(Dated: June 29, 2012)

A combination of density functional theory calculations, many-body model considerations, magnetization and electron spin resonance measurements shows that the multiferroic  $\text{FeTe}_2\text{O}_5\text{Br}$  should be described as a system of alternating antiferromagnetic  $S = 5/2$  chains with strong Fe-O-Te-O-Fe bridges weakly coupled by two-dimensional frustrated interactions, rather than the previously reported tetramer models. The peculiar temperature dependence of the incommensurate magnetic vector can be explained in terms of interchain exchange striction being responsible for the emergent net electric polarization.

## I. INTRODUCTION

Frustrated low-dimensional spin systems exhibit a plethora of exotic magnetic ground states, which are an exciting challenge both for theorists and experimentalists.<sup>1</sup> Since quantum fluctuations enhanced by frustration tend to destabilize classically ordered states, such systems often develop complex orders with broken inversion symmetry thus fulfilling the fundamental condition for multiferroicity. This can lead to strong magnetoelectric (ME) coupling,<sup>2-4</sup> most spectacularly observed as reversal of the electric polarization with the magnetic field.<sup>5</sup> So far, strong ME coupling has been almost exclusively associated with transition metal (TM) oxides.

Unconventional magnetic ground states and multiferroicity have been recently found also in TM selenium compounds<sup>6,7</sup> and tellurite oxohalides.<sup>8-10</sup> The peculiarity of these compounds lies within their exchange network, because TM ions are coupled through complex pathways that involve several atoms, including tellurium<sup>11,12</sup> and selenium.<sup>13,14</sup> This makes determination of the exchange pathways much less intuitive<sup>15-17</sup> as opposed to the TM oxides, where dominant TM-O-TM exchange interactions can be guessed from the bonding angles.<sup>18,19</sup> The structural complexity thus impedes the understanding of the microscopic picture of the exchange interactions and hence blurs the ME coupling mechanism, which both are yet to be established for this rapidly growing class of materials.

As a prominent example we refer here to  $\text{FeTe}_2\text{O}_5\text{Br}$ ,<sup>10,11</sup> which adopts a layered structure of  $[\text{Fe}_4\text{O}_{16}]^{20-}$  tetramer clusters connected via  $\text{Te}^{4+}$

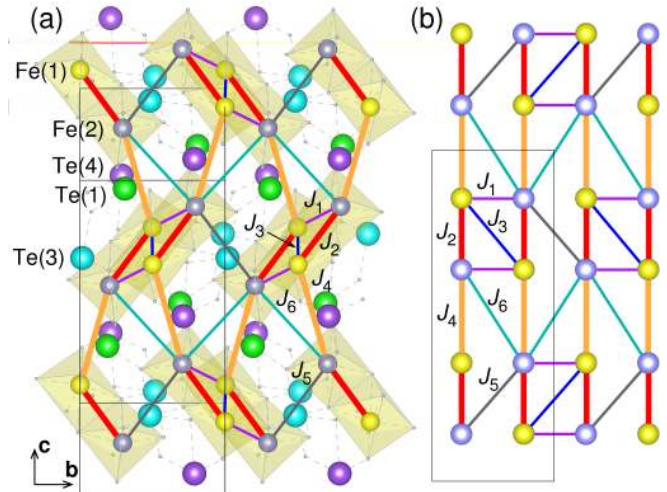

FIG. 1. (Color online) (a) Crystal structure of  $\text{FeTe}_2\text{O}_5\text{Br}$  along the  $bc$  plane where light yellow polyhedra denote  $[\text{Fe}_4\text{O}_{16}]^{20-}$  tetramer units. For clarity only Fe and Te atoms are shown. (b) The DFT magnetic exchange network, where the strongest  $J_2$  and  $J_4$  (thick lines) form alternating spin chains coupled by weaker frustrated interactions (thin lines). The marked unit cell contains 8 magnetic  $\text{Fe}^{3+}$  ions.

