic S-phase, the two sister chromatids of each chromosome develop a common axial structure,

the axial element (AE), which consists of a linear array of protein complexes involved in sister chromatid cohesion (cohesin complexes), associated with various additional proteins (for review, see Page and Hawley 2004). Numerous transverse filaments (TFs) then connect the AEs of two homologs (synapsis) to form an SC. Within the SC, AEs are called lateral elements (LEs).

Genes encoding TF proteins have been identified in mammals (*Sycp1*), budding yeast (*ZIP1*), *Drosophila* (*c(3)G*), and *Caenorhabditis* (*Syp-1* and *Syp-2*). SYCP1, Zip1, and C(3)G are long coiled-coil proteins with globular domains at both ends. Within SCs, they form parallel coiled-coil homodimers, which are embedded with their C termini in the LEs, whereas the N termini of TF protein molecules from opposite LEs overlap in the narrow region between the LEs of the two homologs. *Caenorhabditis* Syp-1 and Syp-2 are two short coiled-coil proteins, which possibly take the place of a single longer coiled-coil protein in other species (for review, see Page and Hawley 2004).

In the three species in which it has been analyzed, *Drosophila*, *Caenorhabditis*, and yeast, TF-deficient mu-

tants still initiate meiotic recombination by induction of DNA double-strand breaks (DSBs) (Storlazzi et al. 1996; Colaiácovo et al. 2003; Jang et al. 2003), and align homologous chromosomes. However, they are deficient in crossover formation (for reviews, see Zickler and Kleckner 1999; Page and Hawley 2004). In *Caenorhabditis* and *Drosophila*, meiotic crossing over is abolished (Page and Hawley 2001; MacQueen et al. 2002; Colaiácovo et al. 2003), whereas in yeast *zip1* null mutants, meiotic crossing over is reduced (Sym et al. 1993; Börner et al. 2004). Interestingly, Zip1 contributes to crossover formation even if no SC is assembled (Storlazzi et al. 1996), so not all functions of TF proteins in crossover formation require an intact SC structure; Storlazzi et al. (1996) proposed that Zip1 has a role in crossover designation before an SC is formed.

Börner et al. (2004) analyzed the crossover defect of yeast *zip1* null mutants in detail. In wild-type yeast meiosis, DSB ends are resected so that 3' single-stranded tails arise (Sun et al. 1991). *zip1* mutants show wild-type levels and kinetics of DSB formation and resection, but coordinate defects in later steps, namely, the formation of single end invasions (SEIs), double Holliday junctions (dHJs), and crossovers, which indicates that the progression from resected DSBs to SEIs is affected in *zip1* mutants. Because in wild-type yeast SEIs appear in late zygonema (Hunter and Kleckner 2001), Zip1 fulfills its role in this step in crossover formation before an intact SC structure has been formed.

The relation between SC formation and recombination implies more than a requirement of TF proteins for crossing over. Synapsis and recombination are interdependent in most species, and the interdependency differs between species. In yeast and mouse, but not *Drosophila*, disruption of genes involved in meiotic DSB formation, resection, or strand invasion also affect synapsis, and most recombinational interactions in early meiosis probably serve to establish or stabilize homolog alignment and/or initiation of synapsis (for review, see Hunter 2003). Because of this interdependence it is important to analyze the localization of complexes of recombination-related proteins relative to the SCs/AEs in TF-deficient mutants. Such complexes can be recognized immunocytochemically (Anderson et al. 1997; Moens et al. 2002). Upon immunofluorescent labeling they are visible as foci by light microscopy. The composition of foci changes as meiotic prophase proceeds, which most likely directly or indirectly reflects successive steps in homolog alignment and recombination (for review, see Ashley and Plug 1998).

The mouse provides excellent opportunities for studying the role of TFs in chromosome pairing and recombination by an immunocytological approach, because the cytology of mouse meiosis is very well developed, and successive stages of meiosis can be determined precisely (for review, see Ashley 2004). Furthermore, several SC components, including TF protein SYCP1 (Meuwissen et al. 1992; Sage et al. 1995) and many recombination-related proteins have been identified in the mouse, and the localization of these proteins in mouse meiosis has been

studied in great detail (Heyting and Dietrich 1991; Ashley and Plug 1998; Moens et al. 2002). We disrupted the *Sycp1* gene and analyzed the effect of the disruption on male meiosis, following an immunocytochemical approach. We focused on the state of the AEs and the formation of foci containing recombination-related proteins in order to find out whether and how homolog alignment, meiotic recombination, and SC assembly are affected in *Sycp1*^{-/-} mutants.

Results

Targeted inactivation of *Sycp1*

We disrupted the mouse *Sycp1* gene, using a targeting vector in which exon 2 to exon 8 of the gene had been replaced by a neomycin selection marker. The replaced sequence includes the splice donor sequence of intron 1, the ATG start codon in exon 2, and ~20% of the *Sycp1* ORF (Fig. 1A). The targeting vector was linearized and electroporated into embryonic stem (ES) cells. We tested ~600 neomycin- and gancyclovir-resistant ES cell clones by PCR for correct targeting. About 2% of the clones

Figure 1. Targeted inactivation of mouse *Sycp1*. (A) Structure of the targeted region of the wild-type *Sycp1* gene with exons 1–8 (top), targeting vector (center), and targeted allele (bottom). The ATG start codon is located in exon 2. Solid boxes indicate exons. Targeted integration results in a deletion including the 3'-end of exon 1 and exons 2–8. (E) EcoRI; (B) BglII; (H) HindIII; (S) SphI; (SII) SacII. The SalI site indicated between brackets was derived from the λ phage vector. Arrows indicate the primers used for screening for correctly targeted clones. (B) Blot analysis of DNA from wild-type (+/+) and heterozygous (+/-) ES cells digested with HindIII (left) and SphI (right) and hybridized with the L probe and the M probe, respectively. The wild-type 13.5-kb HindIII fragment is replaced by a 9.0-kb fragment in the mutant and the 8.5-kb SphI fragment from the wild-type allele by a 6.0-kb fragment. (C) Western blot analysis of testis cell extracts from *Sycp1*^{-/-} mice. Strips carrying proteins from testis cell extracts from heterozygous mice (left in each pair of strips) or *Sycp1*^{-/-} mice (right strip) were probed with antibodies against the N-terminal (N), middle (M), or C-terminal part (C) of SCP1 (the rat protein homologous to SYCP1), or against nearly full-length SCP1 (F). (P) Ponceau S-stained strips. Arrows indicate the top of the gel and the electrophoresis front. (kDa) Molecular mass in kilodaltons.

