Abstract Measurements of multiplicity and transverse momentum fluctuations of charged particles were performed in inelastic p+p interactions at 20, 31, 40, 80 and 158 GeV/c beam momentum. Results for the scaled variance of the multiplicity distribution and for three strongly intensive measures of multiplicity and transverse momentum fluctuations $\Delta[P_T, N]$, $\Sigma[P_T, N]$ and Φ_{p_T} are presented. For the first time the results on fluctuations are fully corrected for experimental biases.

The results on multiplicity and transverse momentum fluctuations significantly deviate from expectations for the independent particle production. They also depend on charges of selected hadrons. The string-resonance Monte Carlo models EPOS and UrQMD do not describe the data.

The scaled variance of multiplicity fluctuations is significantly higher in inelastic p+p interactions than in central Pb+Pb collisions measured by NA49 at the same energy per nucleon. This is in qualitative disagreement with the predictions of the Wounded Nucleon Model. Within the statistical framework the enhanced multiplicity fluctuations in inelastic p+p interactions can be interpreted as due to event-by-event fluctuations of the fireball energy and/or volume.

Keywords proton-proton interactions, multiplicity and transverse momentum fluctuations

1 Introduction and motivation

This paper presents experimental results on event-by-event fluctuations of multiplicities and transverse momenta of charged particles produced in inelastic p+p interactions at 20, 31, 40, 80 and 158 GeV/c. The measurements were performed by the multi-purpose NA61/SHINE [1, 2] experiment at the CERN Super Proton Synchrotron (SPS). They are part of the strong interaction programme devoted to the study of the properties of the onset of deconfinement and search for the critical point of strongly interacting matter. Within this program a two dimensional scan in collision energy and size of colliding nuclei is in progress. Data on p+p, Be+Be and Ar+Sc collisions were already recorded and data on p+Pb and Xe+La collisions will be registered within the coming years. The expected signal of a critical point is a non-monotonic dependence of various fluctuation measures in such a scan, for recent review see Ref. [3].

The NA49 experiment [4] published results for central Pb+Pb collisions in the range 20A to 158A GeV/c, as well as for p+p, C+C and Si+Si reactions at 158A GeV/c. Multiplicity fluctuations were measured in terms of the scaled variance of the multiplicity distribution [5, 6] and fluctuations of the transverse momentum of the particles were studied employing measures Φ_{p_T} [7, 8], recently $\Delta[P_T, N]$ and $\Sigma[P_T, N]$ [9].

An interpretation of the experimental results on nucleus-nucleus collisions relies to a large extent on a comparison with the corresponding data on p+p and p+A interactions. However, in particular the available data on fluctuations are sparse. Suitable fluctuation measurements for p+p interactions only exist at 158 GeV/c beam momentum [5, 7]. Moreover, fluctuation measurements cannot be corrected in a model independent manner for partial phase space acceptance. Thus all measurements of the scan should be performed in the same phase space region.

In nucleus-nucleus reactions the impact parameter of the collisions cannot be tightly controlled. This problem results in additional unwanted contributions to fluctuations the effect of which needs to be suppressed by employing so-called strongly intensive measures. In addition to Φ_{p_T} two recently proposed strongly intensive quantities $\Delta[P_T, N]$ and $\Sigma[P_T, N]$ are studied in this publication.

The paper is organized as follows. In Sec. 2 strongly intensive fluctuation measures are introduced. The experimental setup is presented in Sec. 3. Data processing and simulation and the analysis procedure are described in Sec. 4. and Sec. 5, respectively. Results are presented and discussed in Sec. 6 and compared to model calculations in Sec. 7. A summary and outlook in Sec. 8 closes the paper.

Across this paper the pion rapidity is calculated in the collision centre of mass system: $y_\pi = \text{atanh}(\beta_L)$, where $\beta_L = p_L/E$ is the longitudinal (z) component of the velocity, p_L and E are pion longitudinal momentum and energy given in the collision centre of mass system. The transverse component of the momentum is denoted as p_T and the transverse mass m_T is defined as $m_T = \sqrt{m_\pi^2 + p_T^2}$, where m_π is the charged pion mass. The azimuthal angle ϕ is the angle between transverse momentum vector and the horizontal (x) axis. The nucleon mass and collision energy per nucleon pair in the centre of mass system are denoted as m_N and $\sqrt{s_{NN}}$, respectively.

2 Fluctuation measures

2.1 Intensive fluctuation measures

Event quantities are called intensive if they do *not* depend on the volume of the system within the grand canonical ensemble of statistical mechanics. Examples are the mean transverse momentum of particles or ratios of particle numbers in the events. In contrast, so-called extensive quantities (for example the mean multiplicity or the variance of the multiplicity distribution) are proportional to the system volume. Within the Wounded Nucleon Model [10] intensive quantities are those which are independent of the number of wounded nucleons, and extensive ones those which are proportional to the number of wounded nucleons. The ratio of two extensive

quantities is an intensive quantity [11]. Therefore, the scaled variance of a quantity A

$$\omega[A] = \frac{\text{Var}(A)}{\langle A \rangle} = \frac{\langle A^2 \rangle - \langle A \rangle^2}{\langle A \rangle} \quad (1)$$

is an intensive measure. In fact, due to its intensity property, the scaled variance ($\omega[N]$) of the distribution of multiplicity N in the events is widely used to quantify multiplicity fluctuations in high-energy heavy-ion experiments.

The scaled variance assumes the value $\omega[N] = 0$ for $N = \text{const.}$ and $\omega[N] = 1$ for a Poisson multiplicity distribution.

2.2 Strongly intensive fluctuation measures

Unfortunately, the volume of the matter produced in heavy ion collisions cannot be fixed and changes significantly from one event to another. Therefore, it is very important to be able to measure the properties of the created matter independently of its volume fluctuations. The quantities which allow this are called *strongly intensive* measures. They depend neither on the volume nor on the fluctuations of the volume. Ratios of mean multiplicities are both intensive and strongly intensive measures. The situation is, however, much more difficult for the analysis of fluctuations. For example the scaled variance is an intensive but not strongly intensive measure.

It was shown in Ref. [11], that for certain combinations of scaled variances, terms dependent on the volume fluctuations cancel out. There are at least two families of strongly intensive measures of two fluctuating extensive quantities A and B :

$$\Delta[A, B] = \frac{1}{C_\Delta} \left[\langle B \rangle \omega[A] - \langle A \rangle \omega[B] \right] \quad (2)$$

$$\Sigma[A, B] = \frac{1}{C_\Sigma} \left[\langle B \rangle \omega[A] + \langle A \rangle \omega[B] - 2(\langle AB \rangle - \langle A \rangle \langle B \rangle) \right] \quad (3)$$

For the study of transverse momentum fluctuations one uses:

$$A = P_T = \sum_{i=1}^N p_{T_i}, \quad B = N,$$

where p_{T_i} is the modulus of the transverse momentum of particle i .

