

Murine Cytotoxic Activated Macrophages Inhibit Aconitase in Tumor Cells

Inhibition Involves the Iron-Sulfur Prosthetic Group and Is Reversible

Abstract

Previous studies show that cytotoxic activated macrophages cause inhibition of DNA synthesis, inhibition of mitochondrial respiration, and loss of intracellular iron from tumor cells. Here we examine aconitase, a citric acid cycle enzyme with a catalytically active iron-sulfur cluster, to determine if iron-sulfur clusters are targets for activated macrophage-induced iron removal. Results show that aconitase activity declines dramatically in target cells after 4 h of co-cultivation with activated macrophages. Aconitase inhibition occurs simultaneously with arrest of DNA synthesis, another early activated macrophage-induced metabolic change in target cells. Dithionite partially prevents activated macrophage induced aconitase inhibition. Furthermore, incubation of injured target cells in medium supplemented with ferrous ion plus a reducing agent causes near-complete reconstitution of aconitase activity. The results show that removal of a labile iron atom from the [4Fe-4S] cluster, by a cytotoxic activated macrophage-mediated mechanism, is causally related to aconitase inhibition.

Introduction

Mouse peritoneal macrophages activated in vivo by intracellular pathogens such as *Mycobacterium bovis*, strain BCG, or in vitro by lymphokines or by gamma interferon are cytotoxic for tumor target cells by a nonphagocytic mechanism (1-5). Mouse L1210 leukemia cells and guinea pig L10 hepatoma cells remain viable but develop inhibition of DNA synthesis, inhibition of mitochondrial respiration, and prolonged cytostasis during co-cultivation with cytotoxic activated macrophages (6). Granger and Lehninger (7) identified the sites of inhibition of mitochondrial respiration in cytotoxic activated macrophage-injured L1210 cells permeabilized with digitonin. They found that cytotoxic activated macrophages directly affected the electron transport chain in L1210 target cells. NADH:ubiquinone oxidoreductase (complex I)¹ and succinate:ubiquinone oxidoreductase (complex

II), the proximal reductases in the mitochondrial electron transport system, were markedly inhibited in injured L1210 cells. Furthermore, they found that cytotoxic activated macrophage-induced inhibition of mitochondrial respiration was selective since electron flow in more distal portions of the electron transport system remained intact. We recently observed that cytotoxic activated macrophages induce loss of iron-59 from prelabeled L1210 and L10 target cells (8). This finding raised the possibility that iron loss from cytotoxic activated macrophage injured target cells resulted in inhibition of certain enzymes that required iron for catalytic activity. Iron-sulfur clusters could be a site of iron loss. Inactivation of enzymes with iron-sulfur clusters could explain, at least in part, the pattern of metabolic inhibition observed in target cells of cytotoxic activated macrophages. It is of interest that complex I and complex II contain catalytically active iron-sulfur clusters (9). This raised the possibility that aconitase, a citric acid cycle enzyme that catalyzes the isomerization of citrate to isocitrate via the intermediate *cis*-aconitate, could also be inhibited in injured L10 cells. Aconitase, although not catalyzing a redox reaction, contains a [4Fe-4S] cluster (10). In the experiments reported here, we examined mitochondrial aconitase activity in L10 and L1210 cells that had been co-cultivated with cytotoxic activated macrophages. Our results show that cytotoxic activated macrophages cause rapid inhibition of aconitase in these target cells². In addition, we show that cytotoxic activated macrophage-induced inhibition of aconitase is due to loss of iron from the iron-sulfur cluster.