Figure 2. Morphology, histology, and TUNEL analysis of testes from *Sycp1*^{-/-} mice. The histological sections were stained with hematoxylin and eosin. (A–F) Testicular histology of adult *Sycp1*^{-/-} (–/–, A,C,E) and *Sycp1*^{+/-} (+/–, B,D,F) mice. Note the total absence of post-meiotic germ cells in *Sycp1*^{-/-} sections. Pachytene nuclei are abundant, but show aberrant nuclear morphology. (G–J) TUNEL analysis of testis sections of *Sycp1*^{-/-} (–/–, G,I) and *Sycp1*^{+/-} (+/–, H,J) mice. Tubule sections with numerous TUNEL-positive nuclei occur only in *Sycp1*^{-/-} mice. A few apoptotic nuclei are visible in tubule sections from *Sycp1*^{+/-} mice. (K) Testes from *Sycp1*^{+/-} (+/–) and *Sycp1*^{-/-} (–/–) mice. Bars: A–D,I,J, 50 μm; E,F, 25 μm; G,H, 100 μm; K, 2 mm.

tested contained the disrupted *Sycp1* allele. Correct targeting was confirmed by Southern blot analysis (Fig. 1B). We injected targeted ES clones into C57BL/6 blastocysts and obtained germline transmitting chimeric animals. Intercrosses of *Sycp1*^{+/-} animals yielded *Sycp1*^{+/+}, *Sycp1*^{+/-}, and *Sycp1*^{-/-} offspring in the expected Mendelian ratio. The *Sycp1*^{-/-} mice are viable and don't display obvious developmental defects. Antibodies against peptides covering the N-terminal, middle, or C-terminal part of SCP1 (the rat protein homologous to SYCP1), or against nearly full-length SCP1, did not bind to any proteins in testis cell extracts from *Sycp1*^{-/-} mice (Fig. 1C), indicating that these mice do not express truncated SYCP1. Most likely the *SYCP1* disruption equals a null mutation.

Sycp1^{-/-} mice are infertile

Whereas *Sycp1*^{+/-} mice were fully fertile, repeated breeding attempts of *Sycp1*^{-/-} males and females with wild-type animals did not yield any offspring. If the same wild-type animals were mated with heterozygous (*Sycp1*^{+/-}) males or females, pregnancy was readily achieved. *Sycp1*^{-/-} testes and ovaries were much smaller than those of *Sycp1*^{+/-} or wild-type mice (shown for testis in Fig. 2K), and *Sycp1*^{-/-} testes weighed on average 70% less than wild-type testes. Spermatozoa were lacking in epididymides of *Sycp1*^{-/-} knockout males (data not shown). SYCP1 is thus required for correct development of the reproductive organs and for male and female fertility.

Histological analysis of the gonads revealed various

abnormalities. As is explained in detail in the Supplemental Material, the mouse testis is organized in seminiferous tubules, in which cells differentiate coordinately. The tubules from *Sycp1*^{-/-} mice were much smaller than those from wild type (Fig. 2A–F). They contained spermatogonia and spermatocytes, which appeared normal with respect to the presence of AE/LE proteins SYCP2 and SYCP3 (see below; Supplemental Material), but the morphology of their nuclei was often abnormal. Furthermore, spermatocyte stages beyond diplo-nema were rare in *Sycp1*^{-/-} testes, and post-meiotic spermatogenic cells (spermatids and spermatozoa) were completely lacking. Apparently, spermatogenic differentiation is interrupted predominantly at the pachytene stage of *Sycp1*^{-/-} spermatocytes, which most likely causes the sterility of *Sycp1*^{-/-} males. However, as has been found in other mouse meiotic mutants, the organization of the seminiferous tubules was not disrupted and the residual spermatocytes in *Sycp1*^{-/-} mice formed associations with similar cell types (except spermatids) as the corresponding spermatocytes in wild type (Supplemental Material).

Sycp1^{-/-} ovaries weighed on average 35% less than *Sycp1*^{+/-} or *Sycp1*^{+/+} ovaries. Growing follicles and oocytes were lacking in sections of *Sycp1*^{-/-} ovaries, which suggests a disruption of oocyte development during meiosis, followed by apoptosis.

SYCP1-deficiency leads to increased apoptosis during pachynema

One possible explanation for the lack of spermatids in *Sycp1*^{-/-} testes is that spermatogenic cells enter apopto-

Figure 3. Assembly of AEs in *Sycp1*^{-/-} mice. (A,B) Electron micrographs of AEs and SCs from wild-type (+/+) and *Sycp1*^{-/-} (–/–) male mice. (A) Wild-type SC with closely apposed AEs and a CE. (B) Homologously aligned AEs from a *Sycp1*^{-/-} spermatocyte, connected by AAs. (Figure 3 legend on facing page.)

sis during meiotic prophase (for review, see de Rooij and de Boer 2003). We tested this using TUNEL analysis of

testis sections from ~8-wk-old *SyCP1*^{+/+} and *SyCP1*^{-/-} mice. In *SyCP1*^{+/+} testes, we found on average 0.7 apo-

de Vries et al.

ptotic nuclei per cross-sectioned tubule, which is slightly more than previously found in wild type (Baarends et al. 2003). In *Sycp1*^{+/-} testes, the TUNEL-positive cells were most often in pachynema or metaphase/anaphase I (Fig. 2G–J). In testis sections of *Sycp1*^{-/-} but not of *Sycp1*^{+/-} animals, certain tubules contained many (10 or more) apoptotic nuclei. Accordingly, the percentage of tubule sections with five or more apoptotic nuclei had almost doubled in *Sycp1*^{-/-} compared with *Sycp1*^{+/-} testes (20% vs. 11%). Because the percentage of tubules without apoptotic nuclei had not changed, we think that apoptosis occurs at similar developmental steps in *Sycp1*^{-/-} animals as in wild type, but with a highly increased incidence, resulting in *Sycp1*^{-/-} tubules containing a whole layer of apoptotic nuclei. Thus, in *Sycp1*^{-/-} males, spermatogonia enter meiotic prophase, but most spermatocytes die of apoptosis at pachynema, and exceptionally some get to metaphase I.