There is an important difference between $\Delta[P_T, N]$ and $\Sigma[P_T, N]$. Only the first two moments: $\langle P_T \rangle$, $\langle N \rangle$, and $\langle P_T^2 \rangle$, $\langle N^2 \rangle$ are required to calculate $\Delta[P_T, N]$, whereas $\Sigma[P_T, N]$ includes the correlation term $\langle P_T N \rangle - \langle P_T \rangle \langle N \rangle$. Thus $\Delta[P_T, N]$ and $\Sigma[P_T, N]$ can be sensitive to various physics effects in different ways. In Ref. [11] strongly intensive quantities including the correlation term are named the Σ family, and those based only on mean values and variances the Δ family.

Historically, the first proposed strongly intensive fluctuations measure was Φ [12]. When applied to transverse

momentum fluctuations the measure is called Φ_{p_T} . This has already been used extensively by the NA49 experiment [7, 8]. The measure is a member of the Σ family:

$$\Phi_{p_T} = \sqrt{\overline{p_T} \omega[p_T]} \left[\sqrt{\Sigma[P_T, N]} - 1 \right]. \quad (4)$$

where $\overline{p_T}$ and $\omega[p_T]$ denote the average and scaled variance of the inclusive p_T distribution.

With the normalization proposed in Ref. [13],

$$C_\Delta = C_\Sigma = \langle N \rangle \omega[p_T], \quad (5)$$

these measures are dimensionless and have a common scale required for a quantitative comparison of fluctuations of different, in general dimensional, extensive quantities. More precisely, the values of Δ and Σ are equal to zero in the absence of event-by-event fluctuations ($N = \text{const.}$, $P_T = \text{const.}$) and equal to one for fluctuations given by the independent particle production model (IPM) [13, 14]. The values of $\Delta[P_T, N]$ and $\Sigma[P_T, N]$ have already been determined in several models. The results of the IPM, the Model of Independent Sources (MIS), source-by-source temperature fluctuations (example of MIS), event-by-event (global) temperature fluctuations, correlation between average p_T per event and its multiplicity were published in Ref. [14]. The effects of acceptance losses, efficiency losses, quantum (Bose-Einstein and Fermi-Dirac) statistics and centrality dependence (UrQMD) were investigated in Ref. [15]. Finally, the system size and energy dependence in the UrQMD model was studied in Ref. [13]. One of the conclusions (supported by the UrQMD calculations) is that the $\Delta[P_T, N]$, $\Sigma[P_T, N]$, and Φ_{p_T} quantities measure deviations from the superposition model in different ways. Therefore, in the analysis of experimental data a simultaneous measurement of all three quantities is highly desirable.

A comparison of the properties of these three measure within the IMP and MIS models is shown in Table 1. If one finds, e.g. $\Phi_{p_T} = 10$ MeV/ c one does not know whether this is a large or a small effect, especially when the magnitudes of Φ_{p_T} from several "trivial" effects (Bose-Einstein statistics, resonance decays, etc.) are not estimated. The situation is, however, different for $\Sigma[P_T, N]$. If one measures, for example, $\Sigma[P_T, N] = 1.1$ this means that (for this specific combination of moments) one measures 10% deviation from the IPM (fluctuations are 10% larger than in the IPM). Therefore, the new measures $\Delta[P_T, N]$ and $\Sigma[P_T, N]$ have the advantages of $\omega[N]$ but they also preserve the advantage of Φ_{p_T} , i.e. they are *strongly intensive* measures of fluctuations.

Table 1 Properties of Φ_{p_T} , $\Delta[P_T, N]$, and $\Sigma[P_T, N]$ in the absence of fluctuations, and in the Independent Particle Model (IPM) and the Model of Independent Sources (MIS).

	unit	No fluctuations ($N = \text{const.}, P_T = \text{const.}$)	IPM	MIS
Φ_{p_T}	MeV/c	$\Phi_{p_T} = -\sqrt{p_T} \omega[p_T]$	$\Phi_{p_T} = 0$	does not depend on N_s and its fluctuations
$\Delta[P_T, N]$	dimensionless	$\Delta[P_T, N] = 0$	$\Delta[P_T, N] = 1$	does not depend on N_s and its fluctuations
$\Sigma[P_T, N]$	dimensionless	$\Sigma[P_T, N] = 0$	$\Sigma[P_T, N] = 1$	does not depend on N_s and its fluctuations
$\omega[N]$	dimensionless	$\omega[N] = 0$	$\omega[N] = 1$	does not depend on N_s

3 Experimental facility

3.1 The NA61/SHINE detector

The NA61/SHINE experimental facility [2] consists of a large acceptance hadron spectrometer located in the CERN North Area Hall 887 (EHN1) and the H2 beam-line to which beams accelerated in the CERN accelerator complex are delivered from the Super Proton Synchrotron (SPS). The schematic layout of the NA61/SHINE detector is shown in Fig. 1.

A set of scintillation and Cherenkov counters as well as beam position detectors (BPDs) upstream of the spectrometer provide timing reference, identification and position measurements of incoming beam particles. Trajectories of individual beam particles were measured in a telescope of beam position detectors placed along the beam line (BPD-1/2/3 in Fig. 1). These counters are small ($4.8 \times 4.8 \text{ cm}^2$) proportional chambers with cathode strip readout, providing a resolution of about $100 \mu\text{m}$ in two orthogonal directions. Due to properties of the H2 beam line both the beam width and divergence at the NA61/SHINE target increase with decreasing beam momentum. The trigger scintillator counter S4 placed downstream of the target is used to select events with collisions in the target area. The liquid hydrogen target as well as the proton beams and triggers are described in Secs. 3.2 and 3.3, respectively.

The main tracking devices of the spectrometer are four large volume Time Projection Chambers (TPCs). Two of them, the vertex TPCs (VTPC-1 and VTPC-2 in Fig. 1), are located in the magnetic fields of two super-conducting dipole magnets with a maximum combined bending power of 9 Tm which corresponds to about 1.5 T and 1.1 T fields in the upstream and downstream magnets, respectively. In order to optimize the acceptance of the detector at each collision momentum, the field in both magnets was adjusted proportionally to the beam momentum.

Two large TPCs (MTPC-L and MTPC-R) are positioned downstream of the magnets symmetrically to the beam line. The fifth small TPC (GAP-TPC) is placed between VTPC-1 and VTPC-2 directly on the beam line. It closes the gap along the beam axis between the sensitive volumes of the other TPCs.

The TPCs are filled with Ar:CO₂ gas mixtures in proportions 90:10 for the VTPCs and the GAP-TPC, and 95:5 for the MTPCs.

The particle identification capability of the TPCs based on measurements of the specific energy loss, dE/dx , is augmented by time-of-flight measurements using Time-of-Flight (ToF) detectors. The high resolution forward calorimeter, the Projectile Spectator Detector (PSD), measures energy flow around the beam direction, which in nucleus-nucleus collisions is primarily given by the projectile spectators.

The results presented in this paper were obtained using information from the TPCs the Beam Position Detectors as well as from the beam and trigger counters.