ions [Fig. 1(a)]. The negative Curie-Weiss temperature  $T_{CW} = -98$  K implies strong antiferromagnetic (AFM) interactions between the  $\text{Fe}^{3+}$  ( $S = 5/2$ ) moments, while the system develops long-range magnetic order at a considerably lower temperature  $T_{N1} = 11$  K.<sup>10,11,20</sup> Only 0.5 K below, at  $T_{N2} = 10.5$  K, the second transition to a predominantly amplitude modulated magnetic ground

state with the incommensurate (ICM) magnetic vector  $\mathbf{q}_{ICM}=(\frac{1}{2} 0.463 0)$  occurs<sup>10</sup> and is accompanied by a spontaneous electric polarization pointing perpendicular to the magnetic moments and to  $\mathbf{q}_{ICM}$ . The magnetic susceptibility was explained originally by assuming dominant interactions within tetramers.<sup>11</sup> However, the tetramer model cannot explain the observed ICM magnetic structure, essential for the ME effect in this system. The ambiguity obviously stems from structural complexity and therefore calls for additional experimental and theoretical investigations.

In this article, we disclose the underlying microscopic model for  $\text{FeTe}_2\text{O}_5\text{Br}$  by a combination of density functional theory (DFT) calculations, many-body model considerations, magnetization and electron spin resonance measurements. Our DFT results surprisingly reveal that long Fe-O-Te-O-Fe super-superexchange bridges are stronger than some shorter and more direct Fe-O-Fe ones. Consequently, a quasi-one-dimensional model of alternating AFM Fe chains weakly coupled by frustrated two-dimensional interactions has been derived and verified by experiments. In this picture, the ICM magnetic structure appears naturally. It also reveals a direct effect of the interchain Fe-O-Te-O-Fe exchange pathways on the ICM component of the magnetic vector along the crystallographic  $b$ -axis,  $q_{ICM}^y$ . Close resemblance of its temperature dependence<sup>20</sup> to that of the electric polarization<sup>10</sup> emphasizes the importance of the exchange striction on the interchain bonds that host easily polarizable  $\text{Te}^{4+}$  lone-pair electrons, thus revealing the microscopic origin of the ME effect. A similar mechanism is expected to be active also in selenite chain compounds.

## II. EXPERIMENTAL DETAILS

High-quality single crystals of  $\text{FeTe}_2\text{O}_5\text{Br}$  were grown by the standard chemical-vapor-phase method, reported elsewhere.<sup>11</sup> Their crystallinity and phase purity have been confirmed by x-ray diffraction, which showed no sign of potential impurity phases.

Magnetization and electron spin resonance (ESR) measurements were performed in pulsed magnetic fields up to 30 T in the temperature range between 1.5 K and 20 K at the Institute for Materials Research, Tohoku University, Sendai, Japan. The ESR experiment was conducted using non-polarized microwave radiation at fixed resonant frequencies between 95 GHz and 405 GHz.<sup>21</sup>

Single crystal x-ray synchrotron diffraction data were acquired at the BM01A Swiss-Norwegian Beamline of ESRF (Grenoble, France). Data sets ( $\sim 780$  reflections per temperature point) were collected in the temperature range between 4.5 K and 35 K at a wavelength of 0.64 Å, using a closed-cycle He cryostat mounted on a six-circle kappa diffractometer KUMA, while the interatomic distances were refined using the SHELXL97 program.<sup>22</sup>

## III. RESULTS

### A. Density Functional Theory

The underlying Heisenberg Hamiltonian parameters for  $\text{FeTe}_2\text{O}_5\text{Br}$  (Table I) were determined by total energy calculations. A full potential local orbital basis set<sup>23</sup> and generalized gradient approximation (GGA) as well as GGA+ $U$  functionals were used. The Hubbard parameter  $U$  was chosen as 3 and 5 eV to take into account the intra-atomic Coulomb interactions. The obtained network of exchange interactions (Fig. 1) was checked for consistency by  $N^{\text{th}}$ -order muffin-tin orbital downfolding<sup>24</sup> calculations.