Methods

Materials. ADP, rotenone, antimycin A, oligomycin, tetramethylphenylenediamine (TMPD), isocitrate, α -glycerol phosphate, *cis*-aconitate, L-cysteine, cycloheximide, tartronate, succinate, lipopolysaccharide (LPS; phenol extracted *Escherichia coli* serotype 0128:B12), and fatty acid free bovine serum albumin (BSA) were obtained from Sigma Chemical Co. (St. Louis, MO). Citrate was from Pfizer (New York, NY) or Matheson, Coleman, and Bell (Norwood, OH). Digitonin (Sigma Chemical Co.) was purified according to the method of Kun et al. (11) and a 5% stock solution was prepared in dimethylsulfoxide. Sodium dithionite was purchased from Matheson, Coleman, and Bell and sodium thiosulfate was obtained from Mallinckrodt (St. Louis, MO). Components used to prepare tissue culture medium were from Gibco (Grand Island, NY). Calf serum and fetal bovine serum (FBS) were obtained from HyClone Laboratories, Inc. (Logan, UT). All other chemicals were reagent-grade and were purchased from commercial sources.

Macrophage effector cells. C₃H/HeN female or male mice were obtained from the Frederick Cancer Research Center Animal Facility (Frederick, MD). To obtain activated macrophages, we infected mice intraperitoneally with 5×10^6 - 1×10^7 colony forming units of *M. bovis*,

2. The term inhibition is used in this manuscript to describe loss of aconitase activity in tumor target cells caused by a cytotoxic activated macrophage mediated effect on a cofactor for enzyme activity, the iron-sulfur prosthetic group.

Pasteur strain BCG (TMC/011); originally obtained from the Trudeau Institute, Saranac Lake, NY, 17–22 d before harvest and we inoculated them with 1 ml 10% peptone (Difco Laboratories, Inc., Detroit, MI) 3–5 d before cells were harvested. Treatment of these *in vivo* activated macrophages with small amounts of LPS (20 ng/ml or less) after they are removed from the peritoneal cavity induces them to become cytotoxic for tumor cells (cytotoxic activated macrophages) (12). Stimulated macrophages were obtained from normal mice that were inoculated with 1 ml thioglycolate broth (Difco Laboratories, Inc.) or 1 ml 10% peptone 3–5 d before harvest. Stimulated macrophages do not become cytotoxic for tumor cells when treated with small amounts of LPS *in vitro* (12).

Culture medium. DME was supplemented with 20 mM Hepes, 100 U/ml penicillin, and 100 µg/ml streptomycin (referred to as Dulbecco's modified Eagle's medium, DME). DME for the continuous cultivation of target cells contained 5.6 mM glucose and DME used for the co-cultivation contained 17.6 mM glucose.

Target cells. The methylcholanthrene-induced murine (DBA/2) lymphoblastic leukemia cell line (L1210) and the diethyl-nitrosamine-induced guinea pig (strain 2) hepatoma cell line (L10) were maintained in spinner suspension culture in DME plus 5% FBS (L1210) or 5% calf serum (L10). L1210 cells and L10 cells were tested periodically using the Mycotrin-TC mycoplasma test system (New England Nuclear, Boston, MA) and have been consistently negative for mycoplasma contamination.

Macrophage-tumor cell cocultures. Activated or stimulated macrophage monolayers were prepared by adding peritoneal exudate cells ($1.5 \times 10^6/\text{cm}^2$) to 80-mm diameter tissue culture dishes (Costar 3100; Costar, Cambridge, MA) in DME and adhered for 60–90 min at 37°C in a 5% CO₂ atmosphere. Nonadherent peritoneal exudate cells were then removed by washing three times with phosphate-buffered saline (PBS). Log phase L10 cells ($1.2 \times 10^5/\text{cm}^2$) or L1210 cells ($2.4 \times 10^5/\text{cm}^2$) were added to the activated macrophage monolayers in DME + 20 ng/ml LPS with 5% FBS (L1210) or 5% calf serum (L10).