3.2 Target

NA61/SHINE uses various solid nuclear targets and a liquid hydrogen target (see Sec. 3.3 for details). The solid targets are positioned about 80 cm upstream of the sensitive volume of VTPC-1 (about -580 cm in the experiment's coordinate system). For data taking on p+p interactions a liquid hydrogen target of 20.29 cm length (2.8% interaction length) and 3 cm diameter was placed 88.4 cm upstream of VTPC-1. The Liquid Hydrogen Target facility (LHT) filled the target cell with para-hydrogen obtained in a closed-loop liquefaction system which was operated at 75 mbar overpressure with respect to the atmosphere. At the atmospheric pressure of 965 mbar the liquid hydrogen density is $\rho_{\text{LH}} = 0.07 \text{ g/cm}^3$.

Data taking with inserted (*I*) and removed (*R*) liquid hydrogen (*LH*) in the LHT was alternated in order to calculate a data-based correction for interactions with the material surrounding the liquid hydrogen.

3.3 Beams and triggers

Secondary beams of positively charged hadrons at 20, 31, 40, 80 and 158 GeV/c were produced from 400 GeV/c protons extracted from the SPS onto a beryllium target in a slow extraction mode with a flat-top of 10 seconds. The secondary beam momentum and intensity was adjusted by

Fig. 1 (Colour online) The schematic layout of the NA61/SHINE spectrometer (horizontal cut, not to scale). The beam and trigger detector configuration used for data taking in 2009 is shown in the inset. The chosen coordinate system is drawn on the lower left: its origin lies in the middle of the VTPC-2, on the beam axis. The nominal beam direction is along the z axis. The magnetic field bends charged particle trajectories in the x - z (horizontal) plane. Positively charged particles are bent towards the top of the plot. The drift direction in the TPCs is along the y (vertical) axis.

240 proper setting of the H2 beam-line magnet currents and col-
 limators. The beam was transported along the H2 beam-line
 towards the experiment. The precision of the setting of the
 beam magnet currents was approximately 0.5%. This was
 verified by a direct measurement of the beam momentum at
 245 31 GeV/ c by bending the incoming beam particles into the
 TPCs with the maximum magnetic field [16]. Selected beam
 properties are given in Table 2.

The set-up of beam detectors is illustrated in the inset on
 Fig. 1. Protons from the secondary hadron beam were identi-
 fied by two Cherenkov counters, a CEDAR (either CEDAR-W
 or CEDAR-N) and a threshold counter (THC). The CEDAR
 counter, using a coincidence of six out of the eight photo-
 multipliers placed radially along the Cherenkov ring, pro-
 vided positive identification of protons, while the THC, op-
 255 erated at pressure lower than the proton threshold, was used
 in anti-coincidence in the trigger logic. Due to their lim-
 ited range of operation two different CEDAR counters were
 employed, namely for beams at 20, 31, and 40 GeV/ c the
 CEDAR-W counter and for beams at 80 and 158 GeV/ c
 260 the CEDAR-N counter. The threshold counter was used for
 all beam energies. A selection based on signals from the
 Cherenkov counters allowed to identify beam protons with
 a purity of about 99%. A consistent value for the purity was
 found by bending the 30.1 GeV/ c beam into the TPCs with
 the full magnetic field and using the dE/dx identification
 265 method. The fraction of protons in the beams is given in
 Table 2.

Two scintillation counters, S1 and S2, provided beam
 definition, together with the three veto counters V0, V1 and
 V1P with a 1 cm diameter hole, which were defining the

Table 2 Basic properties of the beam used in the study of $p+p$ interactions at 20, 31, 40, 80 and 158 GeV/ c . The first column gives the beam momentum. The second and third columns list typical numbers of beam particles at NA61/SHINE per spill (about 10 seconds) and the fraction of protons in the beam, respectively.

p_{beam} [GeV/ c]	particles per spill	proton fraction
20	1000k	12%
31	1000k	14%
40	1200k	14%
80	460k	28%
158	250k	58%

beam before the target. The S1 counter also provided the
 timing (start time for the gating of all counters). Beam pro-
 tons were then selected by the coincidence:

$$T_{\text{beam}} = S1 \wedge S2 \wedge \overline{V0} \wedge \overline{V1} \wedge \overline{V1P} \wedge \text{CEDAR} \wedge \overline{\text{THC}}. \quad (6)$$

The interaction trigger (T_{int}) was provided by the anti-coincidence
 of the incoming proton beam and a scintillation counter S4
 ($T_{\text{int}} = T_{\text{beam}} \wedge \overline{S4}$). The S4 counter with a 2 cm diameter, was
 270 placed between the VTPC-1 and VTPC-2 detectors along
 the beam trajectory at about 3.7 m from the target, see Fig. 1.
 A large fraction of beam protons that interact in the target
 does not reach S4. The interaction and beam triggers were
 run simultaneously. The beam trigger events were recorded
 275 with a frequency by a factor of about 10 lower than the fre-
 quency of interaction trigger events.

4 Data processing and simulation

Detector parameters were optimized by a data-based calibration procedure which also took into account their time dependence, for details see Refs. [17, 18].

The main steps of the data reconstruction procedure were:

- (i) cluster finding in the TPC raw data, calculation of the cluster centre-of-gravity and total charge,
- (ii) reconstruction of local track segments in each TPC separately,
- (iii) matching of track segments into global tracks,
- (iv) track fitting through the magnetic field and determination of track parameters at the first measured TPC cluster,
- (v) determination of the interaction vertex using the beam trajectory (x and y coordinates) fitted in the BPDs and the trajectories of tracks reconstructed in the TPCs (z coordinate),
- (vi) refitting the particle trajectory using the interaction vertex as an additional point and determining the particle momentum at the interaction vertex,
- (vii) matching of ToF hits with the TPC tracks.

A simulation of the NA61/SHINE detector response was used to correct the reconstructed data. Several MC models were compared with the NA61/SHINE results on p+p, p+C and π +C interactions: FLUKA2008, URQMD1.3.1, VENUS4.12, EPOS1.99, GHEISHA2002, QGSJetII-3 and Sibyll2.1 [16, 19]. Based on these comparisons and taking into account continuous support and documentation from the developers the EPOS model was selected for the MC simulation. The simulation consisted of the following steps:

- (i) generation of inelastic p+p interactions using the EPOS model,
- (ii) propagation of outgoing particles through the detector material using the GEANT 3.21 package which takes into account the magnetic field as well as relevant physics processes, such as particle interactions and decays,
- (iii) simulation of the detector response using dedicated NA61/SHINE packages which simulates charge clusters in the TPCs and introduces distortions corresponding to all corrections applied to the real data,
- (iv) simulation of the interaction trigger selection by checking whether a charged particle hits the S4 counter, see Sec. 3.3,
- (v) storage of the simulated events in a file which has the same format as the raw data,
- (vi) reconstruction of the simulated events with the same reconstruction chain as used for the real data,
- (vii) matching of the reconstructed to the simulated tracks based on the cluster positions.

It should be underlined that only inelastic p+p interactions in the hydrogen in the target cell were simulated and reconstructed. Thus the Monte Carlo based corrections (see Sec. 5) can be applied only for inelastic events. The contribution of elastic events is removed by the event selection cuts (see Sec. 5.1), whereas the contribution of off-target interactions is subtracted based on the data (see Sec. 5.4).

5 Analysis procedure

The analysis procedures consisted of the following steps:

- (i) applying event and track selection criteria,
- (ii) evaluation of the moments of distributions of quantities needed to calculate fluctuations (Eqs. 1,2,3,4),
- (iii) evaluation of corrections to the moments based on experimental data and simulations,
- (iv) calculation of the corrected fluctuations.