The six considered exchange couplings are all antiferromagnetic. As expected, the intracluster (within a tetramer) Fe-O-Fe exchange  $J_2$  is the strongest. Strikingly, the second strongest exchange is not the remaining intracluster Fe-O-Fe exchange  $J_1$ , but rather the intercluster super-superexchange interaction  $J_4$ , mediated through the Fe-O-Te-O-Fe bridges. This result discloses that in tellurite oxohalides the super-superexchange interactions through long bridges involving  $\text{Te}^{4+}$  ions are important and should not be neglected on the basis of simplified structural arguments. We advise similar caution also in case of  $\text{Se}^{4+}$  ions in selenites.<sup>13,14</sup> The two dominant couplings,  $J_2$  and  $J_4$ , thus effectively form alternating  $\text{Fe}^{3+}$  spin chains. The rest of the considered exchange interactions are weaker and provide frustrated interchain interactions as shown in Fig. 1. We note that the DFT results leave some freedom concerning the overall energy scale, but the ratios of  $J_i$ 's are expected to be subject only to small errors.<sup>25</sup> However, the relative sizes of  $J_i$ 's are somewhat dependent on the chosen value of  $U$ , with  $J_1$  and  $J_5$  showing the highest sensitivity. Thus, we suspect that they could be modified by very small lattice distortions anticipated at the ME transition.

## B. Magnetic properties

We now consider the simple Heisenberg model,

$$H = \sum_{\langle i,j \rangle} J_{\langle i,j \rangle} \vec{S}_i \cdot \vec{S}_j, \quad (1)$$

First, we retain only the leading two exchange constants  $J_2$  and  $J_4$ , forming an alternating chain. Quantum Monte Carlo simulations of the bulk magnetic susceptibility for alternating  $S = 5/2$  chains with  $L = 60$  sites were carried out with the ALPS 1.3<sup>26</sup> directed loop application<sup>27</sup> in the stochastic series expansion framework.<sup>28</sup> For  $J_2 = 16$  K and the DFT determined ratio  $J_4/J_2 = 0.6$  we find a very good agreement between our simulations and the experimental data for  $B = 0.1$  T and  $B \parallel b$  [Fig. 2(a)]. A rather good agreement is also achieved when classical spins are considered (see appendix A for further details). However, since the tetramer model can also fit the susceptibility data,<sup>11</sup> we need an independent experimental proof to discriminate between the two models and to fix the precise values of  $J$ 's.

Additional magnetization measurements performed at  $T = 1.5$  K for  $B$  parallel to the ICM direction ( $b$  axis), show a linear increase of the magnetization with  $B$  and the existence of a clean step at around  $B_{SF} = 11$  T [inset in Fig. 2(a)]. Such a behavior is reminiscent of a spin-flop-like process, implying the presence of considerable magnetic anisotropy which was not considered in the model calculations.

Finally, we note that no anomaly has been observed around 5 T where the peak in the temperature dependence of the dielectric constant disappears.<sup>20</sup> This suggests that the multiferroic ground state is not broken until  $B_{SF}$  is reached and that the observed dielectric re-

sponse probably reflects saturation of the ferroelectric domains by ME coupling.

## C. Electron spin resonance

Magnetic anisotropies can be determined by ESR,<sup>29–32</sup> which in the magnetically ordered state allows a detection of collective low-energy magnetic excitations at  $\mathbf{Q} = 0, \pm \mathbf{q}_{ICM}$  – the so-called antiferromagnetic resonance (AFMR) modes.<sup>33</sup>

In the paramagnetic state, i.e., far above  $T_{N1}$  (at 300 K), a strong ESR signal at  $g = 2.005(5)$  is observed, as expected for  $\text{Fe}^{3+}$  ( $S = 5/2$ ) ions. At  $T_{N1}$  the paramagnetic signal disappears and is replaced by new resonances [marked by arrows in Fig. 2(b,c)] shifted with respect to the paramagnetic value. The new resonances below  $T_{N1}$  are attributed to AFMR modes. We note that at 405 GHz one of the AFMR modes appears relatively close to the paramagnetic resonance, screening its disappearance and causing a shift of the resonant line (Fig. 2c).