Respiration measurements. Oxygen consumption was measured with a Clark oxygen electrode (model 53; Yellow Springs Instrument Co., Yellow Springs, OH). Tumor target cells were removed from the macrophage monolayers and permeabilized with 0.007% digitonin in respiration medium (0.25 M sucrose, 20 mM Hepes, pH 7.2, 2 mM Pi, 10 mM MgCl₂, and 1 mM EGTA) as previously described (7). Digitonin treatment selectively permeabilizes the plasma membrane while not affecting mitochondrial function (13). This permits access of mitochondrial substrates into the cell interior. Permeabilized cells were washed by centrifugation (180 g for 5 min) to eliminate endogenous substrates and to permit added substrates to initiate respiration. To determine the effectiveness of the permeabilization procedure, cells were counted in the presence of trypan blue (cells do not exclude trypan blue after successful permeabilization). Measurement of L1210 respiration was initiated by adding permeabilized L1210 cells to respiratory medium supplemented with 1 mM ADP and appropriate respiratory substrate as described (7). However, for measurement of L10 cell respiration, cells were incubated in respiratory medium containing appropriate respiratory substrate before initiating state 3 respiration rate by adding 1 mM ADP. For both cell lines, the respiration medium was supplemented with 0.7% fatty acid-free BSA during measurement of O₂ consumption. When citrate or isocitrate-dependent respiration was measured in L10 cells, 5 mM tartronate (2-hydroxy malonate) was added to the respiration medium as an exchange partner for the tricarboxylate-transporter, which facilitates the entry of citrate and isocitrate into the mitochondrial matrix (14, 15). Tartronate was not needed for entry of citrate or isocitrate into the mitochondria of L1210 cells. Under these experimental conditions, the respiratory control ratio of control L10 cells or L1210 cells was usually >5 using succinate as substrate (state 3 rate [substrate + 1 mM ADP] and state 4 rate [substrate + 1 mM ADP + 100 nM oligomycin]). The oxygen concentration in the air-saturated respiration medium was taken as 390 ng atoms/ml.

Spectrophotometric measurement of aconitase and isocitrate dehydrogenase. Disappearance of *cis*-aconitase at 240 nm was measured with a Cary 16S recording spectrophotometer (Variant Instruments, Palo Alto, CA) by a modification of a previously described method (16). Cells were

permeabilized with 0.007% digitonin as described above to remove cytoplasmic proteins and then lysed with 0.2% Triton X-100 in 0.15 M NaCl buffered with 30 mM triethanolamine-HCl, pH 7.2. Lysate was centrifuged (5,000 g for 15 min) and the supernatant was immediately assayed for aconitase activity at 25°C in the presence of 0.02% BSA. The reaction was started with the addition of 0.2 mM *cis*-aconitase and enzyme activity was determined from the initial reaction rate. An extinction coefficient of 3.41 cm⁻¹ mM⁻¹ was used for *cis*-aconitase (17). Isocitrate dehydrogenase was measured spectrophotometrically in the lysates by following the reduction of NADP⁺ with isocitrate as substrate. Isocitrate (1 mM final concentration) was added to the lysates to start the reaction and the coupled reduction of NADP⁺ (0.1 mM) was followed at 340 nm. Reaction was performed at 37°C in a buffer, pH 7.2, containing 30 mM triethanolamine-HCl, 0.15 M NaCl, and 10 mM MgCl₂.

Measurement of DNA synthesis and target cell viability. Determination of [³H]thymidine uptake as well as viability of L10 and L1210 cells was as previously described (8, 18).

Measurement of protein synthesis. L10 cells cultivated with cycloheximide for various intervals of time were washed by centrifugation (180 g for 5 min) and counted. Aliquots, in duplicate (10⁵ L10 cells), were pulse-labeled with 2 µCi/ml of L-[³H]leucine in DME + 5% calf serum. Incorporated radioactivity was measured as previously described (8).

Protein determination. Protein content of cell lysates was determined using the Bio-Rad protein assay kit (Bio-Rad Laboratories, Richmond, CA) and with BSA as a standard (19).

Statistical analysis. Statistical analysis of data was by Student's *t* test.