Corrections for the following biases were evaluated and applied:

- (i) contribution of off-target interactions,
- (ii) losses of inelastic p+p interactions due to the trigger and the event and track selection criteria,
- (iii) contribution of particles other than primary charged hadrons,
- (iv) losses of primary charged hadrons due to the track selection criteria.

The final results refer to charged hadrons produced in the analysis acceptance in inelastic proton-proton interactions at 20, 31, 40, 80, and 158 GeV/c beam momenta. Products of electromagnetic decays are included. Products of weak decays and secondary interactions among the tracks satisfying the selection criteria are corrected for. The result is referred to as *accepted primary* hadrons.

The list of analyzed data sets together with statistics of all recorded and selected events in target inserted and target removed configurations is presented in Table 3.

Table 3 Data sets together with the statistics of events recorded and selected for the analysis in target inserted and target removed configurations.

p_{beam} [GeV/c]	$\sqrt{s_{NN}}$ [GeV]	y_{beam}^{CM}	target inserted		target removed	
			all	selected	all	selected
20	6.27	1.90	1 324 k	255 k	122 k	8 k
31	7.62	2.10	3 140 k	1058 k	332 k	35 k
40	8.73	2.23	5 226 k	2008 k	528 k	88 k
80	12.32	2.57	4 444 k	1791 k	458 k	88 k
158	17.27	2.91	3 538 k	1819 k	426 k	74 k

5.1 Event selection criteria

The following event selection criteria were applied to the events recorded with the interaction trigger (Table 4):

- 365 (i) no off-time beam particle was detected within $\pm 1.5 \mu\text{s}$ around the trigger particle,
- (ii) the beam particle trajectory was measured in BPD-3 and at least one of BPD-1 or BPD-2 detectors,
- 370 (iii) there was at least one track reconstructed in the TPCs and fitted to the interaction vertex,
- (iv) events with a single, well measured positively charged track with absolute momentum close to the beam momentum ($p > p_{beam} - 1 \text{ GeV}/c$) were rejected.
- 375 (v) the vertex z position (fitted using the beam and TPC tracks) was not farther away than 50 cm from the center of the LHT,

The off-line (listed above) and on-line (the interaction trigger condition, see Sec. 3.3) event cuts select well measured (cuts (i), (ii)) inelastic p+p interactions. The background due to elastic interactions is removed (cuts (iii) and (iv)) and the contribution of off-target interactions is reduced (cut (v)) and was later subtracted using data recorded in target removed configuration. The losses of inelastic interactions due to the event selection procedure were corrected using a simulation (see below).

5.2 Track selection criteria

In order to select well-measured tracks of primary charged hadrons as well as to reduce the contamination of tracks from secondary interactions, weak decays and off-time interactions the following track selection criteria were applied (Table 4):

- (i) the track momentum fit at the interaction vertex should have converged,
- 395 (ii) the total number of reconstructed points on the track should be greater than 30,
- (iii) the sum of the number of reconstructed points in VTPC-1 and VTPC-2 should be greater than 15 or the number of reconstructed points in the GAP-TPC should be greater than 5,
- 400 (iv) the distance between the track extrapolated to the interaction plane and the interaction point (impact parameter) should be smaller than 4 cm in the horizontal (bending) plane and 2 cm in the vertical (drift) plane,
- 405 (v) the track should be measured in a high ($\geq 90\%$) TPC acceptance and tracking efficiency region (see Sec. 5.3),
- (vi) tracks with energy loss and total momentum values characteristic for electrons were rejected.
- (vii) the transverse momentum was required to be less than $1.5 \text{ GeV}/c$.

Table 4 Summary of event and track selection criteria used in the analysis.

	standard cuts	loose cuts	tight cuts
T2 trigger	applied		
BPD	applied		
off-time	$< \pm 1.5 \mu\text{s}$	no cut	$< \pm 5 \mu\text{s}$
fitted vertex z position	$\pm 50 \text{ cm}$	no cut	$\pm 10 \text{ cm}$
not elastic scatter	applied		
total points	≥ 30	no cut	≥ 30
VTPC (GTPC) points	$\geq 15(5)$	$> 10(5)$	$\geq 30(6)$
$ b_x $	$\leq 4 \text{ cm}$	no cut	$\leq 2 \text{ cm}$
$ b_y $	$\leq 2 \text{ cm}$	no cut	$\leq 1 \text{ cm}$
p_T	$\leq 1.5 \text{ GeV}/c$		
e^\pm	applied		

5.3 Determination of the analysis acceptance

The detection and reconstruction inefficiencies were corrected using the simulation. However, in order to limit the impact of possible inaccuracies of this simulation, only regions were accepted where the reconstruction efficiency (defined as the ratio of the number of reconstructed and matched Monte Carlo tracks passing the track selection criteria to the number of generated tracks) is greater than 90%. These regions were identified using a separate, statistically independent simulation in three dimensional bins of rapidity, azimuthal angle and transverse momentum. The result is stored in the form of three dimensional tables Ref. [20] where zeroes signal bins excluded from the acceptance and ones those that are included. The population of charged particles within this acceptance is shown in Fig. 2 for 20 GeV/c and 158 GeV/c p+p interactions.

Fig. 2 (Color online) Population of all charged hadrons in the analysis acceptance used in this paper to study transverse momentum and multiplicity fluctuations: the two top plots refer to 20 GeV/c and the two bottom plots to 158 GeV/c p+p interactions.

5.4 Data-based correction for off-target interactions

The event quantities used to derive final fluctuation measures were calculated for events recorded in the LH filled (*target inserted, I*) and removed (*target removed, R*) configurations. The latter data set represents interactions with material downstream and upstream of the liquid hydrogen (off-target interactions). Then, in the absence of other corrections, the corrected mean value of the distribution of any quantity (denoted as X) was calculated as:

$$\langle X \rangle = \frac{1}{N_{ev}^I - \varepsilon \cdot N_{ev}^R} \left(\sum_{i=1}^{N_{ev}^I} X_i^I - \varepsilon \cdot \sum_{j=1}^{N_{ev}^R} X_j^R \right), \quad (7)$$

where N_{ev} denotes the number of events and ε is a normalization factor. The value of ε was derived based on the distribution of the fitted z coordinate of the interaction vertex. All vertices far away from the target originate from interactions with the beam line and detector materials. Neglecting the beam attenuation in the target one gets:

$$\varepsilon = \frac{N_{ev}^I}{N_{ev}^R} \Big|_{z > -450 \text{ cm}}. \quad (8)$$

Examples of distributions of the z coordinate of the reconstructed interaction vertex for events recorded with the liquid hydrogen inserted and removed are shown in Fig. 3.

Fig. 3 (Color online) Distributions of the z coordinate of the reconstructed interaction vertex for events recorded with the target inserted (I) and removed (R). The target removed distribution was normalized to the target inserted one in the region $z > -450$ cm.