Since resonant fields for individual AFMR lines strongly depend on the resonance frequency [Fig. 3(a)], we were able to derive their frequency-field dispersions in the range 95 to 405 GHz and 0 to 30 T at 2 K [Fig. 3(b)]. The lowest and at the same time the most intense excitation mode marked by arrows in Fig. 3(a) shows a zero-field gap  $\Delta\nu_{ZF} \sim 240$  GHz [see Fig. 3(b)] corroborating a sizable magnetic anisotropy and in agreement with high-field magnetization measurements. With increasing magnetic field the gap reduces to  $\sim 100$  GHz at  $B_{SF}$ , where the slope is reversed and the gap increases again with increasing field. In addition, at least five more high-frequency modes were detected [Figs. 2(b) and 3(a)], which also dramatically change their behavior at  $B_{SF}$ .

FIG. 3. (Color online) (a) Field dependence of AFMR spectra at 1.5 K for  $B||b$  and various resonant frequencies between 95 and 405 GHz. (b) Frequency-field dependence for intense (solid circles) and weak (empty circles) AFMR modes. Solid lines are simulations to the model described in the text. The dashed line indicates  $B_{SF}$ .

#### D. Magnetic Ground State and AFMR Simulations

In order to relate the high-field magnetization and the AFMR results to DFT calculations the first step is to determine the magnetic ground state of the infinite spin lattice.

In view of the hard axis anisotropy we simplify the Heisenberg model Eq. (1) further and consider in what follows coplanar moments. In this case the classical energy can be written as a function of the angle  $\theta_i$  corresponding to the orientation of the spin  $i$  with respect to the predetermined direction within the confined plane

$$E_{Cl} = S^2 \sum_{\langle i,j \rangle} J_{(i,j)} \cos(\theta_j - \theta_i). \quad (2)$$

The classical energy thus depends only on the differences of orientations from spin to spin. Since  $\text{Fe}^{3+}$  ions are in the high-spin  $S = 5/2$  state, this classical treatment of the model is reasonably justified.

For a spiral order,  $E_{Cl}$  can be written as a function of 8 angles  $\theta_i$  and the twist angles  $q^y$  and  $q^z$  defined as follows:

$$\begin{aligned} \theta_{i,(n+1)r_y+mr_z} &= \theta_{i,nr_y+mr_z} + q^y \\ \theta_{i,nr_y+(m+1)r_z} &= \theta_{i,nr_y+mr_z} + q^z, \end{aligned} \quad (3)$$

where  $n$  and  $m$  are the cell indices.

We used the conjugate gradient method to minimize the energy and to find the magnetic structure of the classical ground state. In all our calculations we fixed the sizes of the magnetic moments and neglected their amplitude modulation.<sup>10</sup>

Starting from the parameters obtained from the GGA+ $U$  calculations with  $U = 0$  eV, 3 eV, and 5 eV (Table I), the solution immediately converges to an ICM order. For  $U = 3$  eV the experimental  $q_{ICM}^y = 0.463$  is

reached by fine tuning of the interchain couplings, i.e.,  $J_1$ ,  $J_3$ , and  $J_6$ , up to 2% (Table I). We note that using the tetramer model parameters, i.e.,  $|J_1| = |J_2| \sim |J_3| \gg |J_4|, |J_5|, |J_6|$ ,<sup>11</sup> we were unable to generate the ICM magnetic order, which clearly demonstrates that the tetramer model is inappropriate.

Due to the excellent agreement with  $q_{ICM}^y$  we now use the optimized parameters (Table I, fourth column) to calculate the AFMR modes. For computing the equations of motion<sup>29</sup> we define a finite magnetic lattice comprising 7 unit cells coupled along the crystallographic  $b$  axis, i.e., mimicking the experimentally observed  $q_{ICM}^y = 0.463 \sim 3/7$ . We assume  $5\mu_B$  for the size of  $\text{Fe}^{3+}$  moments and introduce an easy plane anisotropy,  $DS_z^2$ . Here  $D$  is the magnitude of single-ion anisotropy. To fix the direction of the hard axis along  $z = (0.31, 0, 0.95)$  we take into the account the orientation of the ordered magnetic moments<sup>10</sup> and a two-fold screw axis, which coincides with the  $b$  axis. The only free parameters left in these calculations are thus  $D$  and the strength of the  $J_2$  interaction (all other interactions are scaled appropriately).