AEs are formed in the absence of SYCP1 and align homologously

Sycp1^{-/-} spermatocytes assemble morphologically normal AEs (Fig. 3), which align homologously (Fig. 3; Supplementary Fig. S1), but are not connected by TFs, and do not show a central element between them, i.e., they do not synapse (Fig. 3B). In *Sycp1*^{-/-} spermatocytes, AEs are only connected by a limited number of axial associations (AAs) (Fig. 3A,B), and are farther apart (211 ± 17 nm at AAs) than the LEs in pachytene spermatocytes of wild type (in agar filtrates: 79 ± 3 nm). This resembles the yeast *zip1* phenotype (Sym et al. 1993), including the size of the AAs, and is consistent with the idea that SYCP1 is a TF component. Beyond the most centromere proximal and distal AAs, the AEs tend to be somewhat wider apart, so the AAs are the only or at least the shortest connections between the AEs. All analyzed components of wild-type mouse AEs/LEs were also present in *Sycp1*^{-/-} AEs (Fig. 3; for SYCP2, see Fig. 4).

In the Supplemental Material we present evidence that the order of *Sycp1*^{-/-} and wild-type spermatocyte stages, as defined by AE morphology and extent of alignment/synapsis, is the same (Supplementary Figs. S2, S3), and that corresponding *Sycp1*^{-/-} and wild-type stages have similar life spans, at least until the spermatocytes enter apoptosis. We use, therefore, AE morphology and alignment/synapsis as criteria for staging and comparing *Sycp1*^{-/-} and wild-type spermatocytes. The assembly and alignment of AEs, as detected by REC8/SYCP3 double labeling, proceeds similarly in *Sycp1*^{-/-} and wild type (Fig. 3K–T). The pseudo-autosomal parts of the X and Y chromosome, however, were not aligned in 28% of the *Sycp1*^{-/-} pachytene cells, whereas they were synapsed in 100% of the wild-type pachytene cells (examples shown in Figs. 3, 4). Although most *Sycp1*^{-/-} spermatocytes are lost during pachynema (above), some reach diplonema; 0%–3% (depending on the mouse) of the spermatocytes in spreads of *Sycp1*^{-/-} testis cell suspensions were in diplonema, compared with 15% of the spermatocytes in

spreads of wild-type testis cell suspensions (late meiotic prophase stages are overrepresented in cell suspensions). Diplotene *Sycp1*^{-/-} AEs resemble wild-type LEs/AEs, including the thickened ends and the apparent repulsion of the LEs/AEs of homologous chromosomes (Fig. 3T; Supplementary Fig. S2).

Meiotic recombination is initiated in Sycp1^{-/-} spermatocytes, but repair is not completed

γ H2AX is a phosphorylated form of histone variant H2AX, which marks chromatin domains with DNA damage, including DSBs (Rogakou et al. 1999). γ H2AX appeared throughout *Sycp1*^{-/-} preleptotene and leptotene nuclei (Fig. 4F), as in wild type (Fig. 4A; Mahadevaiah et al. 2001). However, whereas γ H2AX becomes largely restricted to asynapsed portions of wild-type zygotene chromosomes (Fig. 4B; Mahadevaiah et al. 2001), it occurs all along the AEs, including the aligned portions, of *Sycp1*^{-/-} zygotene chromosomes (Fig. 4G). The intensity of γ H2AX labeling along the *Sycp1*^{-/-} bivalents varied somewhat, but in most zygotene cells we could not distinguish separate γ H2AX-positive domains (Figs. 4G, 5N). This pattern changed in *Sycp1*^{-/-} pachynema: Some *Sycp1*^{-/-} pachytene cells displayed a mixture of long stretches of γ H2AX and narrow, intense γ H2AX-positive domains, and other pachytene cells (presumably of a later stage) showed only narrow, γ H2AX-positive domains along otherwise γ H2AX-negative bivalents (Fig. 4H). Diplotene *Sycp1*^{-/-} spermatocytes displayed only the latter pattern (Fig. 4I). Late pachytene/early diplotene *Sycp1*^{-/-} spermatocytes contained 110 ± 4.6 distinct, narrow γ H2AX-positive domains per cell. In earlier spermatocyte stages the γ H2AX-positive domains were too indistinct and heterogeneous to be counted. In wild type, we found only distinct, narrow γ H2AX-positive domains along synapsed stretches in late zygonema and early pachynema (Fig. 4B,C), and these domains were weakly labeled and disappeared during the course of pachynema (Fig. 4D; Mahadevaiah et al. 2001). Taken together, the γ H2AX pattern suggests that meiotic DSBs are formed in *Sycp1*^{-/-} meiosis, but that at least some DSBs are not repaired, or their repair gets stuck at some intermediate step that is still marked by γ H2AX. Another abnormality in the γ H2AX pattern was found on the sex chromosomes: Wild-type pachytene and diplotene spermatocytes have γ H2AX throughout the chromatin of the XY body (Fig. 4C–E; Mahadevaiah et al. 2001) (a condensed chromatin structure containing the sex chromosomes formed during male meiotic prophase in mammals). In striking contrast, the sex chromosomes of *Sycp1*^{-/-} pachytene and diplotene spermatocytes displayed similar narrow γ H2AX-positive domains as the autosomes (Fig. 4H,I).

We also analyzed the putative H2AX phosphorylating kinase ATR (Turner et al. 2004). In leptonema of wild-type mouse, ATR forms foci in association with AE segments (Fig. 4J), and in early zygonema, ATR foci occur along synapsed and asynapsed portions of LEs/AEs (Fig. 4K). From mid-zygonema to early pachynema, ATR dis-

Figure 4. γ H2AX and ATR in wild-type (+/+) and *Sycp1*^{-/-} (-/-) spermatocytes. (A–I) γ H2AX. (A,F) Leptonema. (B,G) Zygonema. (C) Early pachynema. (D,H) Mid-pachynema. (E,I) Diplonema. The sex chromosomes (XY) form an XY body in wild-type spermatocytes (C–E), but not in *Sycp1*^{-/-} spermatocytes, even though the X and Y chromosomes are associated in the cells in H and I. (J–Q) ATR. (J,N) Leptonema. (K,O) Zygonema. (L) Early pachynema. (M,P) Mid-pachynema. (Q) Diplonema. ATR is present throughout the chromatin of the XY bivalent in wild-type spermatocytes (M), but forms foci and distinct domains along the X and Y chromosomes in *Sycp1*^{-/-} cells (P,Q). *Insets* in J and N show the close association of ATR with the ends of AE fragments in wild-type (+/+) and *Sycp1*^{-/-} leptonema. Bars, 10 μ m.