5.5 Simulation-based correction for other biases

The correction for losses due to event and track selections, reconstruction inefficiency and the interaction trigger, as well as for background of non-primary charged hadrons was calculated using the EPOS 1.99 [21] event generator. The simulated data was reconstructed with the standard NA61/SHINE

procedure. Tables of correction factors were calculated as the ratio of generated to reconstructed tracks. The reconstructed tracks were required to pass the event and track selection criteria. The corrections were obtained in bins of N , P_T and $P_{T,2} = \sum_{i=1}^N p_{T_i}^2$ for positively, negatively and all charged hadrons, separately. The event quantity $P_{T,2}$ is needed to calculate $\omega[p_T]$ using only event quantities. $\omega[p_T]$ appears in the normalization factors C_Δ and C_Σ . Thus there are three three-dimensional tables of correction factors. Then for a given charge selection an event i with N , P_T and $P_{T,2}$ is weighted with the correction factor c_i from the table of corrections for this charge selection and from the bin which corresponds to N , P_T and $P_{T,2}$. Thus, in the absence of off-target interactions, the corrected mean value of a quantity X is:

$$\langle X \rangle = \frac{1}{M_{ev}} \left(\sum_{i=1}^{N_{ev}} c_i X_i \right), \quad (9)$$

where $M_{ev} = \sum_{i=1}^{N_{ev}} c_i$.

5.6 The final correction

The final results were obtained by combining the data-based correction for off-target interactions with the Monte Carlo based correction for other biases. It was calculated as:

$$\langle X \rangle = \frac{1}{M_{ev}^I - \varepsilon M_{ev}^R} \left(\sum_{i=1}^{N_{ev}^I} c_i X_i^I - \varepsilon \cdot \sum_{j=1}^{N_{ev}^R} c_j X_j^R \right). \quad (10)$$

In order to illustrate the correction procedure and its impact on the results selected distributions of the relevant event quantities, N , P_T , NP_T and $P_{T,2}$, and results on $\Delta[P_T, N]$, $\Sigma[P_T, N]$, Φ_{p_T} and $\omega[N]$ obtained at the subsequent stages of the procedure are presented and discussed.

Figure 4 shows uncorrected distributions of the event quantities for data recorded with proton beams at 20 GeV/c and 158 GeV/c with the liquid hydrogen inserted and removed. The spectra with the removed liquid hydrogen are multiplied by the ε factor defined in Eq. 8. The distributions with the LH inserted and removed have similar shape. The normalized spectra for the LH removed are about 10 times lower than the ones for the LH inserted. Thus the correction for the off-target interactions is expected to be small (see below).

Figure 5 presents the ratio of fully corrected (see Eq. 10) to uncorrected distributions of the event quantities for p+p interactions at 158 GeV/c for positively and negatively charged particles, separately. The ratio varies significantly from about 0.5 to about 1.7.

Fig. 4 (Color online) Examples of uncorrected distributions of event quantities for p+p interactions at 20 and 158 GeV/c beam for data recorded with the liquid hydrogen inserted (I) and removed (R). The spectra with the removed liquid hydrogen are multiplied by the ϵ factor (see Eq. 8).

Fig. 5 (Color online) Examples of ratios of corrected to uncorrected distributions of event quantities for p+p interactions at 158 GeV/c.

Results for uncorrected, corrected only for the off-target interactions and fully corrected data are shown in Fig. 6. Statistical and systematic uncertainties (see below) of the fully corrected points are also plotted for a comparison. The cor-

rections for off-target interactions only weakly change the results. The corrections for the remaining experimental biases have significant impact in particular on results for $\omega[N]$ and $\Delta[P_T, N]$. It is mostly due to the requirement of well fit-

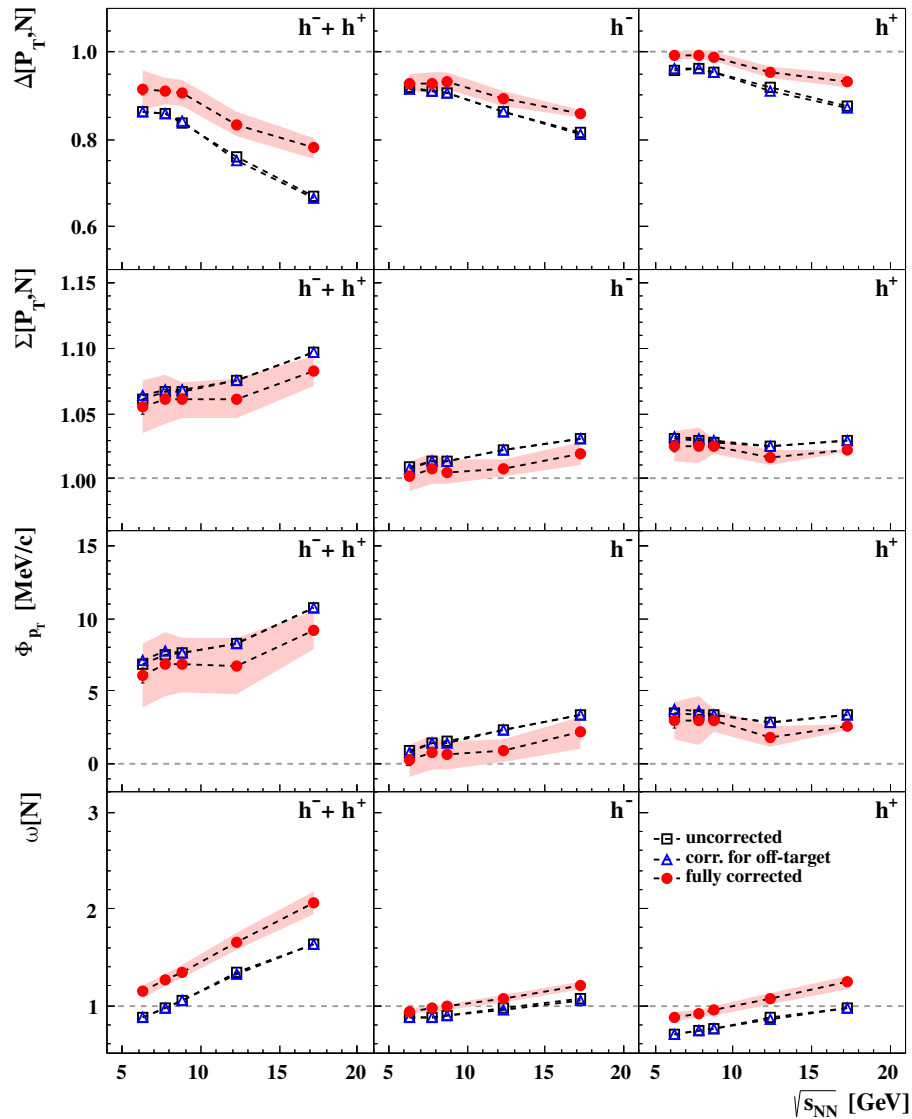

Fig. 6 (Color online) Results on $\Delta[P_T, N]$, $\Sigma[P_T, N]$, Φ_{p_T} and $\omega[N]$ as a function of collision energy before corrections (open squares), corrected for contributions of off-target interactions (open circles) and additionally corrected for all other experimental biases, see Sec. 5.6 (filled circles). Statistical uncertainties (mostly invisible) are shown by vertical bars, systematic uncertainties by shaded bands.

ted interaction vertex as well as corrections for the trigger bias and the off-line selection of events. This is illustrated in Fig. 7 where the collision energy dependence of $\omega[N]$ and $\Delta[P_T, N]$ for fully corrected data, uncorrected for the trigger bias, uncorrected for the trigger bias and for the off-line event selection as well as full uncorrected data are presented.