The strongest AFMR mode is best described [Fig. 3(b)] by  $J_2 = 19.0$  K and  $D = 0.18$  K (Table I). We stress that the theoretical curve nicely reproduces the softening of this mode up to  $B_{SF}$  and its reversed character at higher fields. At the same time, the dispersions of all other intense higher-frequency AFMR modes are in convincing agreement with the experiment [Fig. 3(b)]. We note that the calculated zero-field magnetic ground state is a coplanar cycloidal state, whereas the large number of calculated modes corresponds to 56 sublattice magnetizations considered in the calculations. Moreover, the same set of parameters perfectly simulates the magnetization response to the applied magnetic field including the magnetization step at  $B_{SF}$  [inset in Fig. 2(a)]. To conclude this part, we emphasize a remarkable agreement between experiments and ratios of  $J$ 's obtained by the DFT calculations for GGA+ $U$  with  $U = 3$  eV achieved only by scaling slightly the exchange interactions.

## IV. DISCUSSION

The main result of this study is the discovery that in  $\text{FeTe}_2\text{O}_5\text{Br}$  some Fe-O-Te-O-Fe exchange pathways are stronger than some shorter Fe-O-Fe ones. Thus, the system has to be treated as a system of alternating  $S = 5/2$  chains weakly coupled by frustrated interactions, in contrast to the previously proposed tetramer model. The knowledge of the appropriate spin model allows us to investigate the ME mechanism from a microscopic perspective. In order to identify the exchange pathway responsible for the ME effect we first recall that  $q_{ICM}^y$  is temperature independent in the high-temperature ICM phase (between  $T_{N1}$  and  $T_{N2}$ ), while in the low-temperature ICM phase (below  $T_{N2}$ ) it scales similarly to the electric polarization, i.e., it behaves as  $(T_{N2} - T)^{0.35}$ .<sup>20</sup> To ad-

FIG. 4. (Color online) Dependence of  $q_{ICM}^y$  on interchain exchange coupling constants ratios,  $J_i/J_i^0$  for  $i=1, 3, 6$ , calculated by direct minimization of the classical energy, where  $J_i^0$  are exchange parameters used in AFMR simulations. Inset: the same dependence calculated for  $J_5$ .

dress this important point we return to the minimization of the classical energy for the infinite lattice and calculate how  $q_{ICM}^y$  is affected by small changes of different  $J_i$ 's. Since the ICM modulation is perpendicular to the alternating chains, it suffices to vary only the interchain exchange couplings  $J_i$  ( $i=1,3,5,6$ ) with respect to the values that reproduce the AFMR modes at  $T=2$  K. In order to reproduce the decrease of  $q_{ICM}^y$  observed below  $T_{N2}$ , we find that  $J_1$  has to be reduced, while  $J_3$ ,  $J_5$ , and  $J_6$  have to be increased (Fig. 4).

Given that  $J_1$  and  $J_3$  are superexchange interactions via Fe-O-Fe bridges, they are expected to behave according to Goodenough-Kanamori rules.<sup>18,19</sup> If  $J_1$  is responsible for the ME effect, then the Fe-O-Fe angle should be reduced or the Fe-O distance increased in order to weaken  $J_1$ . No significant structural changes for this bond have been observed in our high-resolution synchrotron x-ray diffraction experiments (Fig. 5) thus ruling out this possibility. An analogous conclusion can be derived also for  $J_3$  (Fig. 5d). We are thus left with the two remaining candidates –  $J_5$  and  $J_6$  super-superexchange interactions – which both involve  $\text{Te}^{4+}$  ions. Since the only sizable change at the ME transition corresponds to the shortening of the  $\text{Fe}_2\text{-Te}_3$  distance,<sup>10</sup> involved in the  $J_5$  pathway, we assign the microscopic origin of the ME coupling to the changes of this interaction. While the realization that the magnetic ordering breaks the inversion symmetry is essential to understand phenomenological aspects of the ME effect,<sup>10</sup> the key to understanding the ME coupling at the microscopic scale lies in the low symmetry of the long Fe-O-Te-O-Fe bridges, which allows emergent magnetic order to provoke a softening of an appropriate phonon mode and hence a net electric polarization. We stress that this is possible even if the spin-orbit coupling is very small. This resembles  $\text{Ni}_3\text{V}_2\text{O}_8$ , where the ex-

FIG. 5. Refinement results for the O-Fe distances obtained from synchrotron x-ray diffraction, corresponding to  $J_1$  (a-d) and  $J_3$  (d) exchange pathways.

change striction mechanism is proposed to be responsible for the ME coupling.<sup>34</sup> Finally, we point out that tellurite oxohalide systems seem particularly inclined to such effects, since their long low-symmetry exchange bridges involve easily polarizable  $\text{Te}^{4+}$  lone-pair electrons, which enable that already minimal changes in the strength of the exchange interactions are sufficient to produce a measurable macroscopic effect.