appears from synapsed portions of SCs and accumulates along the nonautosomal parts of the XY bivalent and late pairing (“laggard”) portions of autosomal LEs/AEs (Fig. 4L; Turner et al. 2004 and references therein). In *Sycp1*^{-/-} leptonema and early zygonema, the ATR pattern was indistinguishable from wild type (Fig. 4N). However, whereas the ATR signals disappeared from the synapsed portions of AEs in wild type, they were present along the aligned AEs in *Sycp1*^{-/-} spermatocytes, usually in AE-associated foci, or incidentally in distinct domains that were reminiscent of the γ H2AX domains (Fig. 4P,Q). The dense ATR coating of laggard asynapsed portions of AEs

as is found in wild type (Fig. 4L) was not found in *Sycp1*^{-/-} spermatocytes. Strikingly, ATR shows the same aberrant pattern on the X and Y chromosome in *Sycp1*^{-/-} pachynema as γ H2AX: It forms few, discrete foci, or occasionally domains, on the AEs of the X and Y chromosome rather than covering all non-pseudo-autosomal parts of the AEs of the sex chromosomes (Fig. 4P,Q). In short, the ATR pattern in *Sycp1*^{-/-} spermatocytes differs in various respects from that in wild type, but the similarity of the ATR and γ H2AX patterns found in wild type (Turner et al. 2004) is also found in *Sycp1*^{-/-} spermatocytes (Fig. 4).

de Vries et al.

(Figure 5 legend on facing page.)

Sycp1^{-/-} spermatocytes barely form crossovers

To find out which step in meiotic recombination could be blocked in *Sycp1*^{-/-}, we analyzed proteins involved in later steps of meiotic recombination. Rad51 and Dmc1 are RecA homologs required for heteroduplex formation in meiosis, probably by assembling on 3' tails of resected DSB ends and initiating the strand invasion step (for review, see Shinohara and Shinohara 2004). In wild-type mouse, RAD51/DMC1 foci are formed along the AEs from leptotema on. In zygonema, they are located along synapsed and asynapsed portions of SCs, and in pachynema they gradually disappear (Fig. 5A,B; Ashley and Plug 1998). In *Sycp1*^{-/-} leptotema, RAD51/DMC1 foci appeared in similar numbers as in wild type, but their number decreased more slowly (Fig. 5C,S; Supplementary Fig. S4). Even late pachytene/early diplotene *Sycp1*^{-/-} spermatocytes displayed appreciable numbers of RAD51/DMC1 foci (Fig. 5D,S). Thirty percent to 50% of the RAD51/DMC1 foci were between the aligned AEs in *Sycp1*^{-/-} late zygonema and late pachynema/early diplotema (Fig. 5D; Supplementary Fig. S4). RAD51/DMC1 foci between aligned AEs occur also in wild-type mouse, maize, and *Sordaria* (for review, see Zickler and Kleckner 1999; Tessé et al. 2003). Because homolog alignment requires DSBs (Tessé et al. 2003), the RAD51/DMC1 foci between aligned AEs might mark recombinational interactions between homologs. Part of the RAD51/DMC1 foci in *Sycp1*^{-/-} pachytene cells colocalize with γ H2AX domains (Fig. 5Q,R).

RPA binds to single-stranded DNA, and in vitro it enhances nucleoprotein formation by RAD51 if added to the reaction mixture after RAD51 (Pâques and Haber 1999). In wild-type spermatocytes, RPA foci appear and disappear on average later than RAD51/DMC1 foci (Fig. 5E,F,S; Supplementary Fig. S4; Moens et al. 2002). In *Sycp1*^{-/-} leptotene and late zygotene spermatocytes, the number of RPA foci and their time of appearance in relation to alignment/synapsis were similar as in wild-type zygonema (Fig. 5G,S; Supplementary Fig. S4). However, *Sycp1*^{-/-} diplotene spermatocytes still have appreciable numbers of RPA foci (Fig. 5H,S; Supplementary Fig. S4). About 80% of the RPA foci were located between two aligned AEs of *Sycp1*^{-/-} spermatocytes (Fig. 5G; Supplementary Fig. S4). RPA foci between aligned AEs occur also in wild-type zygonema (Fig. 5G) and between homologously aligned but not synapsed LE/AE segments between translocation breakpoints in *Sycp1*^{+/+} pachynema (Plug et al. 1997).

Msh4 is a MutS homolog, which forms a heterodimeric complex with another MutS homolog, Msh5. The Msh4/Msh5 heterodimer probably recognizes and stabilizes meiotic recombination intermediates (Ross-Macdonald and Roeder 1994; Snowden et al. 2004). Yeast Msh4 localizes to sites of synapsis initiation. *msh4* mutants show partial and delayed synapsis and 30%–50% of the wild-type level of crossing over, and *msh4* mutations affect the same subset of crossovers as *zip1* mutations (Novak et al. 2001). In mouse, MSH4 foci colocalize extensively with RPA foci, but appear and disappear slightly later (Moens et al. 2002). Otherwise than in yeast, the number of MSH4 foci in mouse far exceeds the number of chiasmata that will be formed (Fig. 5I,S; Supplementary Fig. S4). Neyton et al. (2004) proposed that in mouse meiosis, MSH4 cooperates first in zygonema with RAD51/DMC1 in homolog alignment, synapsis initiation, and/or in resolution of early DNA–DNA interactions, and subsequently, in pachynema, with MLH1 and MLH3 in crossover formation. In *Caenorhabditis*, MSH-4 and MSH-5 appear to fulfill only this second role: *msh-4* or *msh-5* mutants align homologs and assemble SC, but RAD-51 foci persist and crossovers are not formed, which suggests a role for MSH-4/5 downstream RAD-51 in crossover formation in *Caenorhabditis* (Colaiácovo et al. 2003). In mouse, *Sycp1*^{-/-} leptotene and zygotene spermatocytes display similar numbers of MSH4 foci as wild-type spermatocytes (Fig. 5K,M,S; Supplementary Fig. S4). Most *Sycp1*^{-/-} MSH4 foci are between aligned AEs, indicating that they mark DNA interactions between homologs. However, in *Sycp1*^{-/-} late pachynema/early diplotema, the number of MSH4 foci is still 70% of that in late zygonema (Fig. 5L,S; Supplementary Fig. S4). This might suggest that the DNA–DNA interactions to which MSH4 binds are formed normally in *Sycp1*^{-/-}, but that most of these cannot be processed.