5.7 Statistical uncertainties

The statistical uncertainties of Φ_{p_T} , $\Delta[P_T, N]$ and $\Sigma[P_T, N]$ were estimated as follows. The whole sample of events was divided into 30 independent sub-samples. The values of Φ_{p_T} , $\Delta[P_T, N]$, and $\Sigma[P_T, N]$ were evaluated for each sub-sample separately (following all the procedures described above, in-

cluding target removed and Monte Carlo corrections) and the dispersions (D_Φ , D_Δ , and D_Σ) of the results were then calculated. The statistical uncertainty of Φ_{p_T} ($\Delta[P_T, N]$ or $\Sigma[P_T, N]$) is taken to be equal to $D_\Phi/\sqrt{30}$ ($D_\Delta/\sqrt{30}$ or $D_\Sigma/\sqrt{30}$).

For each beam momentum, 5 million events were generated and reconstructed, several times more than the recorded experimental data. Therefore statistical uncertainties arising from the event statistics of the simulation were neglected.

5.8 Systematic uncertainties

Systematic uncertainties were estimated by changing:

- (i) event selection criteria,
- (ii) track selection criteria and

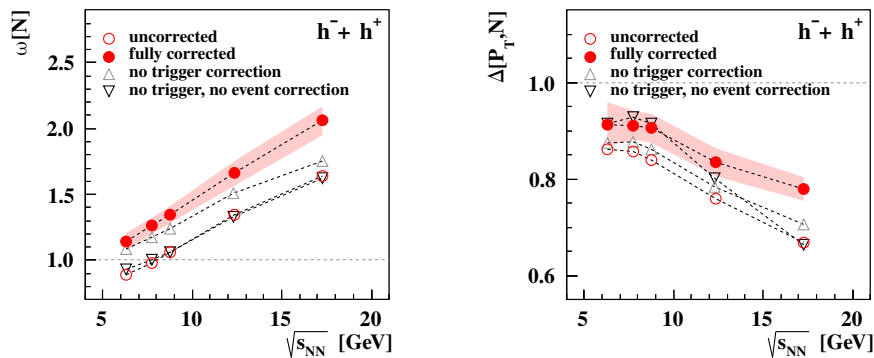

Fig. 7 (Color online) Results on $\omega[N]$ and $\Delta[P_T, N]$ as a function of collision energy for all charged hadrons after all corrections (full circles), without the correction for the trigger bias (upward pointing triangles), without corrections for the trigger bias and the off-line event selection (downward pointing triangles) and uncorrected (open circles). Statistical uncertainties (mostly invisible) are shown by vertical bars, systematic uncertainties by shaded bands.

485 (iii) event generator chosen for the simulation.

To estimate the contribution of each source, the complete analysis was repeated under these different conditions. The final systematic uncertainty was calculated as the square root of sums of differences in results with:

- 490
- *tight* and *loose* event and track cuts (see Table 4) and
 - EPOS1.99 [21] and VENUS4.12 [22,23] event generators.

6 Results

495 The results shown in this section refer to *accepted* particles, i.e., particles that are accepted by the detector and pass all kinematic cuts and track selection criteria as discussed in Sec. 5. They are corrected for event and track losses due to detector inefficiencies, selection criteria and the interaction trigger, as well as contamination of tracks from weak decays and secondary interactions and leptons from primary interactions. The correction procedure is described in detail in Sec. 5. Results are *not* corrected for limited kinematic acceptance. This acceptance should be taken into account when the data are compared with models. Table 5 shows mean multiplicities of negatively and positively charged hadrons selected by the NA61/SHINE acceptance as well as by the NA49 acceptances (see below) used to compare with the NA49 results on central Pb+Pb collisions. Moreover the table includes the mean multiplicity in full phase space of negatively charged pions determined by NA61/SHINE [17] in inelastic p+p interactions.

500 Figure 8 shows the results on $\Delta[P_T, N]$, $\Sigma[P_T, N]$, Φ_{p_T} and $\omega[N]$ calculated separately for all charged, negatively charged, and positively charged hadrons produced in inelastic p+p interactions at 20–158 GeV/c beam momentum.

505 First, one observes that the results, in general, significantly deviate from the reference values $\Delta[P_T, N] = \Sigma[P_T, N] =$

1 and $\Phi_{p_T} = 0$ MeV/c which are expected in case of independent particle production.

520 Second, the results for the three charge selections show differences. The effect of long-range correlations, e.g., caused by conservation laws, decreases with decreasing fraction of accepted particles. In particular, many charged hadrons come from decays of resonances into two or more hadrons, e.g., $\rho \rightarrow \pi^+ + \pi^-$. Positively charged hadrons are mostly π^+ mesons and protons. Less of them come from resonance decays into two or more positively charged hadrons. The majority of negatively charged hadrons are negatively charged pions and only a small fraction comes from resonance decays into two or more negatively charged hadrons. Thus the correlations due to resonance decay kinematics decrease from all charged hadrons to positively and negatively ones. Other sources of correlations like quantum statistics and Coulomb interactions are also expected to impact fluctuations differently for different charge selections.

530 Third, the collision energy dependence of $\Delta[P_T, N]$ and $\Sigma[P_T, N]$ are opposite. With increasing collision energy $\Delta[P_T, N]$ decreases, whereas $\Sigma[P_T, N]$ increases. The largest deviations from unity for both $\Delta[P_T, N]$ and $\Sigma[P_T, N]$ are observed for all charged hadrons at 158 GeV/c. Note, that at this energy the fraction of accepted particles is the largest.

7 Comparison with models and central Pb+Pb collisions

545 Figure 8 shows a comparison of the measured fluctuations with predictions of two commonly used models: EPOS1.99 [21] and UrQMD [24]. The predictions were calculated for the NA61/SHINE acceptance [20].

550 The EPOS1.99 predictions agree quantitatively with results on $\omega[N]$. They exhibit the same trend with increasing collision energy as the experimental results on $\Sigma[P_T, N]$ and Φ_{p_T} , but there is qualitative disagreement with results on $\Delta[P_T, N]$. Note that the EPOS1.99 model agrees reasonably

Table 5 Mean multiplicities of negatively and positively charged hadrons produced in inelastic p+p interactions at 20, 31, 40, 80 and 158 GeV/c in different acceptances used in this paper and in the NA49 publications. For comparison also the mean multiplicity of π^- mesons in full phase space as determined by NA61/SHINE [17] is shown in the first column.