Results

Polarographic measurement of aconitase, complex I, and complex II activity in L10 cells co-cultivated with cytotoxic activated macrophages. In Fig. 1, a simplified diagram of the citric acid cycle and the electron transport system is outlined for reference. Aconitase activity as well as different segments of the electron transport chain can be measured *in situ* using polarographic technique in the same sample of digitonin-treated cells. Fig. 2 shows the oxygen electrode trace of L10 cells cultured alone (A) or co-cultivated with cytotoxic activated macrophages (B). Citrate-dependent respiration in the presence of ADP (state 3 respiration) was strongly inhibited in L10 cells that had been co-cultivated with cytotoxic activated macrophages for 7 h. Addition of isocitrate resulted in resumption of O₂ uptake, showing that

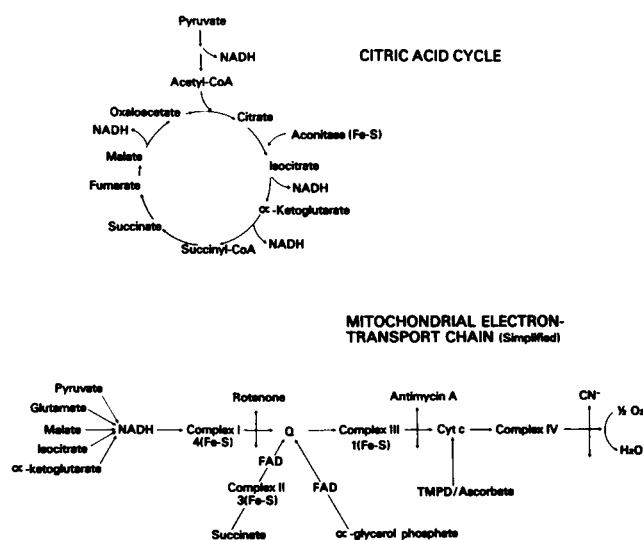

Figure 1. Schematic representation of the citric acid cycle and the mitochondrial electron transport chain.