MLH1 is essential for crossover formation, both in mammals and yeast (Baker et al. 1996; Hunter and Borts 1997). In mouse, MLH1 foci appear in mid-pachynema, and their position and number closely correlate with those of chiasmata (Froenicke et al. 2002). MLH3 foci largely colocalize with MLH1 foci in the mouse (Svetlanov and Cohen 2004), and MLH3 most probably cooperates with MLH1 in crossover formation (Wang et al. 1999; Lipkin et al. 2002). *Sycp1*^{-/-} spermatocytes do not form MLH1 and MLH3 foci (Fig. 6), which indicates that SYCP1 is required for crossover formation. Accordingly, we observed only univalents in the two natural meta-

Figure 5. Recombination-related proteins along AEs and SCs in wild-type (+/+) and *Sycp1*^{-/-} (-/-) spermatocytes. (A–D) RAD51/DMC1. (A,C) Late zygonema. (B,D) Late pachynema. (E–H) RPA. Figure 6. Formation of crossovers and chiasmata. MLH1 labeling (A,B) and MLH3 labeling (C,D) of wild-type (+/+) or *Sycp1*^{-/-} pachytene spermatocytes. The *Sycp1*^{-/-} spermatocytes do not assemble MLH1 or MLH3 foci. (E,F) A natural (E) and an OA-induced (F) metaphase I spermatocyte of *Sycp1*^{-/-}. In the cells shown here, only univalents can be identified; the inset in F shows a bivalent found in another OA-induced *Sycp1*^{-/-} metaphase I. Bars: A–F, 10 μm; inset in F, 1 μm.

phases I that we found among spread spermatocytes of *Sycp1*^{-/-} mice (Fig. 6E). If we forced pachytene or diplo-tene *Sycp1*^{-/-} spermatocytes to condense their chromosomes, using okadaic acid (OA), most chromosomes formed univalents (Fig. 6F). Chromosomal fragments were rare in natural metaphase I or OA-induced metaphase I-like configurations of *Sycp1*^{-/-} (Fig. 6E,F).

Taken together, the immunofluorescence labeling of foci suggests that *Sycp1*^{-/-} spermatocytes can initiate meiotic recombination at wild-type level and establish stable homologous alignment of autosomes. However, many repair/recombination intermediates are not repaired and crossovers are not formed.

Sycp1^{-/-} spermatocytes do not form XY bodies

In 28% of the *Sycp1*^{-/-} pachytene spermatocytes, the X and Y chromosome were associated, but this did not ensure formation of an XY body. In *Sycp1*^{-/-} pachynema, γ H2AX and ATR occurred in a similar discrete pattern along the AEs of the XY bivalent as along autosomal AEs

(Fig. 4I,P,R) (rather than covering the nonautosomal parts of the sex chromosomes), the characteristic DAPI-intense domain of the XY body was not formed, and the AEs of the X and Y chromosomes were not curled or bent, as is usually seen in wild-type XY bodies (Fig. 4, cf. D,E and H,I,Q). We will analyze the XY bivalent in *Sycp1*^{-/-} spermatocytes in more detail in a separate study.

Discussion

In this study we disrupted the mouse *SYCP1* gene and analyzed the effect on meiotic recombination and chromosome behavior by an immunocytochemical approach. We will assume that immunofluorescence signals represent functional protein complexes and that orthologous proteins fulfill similar roles in mouse and yeast meiosis, unless there are indications that this is not so. In addition, we will have to make assumptions when and how the proteins act that we detect by immunofluorescence, to link the cytological observations in *Sycp1*^{-/-} mice to studies at the DNA and cytological level in other organisms.

Early meiosis in *Sycp1*^{-/-} spermatocytes

We used AE morphology as detected by SYCP2 or SYCP3 labeling and alignment/synapsis as a basis for staging (Fig. 3; Supplementary Fig. S3). *Sycp1*^{-/-} and wild-type spermatocyte stages that correspond by these criteria also show similar patterns of cohesins (shown for REC8 in Fig. 3K–T), but display largely different patterns of recombination-related proteins other than cohesins. Leptonema is the only analyzed stage in which *Sycp1*^{-/-} and wild-type spermatocytes show similar immunofluorescence patterns of all analyzed proteins: The γ H2AX and ATR patterns are similar, and RAD51/DMC1, RPA, and MSH4 foci occur in similar numbers in wild-type and *Sycp1*^{-/-} leptonema, indicating that DSBs are induced and that some post-DSB step(s), presumably at least resection of DSB ends (Xu et al. 1997), take place at wild-type levels in *Sycp1*^{-/-} leptonema. However, differences (other than synapsis) between *Sycp1*^{-/-} and wild type become apparent between leptonema and zygonema, in particular with respect to γ H2AX and ATR (Fig. 4K). Furthermore, the number of RAD51/DMC1 foci has decreased between leptonema and zygonema, but less so in *Sycp1*^{-/-} than in wild type (Fig. 5S; Supplementary Fig. S4). The numbers of RPA and MSH4 foci on the other hand are similar in late zygonema in mutant and wild type (Fig. 5S; Supplementary Fig. S4). In wild type, RPA and MSH4 foci most likely arise from RAD51/DMC1 foci, and then lose RAD51/DMC1 (Moens et al. 2002). Although the RAD51/DMC1 foci occur in similar numbers per cell as MSH4 and RPA foci in *Sycp1*^{-/-} late zygonema (Fig. 5S), they cannot completely overlap with these foci, because >80% of the MSH4 and RPA foci are between the aligned AEs, but only 46% of the RAD51/DMC1 foci (Supplementary Fig. S4). Possibly MSH4 foci

are normal in *Sycp1*^{-/-} late zygonema, but some repair pathway is affected that is marked by RAD51/DMC1 but not by MSH4 foci. However, as the turnover of MSH4 and RAD51/DMC1 foci is not known, other explanations are conceivable.