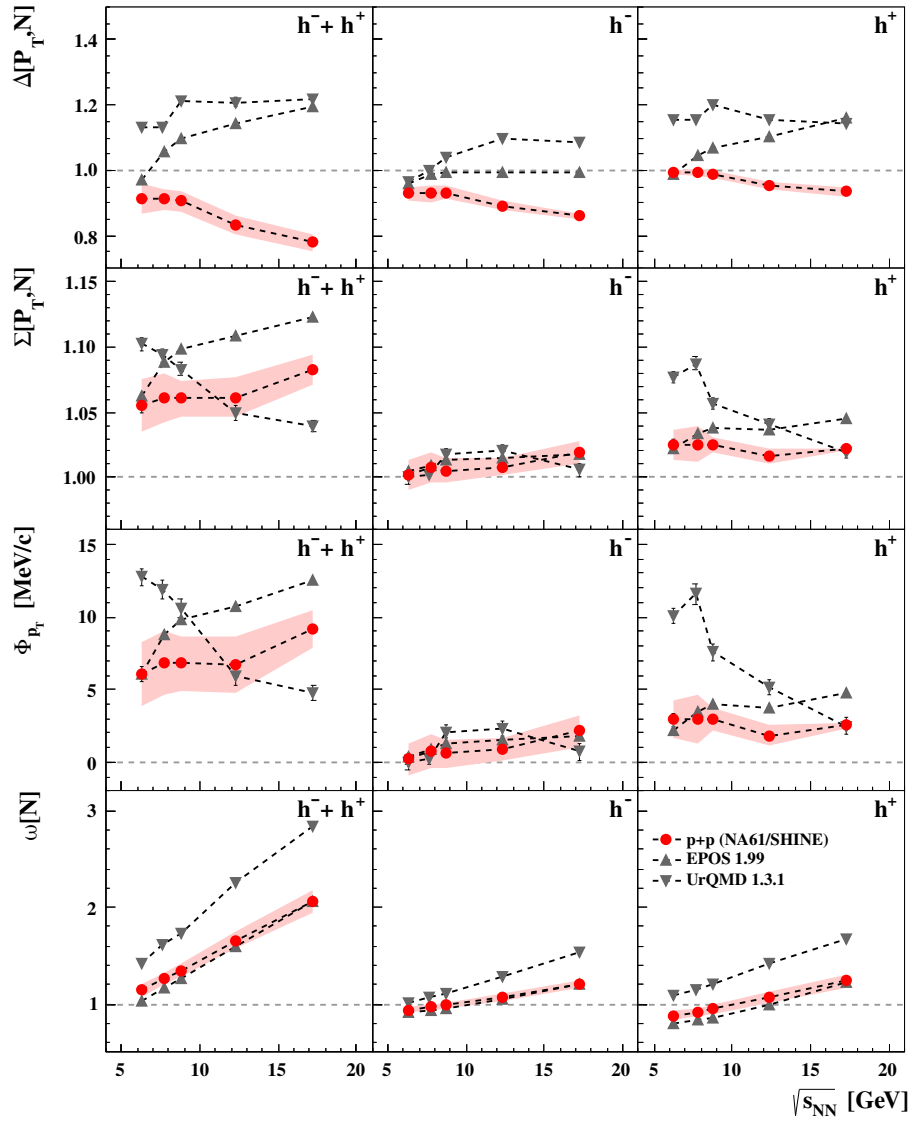

Fig. 8 (Color online) Collision energy dependence of $\Delta[P_T, N]$, $\Sigma[P_T, N]$, Φ_{p_T} and $\omega[N]$ for inelastic p+p interactions. The NA61/SHINE measurements (filled circles) are compared with predictions of the EPOS1.99 (upward pointing triangles) and UrQMD (downward pointing triangles) models (both in the NA61/SHINE acceptance). Statistical uncertainties (mostly invisible) are shown by vertical bars, systematic uncertainties by shaded bands.

well with single particle spectra of identified hadrons produced in the same inelastic p+p interactions [25].

Essentially all UrQMD predictions disagree with the data. In many cases even qualitative disagreement is observed. Note, that UrQMD also fails to describe single particle spectra in p+p reactions [25]. These disagreements are probably due to problems in modelling of hadron production via resonance decays [26].

NA61/SHINE records data at beam momenta per nucleon identical to or close to those at which NA49 [4] performed measurements of central Pb+Pb collisions. This allows for a direct study of the system size dependence of various hadron production properties in the SPS energy range.

The NA61/SHINE results presented in this paper are obtained in a phase space acceptance [20] which is larger than the acceptances used by NA49 to obtain the corresponding results for central Pb+Pb collisions [5, 6, 7, 8]. Thus, in order to compare the NA61/SHINE measurements with the NA49 data, the more restrictive NA49 cuts were applied to the NA61/SHINE data.

The narrowest acceptance (referred as to the NA49- N acceptance) was used in the NA49 study of collision energy dependence of (transverse momentum)-multiplicity fluctuations [8]. The NA49- N acceptance is limited to the rapidity range $1.1 < y_\pi < 2.6$, where y_π is the rapidity calculated in the cms assuming the pion mass, and selects particles in a common narrow azimuthal angle wedge at all beam momenta.

Figure 9 shows the NA61/SHINE results on Φ_{p_T} in inelastic p+p interactions within the full NA61/SHINE acceptance and within the NA49- N acceptance. As expected, the restriction of the acceptance strongly reduces the values of the fluctuation measure.

Figure 10 presents a comparison of Φ_{p_T} for inelastic p+p (NA61/SHINE) interactions and the 7.2% most central Pb+Pb (NA49) collisions within the NA49- N acceptance. No significant difference is observed between the results for the two reactions. Moreover, neither shows a structure in the collision energy dependence which could be attributed to the onset of deconfinement or the critical point.

Figure 11 shows the collision energy dependence of the scaled variance of the multiplicity distributions for inelastic p+p (NA61/SHINE) interactions and the 1% most central Pb+Pb (NA49) collisions within the NA49- M (top row) and NA49- B (bottom row) acceptances [6]. The NA49 medium (NA49- M) acceptance includes all particles well measured by the NA49 detector within the rapidity range $1.1 < y_\pi < y_{beam}$ and the NA49 broad acceptance (NA49- B) extends the range to $0 < y_\pi < y_{beam}$. Significant differences are observed between the results for p+p and Pb+Pb reactions, see below for a discussion. However, neither shows a structure in the collision energy dependence which could be attributed to the onset of deconfinement or the critical point.

The scaled variance is significantly larger for inelastic p+p interactions at 158 GeV/c than for the 1% most central Pb+Pb collisions at 158A GeV/c. In the following this difference will be discussed within the Wounded Nucleon Model (WNM) [10] and the Statistical Model (SM) [27] of particle production. These models are selected because they are simple and play a special role in analyzing the physics of heavy ion collisions. The discussion will be focused on the results for negatively charged hadrons as they are weakly influenced by decays of resonances [28].