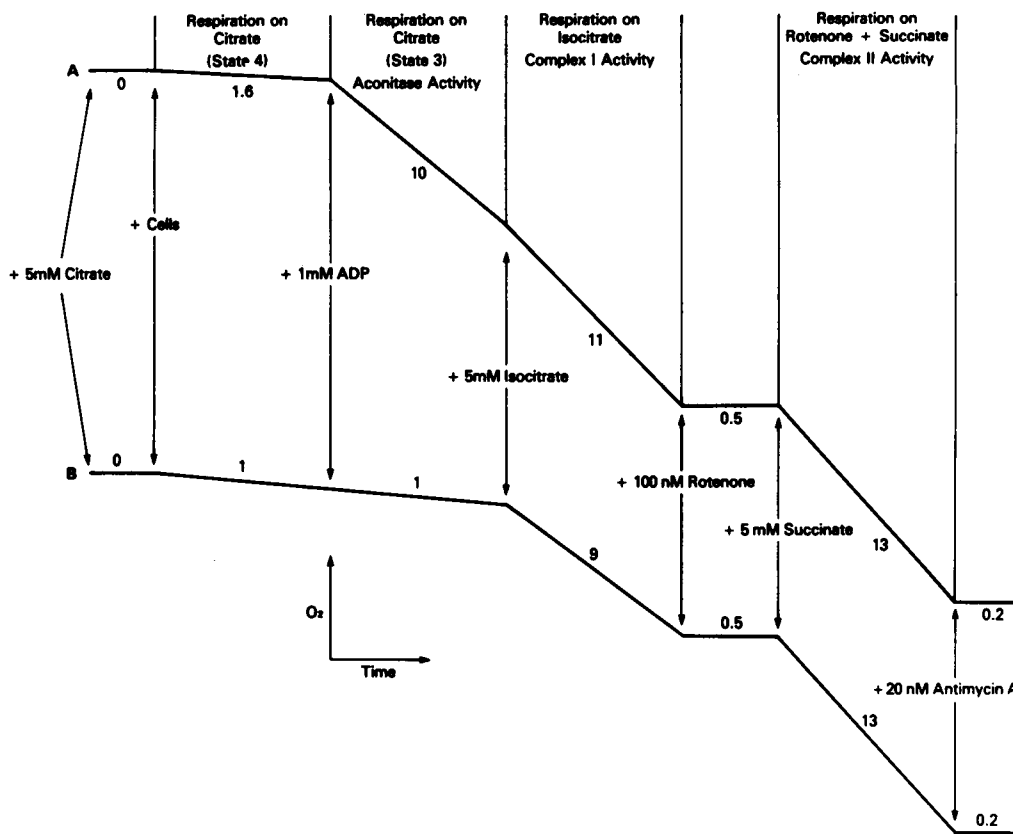

Figure 2. Comparison of citrate, isocitrate, and succinate plus rotenone oxidation in control L10 cells (A) and in L10 cells co-cultivated for 7 h with cytotoxic activated macrophages (B). L10 cells (5×10^6) were permeabilized with 0.007% digitonin and washed by centrifugation (180 g) to remove endogenous substrate. Cells were resuspended in 2.8 ml respiration medium and O₂ consumption was measured in a magnetic stirred thermostated chamber with a Clark oxygen electrode. The numbers are rates of oxygen consumption in ng atoms O · min⁻¹ · 10⁻⁶ L10 cells. Antimycin A, an inhibitor of mitochondrial respiration (see Fig. 1), inhibited O₂ consumption by both co-cultivated L10 cells and control L10 cells. This demonstrates that the O₂ consumption measured was of mitochondrial origin.

the citric acid cycle enzyme isocitrate dehydrogenase as well as complex I, ubiquinol:ferricytochrome C oxidoreductase (complex III), and ferricytochrome C: oxygen oxidoreductase (complex IV) of the electron transport chain were intact at this relatively early time during the co-cultivation period. Complex II activity, as assessed by oxidation of succinate in the presence of rotenone, was unimpaired after 7 h of co-cultivation of L10 cells with cytotoxic activated macrophages. This pattern of results, inhibition of citrate oxidation but near normal oxidation of isocitrate (complex I) and normal oxidation of succinate plus rotenone (complex II), suggests that cytotoxic activated macrophage mediated inhibition of the isomerization of citrate to isocitrate catalyzed by aconitase occurs before inhibition of complex I and complex II.

Kinetics of inhibition of aconitase, complex I, and complex II activity in L10 cells co-cultivated with cytotoxic activated macrophages. Fig. 3 shows that citrate-dependent respiration in L10 cells is significantly depressed after 4 h of co-cultivation and is undetectable after 8 h of co-cultivation. At this time, isocitrate (complex I), is still an effective substrate but respiration supported by isocitrate slowly declines versus time and is reduced more than 80% after 22 h of co-cultivation. Complex II activity, oxidation of succinate in the presence of rotenone, declines even more gradually than complex I activity in L10 target cells and is reduced to 71% of control cells after 22 h of co-cultivation with cytotoxic activated macrophages.

The following evidence suggests that after 20–24 h of co-cultivation of L10 cells with cytotoxic activated macrophages, the limiting steps for isocitrate and succinate plus rotenone oxidation are at the level of complex I and complex II, respectively: (a) The oxidation of other NADH-linked substrates (e.g., 5 mM malate) is inhibited to the same extent as oxidation of isocitrate.

(b) Isocitrate dehydrogenase was functionally intact in digitonin permeabilized L10 cells. For example, after 20 h of co-cultivation, at a time when isocitrate-dependent respiration was 80% inhibited, isocitrate dehydrogenase activity in L10 cells co-cultivated with cytotoxic activated macrophages was 48 nM NADP⁺ reduced · min⁻¹ · mg protein⁻¹ while that of control cells was 35 nM NADP⁺ reduced · min⁻¹ · mg protein⁻¹. (c) Complex III and complex IV of the mitochondrial electron transport chain remain functionally intact in co-cultivated L10 cells. The rate of state

Figure 3. Kinetics of cytotoxic activated macrophage-induced inhibition of aconitase, complex I, and complex II activity in L10 target cells. Co-cultivated L10 cells (●) and control L10 cells (○) were removed from culture at the time indicated and ADP-stimulated rates of O₂ uptake were measured. Substrates were: 5 mM citrate (A); 5 mM isocitrate (B); 5 mM succinate and 100 mM rotenone (C). Experiment is representative of three performed.