Important questions about the immunofluorescence signals in zygonema are, What does the γ H2AX signal throughout the *Sycp1*^{-/-} nuclei indicate? And what do the MSH4 foci represent? In yeast, the number of Msh4 foci per cell roughly equals the number of Zip1-dependent crossovers per cell (Novak et al. 2001), and it seems likely that most or all MSH4 foci in yeast mark sites of future crossovers. In mammals and *Arabidopsis*, the number of MSH4 foci exceeds the number of crossovers by far, so in these organisms most MSH4 foci will not become crossovers, but mark possibly recombinational interactions that serve homolog alignment (Higgins et al. 2004; Neyton et al. 2004); the MSH4 images of late zygotene cells (Fig. 5K,M; Supplementary Fig. S4) suggest that such interactions occur normally in *Sycp1*^{-/-}. An ensuing question is whether there are any crossover-designated MSH4 foci at all among the MSH4 foci in mouse zygonema. In wild-type mouse this might be the case, because some MSH4 foci colocalize with MLH1 in pachynema (Santucci et al. 2000), but the question remains whether these colocalizing MSH4 foci were already present in zygonema. Based on work in yeast (Börner et al. 2004) we would expect so. If so, then they would comprise <10% of all late zygotene MSH4 foci in wild type. It would probably have escaped us if *Sycp1*^{-/-} would lack this type of MSH4 foci (if any) in zygonema. So we do not know whether crossover-designated MSH4 foci are missing from *Sycp1*^{-/-} zygotene spermatocytes (either because crossovers are not designated, or because crossover-designated intermediates fail to form MSH4 foci), or whether crossover-designated MSH4 foci are assembled in *Sycp1*^{-/-} zygonema, but fail to become crossovers in a later stage.

Similar questions arise with respect to γ H2AX. γ H2AX is not restricted to AEs, but occurs throughout chromatin loops. Possibly, a single meiotic DSB causes H2AX phosphorylation on megabases of DNA (which corresponds to tens of loops), like DSBs in somatic cells (Rogakou et al. 1999). Therefore γ H2AX-positive domains might contain only one or a few DSBs (or other γ H2AX-marked recombination intermediates) associated with the AEs (Fig. 5O–R), but do not necessarily also have DSBs in the loops. However, even if we assume this, it is not clear which lesions γ H2AX might mark in *Sycp1*^{-/-} zygonema. Late zygotene spermatocytes of wild type and *Sycp1*^{-/-} have similar numbers of RPA and MSH4 foci (Fig. 5S; Supplementary Fig. S4), yet γ H2AX is restricted to asynapsed AEs and some weak domains in synapsed SC segments in wild type (Fig. 4B), but covers all the chromatin in *Sycp1*^{-/-} (Figs. 4C, 5M). Possible explanations for this difference are (1) MSH4, RPA, and/or RAD51/DMC1 foci in wild type and *Sycp1*^{-/-} look similar but contain different recombination intermediates; only those present in *Sycp1*^{-/-} are marked by γ H2AX. (2) The 70% “extra” RAD51/DMC1 foci in

Sycp1^{-/-} late zygonema (Fig. 5S) bring about the overall γ H2AX labeling. We doubt whether this relatively small number of RAD51/DMC1 marked DSBs or recombination intermediates (60–70 per cell) could cause this. (3) Late zygotene *Sycp1*^{-/-} spermatocytes contain, besides the RAD51/DMC1, RPA, and MSH4 marked DNA structures, other DNA lesions that are not marked by any of these proteins, but are marked by γ H2AX, e.g., unresected DSBs. This seems unlikely: If yeast *zip1* mutants are similar to *Sycp1*^{-/-} in this respect, it would predict an elevated level of that type of DNA-lesions in *zip1*; there are no indications for this (Börner et al. 2004). (4) The γ H2AX labeling in late zygotene *Sycp1*^{-/-} spermatocytes reflects some disorganization in the *Sycp1*^{-/-} cell that is not related to the presence of DSBs. (5) Loss of DSBs or recombination intermediates (due to repair) is uncoupled from loss of γ H2AX staining in *Sycp1*^{-/-}. This may result in the persistence of γ H2AX labeling at sites where there are no breaks (anymore). Although there are no conclusive arguments against the other possible explanations, we prefer the last one, because it accounts for the close correlation between asynapsis and the presence of γ H2AX in wild type. A similar correlation exists between asynapsis and the presence of ATR (Turner et al. 2004) and RAD50 and MRE11 (Eijpe et al. 2000). This correlation could either mean that synapsis can only occur in chromosomal regions where these proteins have been lost, or that these proteins are lost from chromatin loops upon synapsis (or some local SYCP1-dependent event preceding synapsis). The presence of γ H2AX all over the chromatin in *Sycp1*^{-/-} zygotene nuclei argues for the second interpretation: Perhaps synapsis/SYCP1 causes first the loss of ATR, which is then followed by loss of γ H2AX. In *Sycp1*^{-/-} mid- to late pachynema, most γ H2AX eventually disappears from the chromatin, except from a number of distinct domains (Fig. 4H). Since most of these domains have RAD51/DMC1 (Fig. 5Q,R) or MSH4 (Fig. 5O,P) foci at their bases, they probably represent loops in which repair has not been completed.

Role of SYCP1 in later steps of meiotic recombination

In wild-type late pachynema/early diplonema, most or all RAD51/DMC1, RPA, and MSH4 foci have disappeared, whereas *Sycp1*^{-/-} late pachytene/early diplotene cells still have 50%–70% of the number of foci found in zygonema (Fig. 5S; Supplementary Fig. S4). Similar observations have been made in TF mutants of *Caenorhabditis* (Alpi et al. 2003; Colaiacovo et al. 2003) and yeast (Novak et al. 2001). Apparently meiotic recombination is blocked or impeded at a step where these proteins act, possibly single end invasion, because yeast Rad51 and Dmc1 are required for strand invasion (Hunter and Kleckner 2001). Thirty percent to 50% of the RAD51/DMC1, RPA, and MSH4 foci disappear between zygonema and late pachynema/diplonema of *Sycp1*^{-/-}. Whether these foci represent a specific subpopulation or a random sample of the foci in late zygonema is not clear.