## V. CONCLUSIONS

We have shown that the magnetic exchange network of the  $\text{FeTe}_2\text{O}_5\text{Br}$  system should be regarded as a system of alternating Fe chains with weaker frustrated interchain interactions. Frustration is found to be responsible for the observed low-symmetry ICM magnetic ordering, essential for the establishment of the multiferroic phase. Additionally, we show that in  $\text{FeTe}_2\text{O}_5\text{Br}$  the ME effect on the microscopic level originates from the exchange striction of interchain  $J_5$  Fe-O-Te-O-Fe exchange pathway, where the net electric polarization comes from the  $\text{Te}^{4+}$  lone-pair electrons. Finally, our findings clearly demonstrate that in tellurite and selenite oxohalides one needs to be extremely cautious when making assumptions about the exchange network, as arguments based solely on the crystal structure may be very misleading. Long super-superexchange bridges can lead to surprisingly strong interactions and their structural volatility is at the core of the ME effect.

### Appendix A: Magnetic susceptibility calculations

The magnetic susceptibility was computed by classical and quantum Monte Carlo simulations of the Heisenberg model (1) and compared to our single crystal  $\chi(T)$  measurements for  $B = 0.1$  T and  $B \parallel b$ . Results for the alternating spin chain model were already presented in Sec. III B; here we also present results for magnetic susceptibility of the  $64 \times 64$  lattice of classical spins with the exchange ratios determined from the ground state minimization and AFMR calculations (Fig. 6). In order to explain the observed high-temperature behavior within the two-dimensional model, we need to scale to  $J_2 = 12$  K, while for simplicity we set  $D = 0$ . All numerical results are for a fixed system size and periodic boundary conditions, but we have checked that finite-size effects are negligible except possibly at very low temperatures. Theoretical results were converted to experimental units assuming a spectroscopic g-factor  $g = 2$ .

Inspired by the scaling of the high-temperature behav-

ior with spin quantum number  $S$ , we used a phenomenological scaling

$$\chi_{S,\text{phen}}(T) = \chi_{\text{cl}}(S(S+1)T) \quad (\text{A1})$$

to map the classical result  $\chi_{\text{cl}}$  to the quantum result for spin  $S$ . As is illustrated by the results for the alternating chain, this works well at high temperatures, but misses a suppression of  $\chi$  by quantum fluctuations at low temperatures.

In the two-dimensional model, interchain coupling is frustrated. Since this gives rise to a sign problem in the quantum Monte Carlo approach, we have to rely exclusively on the classical Monte Carlo simulations for this case. The two-dimensional model fits the experimental magnetic susceptibility at high temperatures at least as well as the chain model, while it does not appear to be so good around and below the maximum of  $\chi(T)$  (Fig. 6). However, we have to keep in mind that in analogy to the one-dimensional model, quantum fluctuations are expected to reduce  $\chi(T)$  at low temperatures also in two dimensions. Furthermore, the frustrated nature of the interchain coupling might enhance this reduction. In any case, we attribute the fact that a one-dimensional model yields a good effective description to the frustration in the interchain coupling. Finally, we note that the two-dimensional model exhibits signatures of an ordering transition at  $T \approx 9.5$  K. This is remarkably close to the experimentally observed ordering transitions, although the Mermin-Wagner theorem forbids a true finite-temperature ordering transition in a strictly two-dimensional Heisenberg model.

In conclusion, the fact that one-dimensional, two-dimensional, and tetramer<sup>11</sup> models provide good fits to the magnetic susceptibility of  $\text{FeTe}_2\text{O}_5\text{Br}$  demonstrates that further data is needed to clarify the nature of the microscopic exchange network.