Table I. State 3 Respiration of L10 Cells Cultured Alone or with Macrophages

L10 cells cultured with:	Experiments	Substrate and oxygen consumption		
		Citrate (aconitase activity)	Isocitrate (complex I activity)	Succinate and rotenone (complex II activity)
Cultured alone (control L10 cells)	26	9.3±2.2	10.8±2.6	13.2±2.5
Cytotoxic activated macrophages (BCG, activated)	24	1.4±1.4* (15%)	7.2±1.8* (77%)	12.8±2.8 (97%)
Stimulated macrophages (thioglycollate-elicited)	4	10.0±1.3	11.5±1.2	12.2±1.2
Stimulated macrophages (proteose-peptone-elicited)	4	9.8±0.3	11.4±1.8	14.8±0.6

L10 cells were cultured alone or co-cultivated with macrophages for 6.5 h before respiration measurements were made using digitonin-treated L10 cells. Concentration of substrates and inhibitor added to the respiration medium: aconitase activity, 5 mM citrate; complex I activity, 5 mM isocitrate; and complex II activity, 5 mM succinate + 100 nM rotenone. Data are presented as rates of substrate oxidation in ng atoms $0 \text{ min}^{-1} \cdot 10^{-6}$ L10 cells. Values are the mean±SD for the number of experiments shown. Numbers in parentheses are percent of activity of control L10 cells.

* $P < 0.001$ vs. control L10 cells.

3 oxidation of α -glycerol phosphate by L10 cells that were co-cultivated with cytotoxic activated macrophages for 22 h was $2.5 \text{ ng atoms } 0 \cdot \text{min}^{-1} \cdot 10^{-6}$ L10 cells, which was identical to state 3 oxidation of α -glycerol phosphate by control L10 cells. This shows that, as in co-cultivated L1210 cells (7), the respiratory chain between ubiquinone and O_2 is functional in L10 cells after activated macrophage-induced injury. In addition, the terminal segment of the electron chain can support electron flow at high rates in injured L10 cells. The oxidation of 0.2 mM TMPD plus 1 mM ascorbate (in the presence of 100 nM rotenone and 20 nM antimycin A) was $25 \text{ ng atoms } 0 \cdot \text{min}^{-1} \cdot 10^{-6}$ L10 cells co-cultivated with cytotoxic activated macrophages for 22 h and $30 \text{ ng atoms } 0 \cdot \text{min}^{-1} \cdot 10^{-6}$ control L10 cells. Thus, the terminal part of the electron transport chain of injured L10 cells, like injured L1210 cells (7), can support electron flow above usual state 3 rates.

Measurement of aconitase, complex I, and complex II activity in L10 cells co-cultivated with stimulated macrophages. Stimulated macrophages elicited in normal mice by intraperitoneal injection of sterile nonimmunogenic inflammatory stimulants such as 10% proteose peptone broth or thioglycollate broth are not cytotoxic for tumor cells (12). Table I shows that citrate, isocitrate, or succinate plus rotenone oxidation was unchanged in L10 cells after 6.5 h of co-cultivation with stimulated macrophages (thioglycollate or proteose peptone-elicited macrophages). At this same time, citrate oxidation in L10 cells co-cultivated with cytotoxic activated macrophages was only 15% and isocitrate oxidation was 67% of that measured in control L10 cells. Even after 20 h of co-cultivation of L10 cells with stimulated macrophages, there was no decrease in O_2 consumption with citrate, isocitrate, or succinate plus rotenone as substrate when compared with control L10 cells (data not shown). These results show that co-cultivation of L10 cells with stimulated macrophages, unlike co-cultivation of L10 cells with cytotoxic activated macrophages, has no effect on aconitase activity or complex I and complex II of the mitochondrial electron transport chain.