Mouse *Sycp1*^{-/-} mutants have in common with TF

de Vries et al.

mutants in other species that crossover formation is affected. More than 90% of the crossovers in the mouse depend on synapsis/SYCP1 (Fig. 6E,F). However, the number of RAD51/DMC1, RPA, and MSH4 foci and γ H2AX signals that are still present in *Sycp1*^{-/-} diplo-nema exceeds the number of crossovers in wild type about fivefold: We counted 117 ± 17 MSH4 foci per diplo-tene *Sycp1*^{-/-} spermatocyte, whereas there are on average 21–25 exchanges per cell in male mouse meiosis (Koehler et al. 2002). SYCP1 is therefore not only required for crossover formation, but also for repair of DSBs that will not become crossovers, at least if persisting MSH4 foci in *Sycp1*^{-/-} still mark DNA lesions. Upon exposure to OA, *Sycp1*^{-/-} spermatocytes repair the recombination intermediates (if any) that underlie the RAD51/DMC1, RPA, and MSH4 foci, because chromatid breaks are rare in OA-induced metaphases I (Fig. 6F). Possibly, OA opens up a DNA repair pathway that is not normally used in wild type, for instance, by releasing the sister chromatid as template for repair. However, exposure to OA reveals little or no crossing over in *Sycp1*^{-/-}, whereas it reveals crossover formation in wild type. Therefore, SYCP1 must have a role in crossover formation besides its proposed role in the repair of breaks that will not become crossovers.

To summarize the role of SYCP1 in recombination: A substantial fraction of meiotic DSBs does not require SYCP1 for repair (Fig. 5S); it is not known whether these breaks are a random sample or a specific subset of breaks. One hundred to 200 breaks per cell (as estimated from the number of foci and γ H2AX signals in late pachy-nema) require SYCP1 and/or synapsis for repair. And the formation of >90% of the crossovers depends on SYCP1 and/or synapsis. This resembles the yeast *zip1* phenotype. The role of SYCP1 in crossover formation is a conserved TF function in all species analyzed thus far. Possibly SYCP1/the SC serve as support for the assembly of MLH1 foci and/or enhance crossing over by providing a close apposition of homologs. Alternatively, or in addition, TF proteins/synapsis might ensure certain overall structural alterations in the bivalents that lead to cross-over formation (Börner et al. 2004).

Role of SYCP1 in XY body formation

This study revealed an unexpected role of SYCP1 in the formation of the XY body. Turner et al. (2004) presented recently evidence that coating of asynapsed portions of AEs with BRCA1 and ATR was correlated with H2AX phosphorylation and transcriptional inactivation. In the XY bivalent this would ultimately result in the formation of an XY body. The aberrant distribution of ATR and γ H2AX in *Sycp1*^{-/-} pachytene spermatocytes provides therefore an obvious explanation for the failure to form XY bodies. However, the question remains why ATR is distributed aberrantly. Perhaps ATR relocates to asynapsed portions of AEs after it has disappeared from synapsed portions of AEs; this might explain the dense coating (rather than discrete foci) of ATR along the last asynapsed portions of AEs, including those of the sex

chromosomes. Possibly ATR does not relocate in *Sycp1*^{-/-}, because it is sequestered at unrepaired DNA breaks, and/or because SYCP1/synapsis is directly or indirectly required for relocation of ATR.

Comparison with other meiotic recombination-deficient mouse mutants

Besides *Sycp1*, other mouse genes homologous to yeast genes involved in the Zip1-dependent pathway of cross-over formation have been knocked out, namely, *Msh4* (Kneitz et al. 2000), *Msh5* (de Vries et al. 1999; Edelmann et al. 1999), and *Dmc1* (Pittman et al. 1998; Yoshida et al. 1998). Contrary to *Sycp1*^{-/-} mice, these knockouts display partial and nonhomologous alignment/synapsis rather than full-length homologous alignment. Presumably, MSH4, MSH5, and DMC1 are indispensable for establishment of stable recombinational interactions between homologs in the mouse, whereas SYCP1 contributes only to a minor extent to the stability of such interactions, at least in leptone-ma till pachynema. *Msh4*, *Msh5*, and perhaps *Dmc1* knockouts enter apoptosis when the spermatogenic epithelium is in developmental stage IV and the spermatocytes should be in early/mid-pachynema (de Vries et al. 1999; de Rooij and de Boer 2003). At least a small proportion of *Sycp1*^{-/-} spermatocytes progresses further and reaches diplo-nema or exceptionally metaphase I. This could be related to the ability of *Sycp1*^{-/-} spermatocytes to establish reasonably stable homologous alignment. Among other mutant mice with a less defined but on average later arrest in meiosis than early/mid pachytene (stage IV), there are several that can align or synapse chromosomes homologously, including *Mlh1*, *Mlh3*, and *Brca1* mutants (for review, see de Rooij and de Boer 2003).

Materials and methods

Construction of the targeting vector

To inactivate the *Sycp1* gene, we designed a targeting construct to replace exons 2–8 by a neomycin gene, using pKO Scrambler V905 as a vector (Lexicon Genetics, Incorporated). The neomycin phosphotransferase gene was isolated as an *AscI* fragment from pKO Select Neo (Lexicon Genetics) and inserted at the unique *AscI* site of pKO V905. The thymidine kinase gene was derived from pKO Select TK (Lexicon Genetics) by *RsiII* digestion and subcloned at the unique *RsiII* site of pKO V905. Genomic fragments were isolated after screening of a λ FixII library derived from 129/Ola E14 cells (a gift of B. Vennström, Mouse Camp Transgene Facility, Karolinska Institute, Stockholm, Sweden). A 2.4-kb *SalI* (vector derived)–*SacII* fragment was used as a left arm. This fragment was first cloned in pGEM-T Easy (Promega), excised as a *SalI*–*NotI* fragment, and cloned as a blunt fragment on the *HpaI* site of pKO V905. A 6-kb *EcoRI* fragment was used as the right arm and inserted in the *EcoRI* site of the targeting vector (Fig. 1). The final pKO plasmid mentioned above, containing all four elements, was linearized with *SalI* before electroporation.