The Wounded Nucleon Model [10] assumes that particle production in nucleon-nucleon and nucleus-nucleus collisions is an incoherent superposition of particle production from wounded nucleons (nucleons which interacted inelastically and whose number is calculated using the Glauber approach). Properties of wounded nucleons are assumed to be independent of the size of the colliding nuclei, e.g. they are the same in p+p and Pb+Pb collisions at the same collision energy per nucleon. The scaled variance of the multiplicity distribution of produced particles calculated within the WNM reads [11]:

$$\omega[N] = \omega^*[N] + \langle N \rangle / \langle W \rangle \cdot \omega[W], \quad (11)$$

where W is the number of wounded nucleons and $\omega^*[N]$ denotes the scaled variance calculated for any fixed value of W . The number of wounded nucleons (protons) in p+p interactions is fixed to two and the measured scaled variance for p+p interactions can be used as $\omega^*[N]$. The second component of the sum Eq. 11 vanishes or is positive. Consequently the WNM predicts that the scaled variance in nucleus-nucleus collisions has to be equal or larger than the one in inelastic proton-proton interactions. The NA61/SHINE and NA49 results presented in Fig. 12 clearly contradict this prediction.

Note that at SPS energies multiplicity distributions of negatively charged hadrons in inelastic p+p, n+p and n+n interactions are different [29]. The largest difference is observed between the distributions in p+p and n+n interactions. Thus the prediction of the WNM for Pb+Pb collisions which takes into account the isospin effects estimated using the EPOS model ranges between the results for p+p (the measured NA61/SHINE data) and n+n interactions (estimated based on the EPOS predictions and the NA61/SHINE data). This range is bounded in Fig. 12 (left) by the horizontal dashed lines.

The Statistical Model of multi-particle production was initiated by Fermi in 1950 [27]. Its basic assumption states that all possible micro-states of the macroscopic system created in a collision are equally probable. For a non-interacting (ideal) gas of Boltzmann particles in the grand canonical ensemble (IB-GCE) the multiplicity distribution is Poissonian ($\omega[N] = 1$) independent of the (fixed) system volume (upper dashed line in Fig. 12 (right)). Resonance decays and Bose

Fig. 9 (Color online) NA61/SHINE results on Φ_{p_T} vs collision energy for inelastic p+p interactions within the full NA61/SHINE acceptance (see Fig. 8) and within the NA49-N acceptance (see Ref. [8]). Statistical errors (mostly invisible) are shown by vertical bars, systematic uncertainties by shaded bands.

Fig. 10 (Color online) Φ_{p_T} versus collision energy for inelastic p+p (NA61/SHINE) interactions and the 7.2% most central Pb+Pb (NA49 [8]) collisions in the NA49-N acceptance. Statistical errors are shown by vertical bars, systematic uncertainties by shaded bands.

Fig. 11 (Color online) Collision energy dependence of the scaled variance of the multiplicity distribution for inelastic p+p (NA61/SHINE) interactions and the 1% most central Pb+Pb (NA49 [6]) collisions in the NA49-M (top) and NA49-B (bottom) acceptances (see text for details). Statistical errors (mostly invisible) are shown by vertical bars, systematic uncertainties by shaded bands.

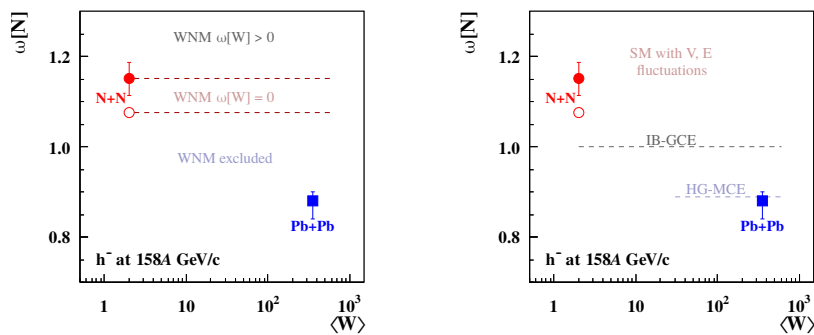

Fig. 12 (Color online) Scaled variance of the multiplicity distribution of negatively charged hadrons as a function of the mean number of wounded nucleons. Results for inelastic p+p (NA61/SHINE) interactions (filled circles) and the 1% most central Pb+Pb (NA49 [6]) collisions (squares) in the NA49-B acceptances are shown together with the predictions of the Wounded Nucleon Model (*left*) and the statistical model (*right*) (see text for explanations).

645 effects increase the scaled variance from 1 to 1.1, whereas
the conservation laws reduce it if the system volume is suf-
ficiently large [28]. The combined effect is demonstrated by
the lower dashed line in Fig. 12 (*right*). In fact the NA49
650 result for the 1% most central Pb+Pb collisions at 158A GeV/c
is well described by the hadron gas model in the micro-
canonical ensemble (HG-MCE) [28]. Within the statistical
models a scaled variance significantly larger than one as
measured in inelastic p+p interactions at high collision en-
ergies (top SPS and higher) can be understood as a result of
655 volume and/or energy fluctuations [30].

Multiplicity and transverse momentum fluctuations quan-
tified using strongly intensive measures were studied in a
number of theoretical papers. In particular, the influence of
resonance decays [31, 14], quantum statistics [31, 15] and a
660 dependence of the mean transverse momentum on multiplic-
ity [31, 14] was considered. These studies are important for
a qualitative understanding of experimental data and predic-
tions of complicated Monte Carlo models. However, the ob-
tained results cannot be directly compared to the measure-
665 ments as they did not include important effects. In particular,
the limited experimental acceptance is difficult to take into
account in simple models.

8 Summary

670 This paper presents measurements of multiplicity and trans-
verse momentum fluctuations of negatively, positively and
all charged hadrons produced in inelastic p+p interactions
at 20, 31, 40, 80 and 158 GeV/c beam momentum. Values
for the scaled variance of multiplicity distributions and three
strongly intensive measures of multiplicity–transverse mo-
675 mentum fluctuations $\Delta[P_T, N]$, $\Sigma[P_T, N]$ and Φ_{p_T} were ob-
tained. These results were calculated in the NA61/SHINE
acceptance which has to be taken into account in a quan-
titative comparison with models and other results. For the
first time the results on fluctuations are fully corrected for

experimental biases, in particular, for the losses of inelas-
680 tic events due to the trigger and analysis event selections as
well as for the contamination of particles from weak decays
and secondary interactions.

The measurements of multiplicity and transverse mo-
mentum fluctuations significantly deviate from expectations
685 for independent particle production ($\Delta[P_T, N] = \Sigma[P_T, N] =$
1, $\Phi_{p_T} = 0$ MeV/c). They also depend on the charges of the
selected hadrons. The scaled variances of the multiplicity
distributions increase with increasing collision energy and
for all charged hadrons at 158 GeV/c reach the value of 2. 690

The string-resonance Monte Carlo models EPOS and UrQMD
do not describe the data well. In several cases the collision
energy dependence predicted by the models even shows a
trend qualitatively different from the measurements.

The scaled variance of multiplicity distributions is sig-
nificantly higher in inelastic p+p interactions than in the
695 1% most central Pb+Pb collisions measured by NA49 at
the same energy per nucleon. The largest difference is ob-
served at 158A GeV/c. This result is in qualitative disagree-
ment with the predictions of the Wounded Nucleon Model.
700 The low level of multiplicity fluctuations measured in cen-
tral Pb+Pb collisions is well reproduced by the statistical
model in the micro-canonical ensemble formulation. Within
the statistical framework the enhanced multiplicity fluctua-
tions in inelastic p+p interactions can be interpreted as due
705 to event-by-event fluctuations of the fireball energy and/or
volume.