Targeted inactivation of the *Sycp1* gene

129/Ola-derived IB10 ES cells (a subclone from E14 ES cells) were cultured on lethally irradiated mouse embryonic fibro-

blasts in Dulbecco's modified Eagle's medium supplemented with 10% fetal calf serum (Biocell Laboratories Inc.), 2 mM L-glutamate, 1 mM sodium pyruvate, nonessential amino acids, 0.1 mM β -mercaptoethanol, 10^3 U/mL leukemia inhibitory factor (LIF), penicillin (100 U/l) and streptomycin (100 μ g/L). 4×10^7 ES cells were resuspended in 300 μ L PBS, containing 65 μ g linearized targeting vector and electroporated at 800 V and a capacitance of 3 μ F. Cells were seeded in five 9-cm dishes and after 24 and 72 h G418 (175 μ g/mL) and gancyclovir (1.3 μ g/mL) were added, respectively. Resistant colonies were isolated after 10 d of selection and expanded and genomic DNA was analyzed by PCR and blot hybridization. The sequences of the upstream and downstream primers FW4 and neoFW3 are 5'-GGATTG CACGCAGGTTCTCC-3' and 5'-CATACATGCCACGGAGG AAG-3', respectively. Amplifications were performed using the Expand High Fidelity PCR system according to the manufacturer's instructions (Roche Applied Science). Primers were annealed at 60°C. Correct targeting results in a 3.8-kb PCR fragment, which was confirmed by blot hybridization. We micro-injected targeted ES cells into C57BL/6 blastocysts to generate chimeras, and chimeric males were mated with C57BL/6 females. To produce *Sycp1*^{-/-} mice, we intercrossed heterozygous offspring. We genotyped mice by PCR on tail DNA using the primers scp40 (5'-CATGCTCGAACAGGTTAGTA-3'), scp41 (5'-GTGACAAGTCCAGAATTAG-3'), neo7 (5'-CATACGC TTGATCCGGCTC-3'), and neo9 (5'-GATGGCTGGCAACTA GAAGG-3'). Scp40 and scp41 give a 382-bp fragment diagnostic of the wild-type *Sycp1* allele, while neo7 and neo9 give a 488-bp fragment diagnostic of the neomycin selectable marker. PCR conditions were 1 min at 93°C, 1 min at 55°C, and 2 min at 72°C for 35 cycles.

Western blot analysis

We prepared cell suspensions from testes of *Sycp1*^{-/-} and *Sycp1*^{+/-} mice (Heyting and Dietrich 1991) and lysed the cells in Laemmli sample buffer. We loaded 5×10^5 lysed cells per 0.8-cm-wide slot of a 10% polyacrylamide gel and separated the proteins by sodium dodecyl sulfate-polyacrylamide gel electrophoresis. After transfer of the proteins to nitrocellulose (Schleicher & Schuel) by electroblotting, we stained the resulting blots with Ponceau S and scanned them using an Agfa Snapscan 1212 flatbed scanner before we probed them with antibodies. From each lane, four strips were cut, which were each incubated in one of the anti-SYCP1 antisera, and then in secondary (anti-rabbit) antibodies conjugated to alkaline phosphatase (AP; Promega), as described (Offenberg et al. 1998).

Histological analysis and TUNEL assay

Animals were killed by cervical dislocation. Testes, epididymides, and seminal vesicles, or ovaries and uterus were examined and weighed. From each male, we fixed one testis and epididymis in Bouin's fixative for 24 h at room temperature, and the other testis in phosphate-buffered formalin for 24 h at 4°C. Subsequently, organs were embedded in paraffin. Mounted sections were deparaffinized, rehydrated, and stained with hematoxylin and eosin. For TUNEL analyses, formalin-fixed sections were mounted on glass slides coated with a 2% solution of 3-aminopropyltriethoxysilane in acetone, deparaffinized, and pretreated with proteinase K (Sigma) and peroxidase (Gavrieli et al. 1992). Slides were subsequently washed in terminal deoxynucleotidyl transferase (TdT) buffer (100 mM cacodylate buffer, 1 mM CaCl₂, 0.1 mM dithiothreitol at pH 6.8) for 5 min (Gorczyca et al. 1993) and incubated for at least 30 min at 25°C in TdT buffer containing 0.01 mM Biotin-16-dUTP (Roche Diag-

nostics) and 0.4 U/ μ L TdT enzyme (Promega). The enzymatic reaction was stopped in TB buffer (300 mM NaCl, 30 mM Na-citrate at pH 7.0), and the sections were washed (Gavrieli et al. 1992). Slides were then incubated with streptABCComplex/horseradish peroxidase conjugate (Dako) for 30 min and washed in PBS. dUTP-biotin labeled cells were visualized with 3,3'-diaminobenzidine tetrahydrochloride (DAB)/metal concentrate (Pierce). Then we counterstained the sections with hematoxylin and counted the number of TUNEL-positive cells per cross-sectioned tubule. However, for *Sycp1*^{-/-} mice this was not possible, because numerous TUNEL-positive nuclei were clustered in single cross-sectioned tubules. Therefore we counted the number of cross-sectioned tubules with no, one to five, or more than five apoptotic nuclei. Tubules without germ cell development up to meiotic prophase were excluded from the analysis. We performed this analysis on two *Sycp1*^{+/-} and two *Sycp1*^{-/-} mice, classifying a minimum of 150 tubule sections for each genotype.

Cytology, immunocytochemistry, and chromosome painting

The antibodies used in this study are listed in the Supplemental Material. Paraffin and frozen sections of mouse testis (Meuwissen et al. 1992), and dry-down (Peters et al. 1997) or squash (Page et al. 1998) preparations of testis cell suspensions were prepared, incubated for immunocytochemistry, and analyzed as described (Meuwissen et al. 1992; Eijpe et al. 2003). In some experiments, we exposed the cells to 1.25 μ M OA for 5 h (Wiltshire et al. 1995) before spreading. For ultrastructural analysis we prepared uranyl-acetate-stained agar filtrates of lysed spermatocytes and analyzed them as described (Heyting and Dietrich 1991).

Acknowledgments

We thank C. Beerends, P. de Boer, P. Cohen, M.A. Handel, Ch. Her, R. Jessberger, R. Kanaar, T. de Lange, P. Moens, J.-M. Peters, and M. Volker for antibodies, and B. Vennström for the λ FixII library. We are indebted to the Central Mouse Facility at the LUMC for blastocyst injections and general mouse facilities. We thank Jaap Jansen (LUMC) for his advice in culturing ES cells; M. Eijpe, H.H. Offenberg, and A.J.J. Dietrich for help and practical advice; and two anonymous reviewers for several useful suggestions. The Netherlands Society for Scientific Research (NWO) (grant 901-01-097) and the EU (contract QLK3-2000-00365) financially supported this work.

An advertisement banner for Dharmacon Reagents and Horizon. On the left, it says 'Dharmacon Reagents' with the tagline 'Custom synthesis, RNAi, and CRISPR solutions'. In the center, the text 'Infinite Reliability' is displayed in a large, white, sans-serif font. To the right of this text is a 'More' button. On the far right, the 'horizon' logo is shown in white, with 'a PerkinElmer company' written in smaller text below it. The background of the banner features a close-up image of colorful, multi-colored DNA microarray spots.