Spectrophotometric measurement of aconitase activity. The above results show marked inhibition of citrate oxidation in the presence of significant isocitrate-dependent O_2 consumption in L10 cells co-cultivated with cytotoxic activated macrophages for 6–7 h. This strongly suggests inhibition of aconitase activity is an early event in the development of activated macrophage-

mediated cytotoxicity by L10 cells. It is unlikely that inhibition of citrate transport, but not isocitrate transport, into mitochondria explain the polarographic results obtained. However, to rule out this possibility, we also measured the enzymatic activity of aconitase by recording the aconitase-dependent change in ultraviolet absorbance of *cis*-aconitate in L10 cell lysates. The results of the spectrophotometric assay are in agreement with the polarographic results. Table II shows that aconitase activity present in lysates of L10 cells co-cultivated with cytotoxic activated macrophages for 6.5 h was only 14% of the activity present in lysates of control L10 cells. Thus, cytotoxic activated macrophage-mediated inhibition of aconitase activity in L10 target cells can be documented in two independent assays of enzymatic activity.

Comparison of citrate oxidation and [^3H]thymidine uptake by L10 target cells. Fig. 4 shows the kinetics of inhibition of citrate oxidation and [^3H]thymidine uptake in L10 target cells. The results show that inhibition of aconitase activity and inhibition of DNA synthesis in L10 cells co-cultivated with cytotoxic activated macrophages are early and simultaneous events.

Polarographic measurement of aconitase, complex I, and complex II activity in L1210 cells co-cultivated cytotoxic activated macrophages. To determine if aconitase activity is inhibited in another cell line, we examined the kinetics of inhibition of citrate, isocitrate, and succinate plus rotenone oxidation in mouse L1210 leukemia cells co-cultivated with cytotoxic activated macro-

Table II. Spectrophotometric Measurement of Aconitase Activity in L10 Cells Cultured Alone or with Macrophages

L10 cells cultured with:	Experiments	Aconitase activity
Cultured alone (control L10 cells)	5	39.0±6.9
Cytotoxic activated macrophages (BCG-activated)	3	5.4±1.0 (14%)
Stimulated macrophages (thioglycollate-elicited)	3	41.3±7.3

L10 cells were cultured alone or co-cultivated with macrophages for 6.5 h before performance of the spectrophotometric assay. Results are expressed as rate of *cis*-aconitate disappearance in nanomoles per minute per mg protein. Values are the mean±SD for the number of experiments shown. Number in parentheses is the percent of activity of control L10 cells.

Figure 4. The kinetics of citrate-dependent respiration (aconitase activity) and [³H]thymidine incorporation into DNA in L10 cells cultured alone (■) or co-cultivated with cytotoxic activated macrophages (●). Measurement of aconitase activity: L10 cells were removed from culture at the indicated times, washed by centrifugation (180 g), permeabilized with digitonin, and state 3 respiration was measured in medium with 5 mM citrate. Measurement of DNA synthesis: aliquots of L10 cells were removed from the same cultures used as a source of cells for measurement of aconitase activity, washed by centrifugation (180 g), pulse-labeled in duplicate for 30 min with 0.5 $\mu\text{Ci ml}^{-1}$ [³H]thymidine in DME plus 5% calf serum, and processed as described (8, 18).

phages. Similar to the results with L10 cells, citrate oxidation (aconitase activity) rapidly declined after 4 h of co-cultivation of L1210 cells with cytotoxic activated macrophages (Fig. 5). Isocitrate (complex I) and succinate plus rotenone (complex II) also gradually declined in co-cultivated L1210 cells, which confirms the findings of Granger and Lehninger (7). These results show that the same pattern of enzyme inhibition develops in L10 cells and L1210 cells during co-cultivation with cytotoxic activated macrophages.

Measurement of aconitase turnover. L10 cells were cultivated in the presence of cycloheximide to determine if decreased protein synthesis could explain the rapid inhibition of aconitase activity in co-cultivated cells. Table III shows that aconitase was 91% active after 10 h of cycloheximide treatment (a time when aconitase is completely inhibited in L10 cells co-cultivated with cytotoxic activated macrophages) and that its half-life was 20 h in the presence of cycloheximide. L10 cells treated with cycloheximide incorporated L-[³H]leucine at 19, 13, and 10% of the rate of control L10 cells after 10, 20, and 40 h, respectively (average of four experiments). Similar results were found with L1210 cells. This shows that inhibition of protein synthesis cannot explain the rapid inhibition of aconitase activity caused by cytotoxic activated macrophages.

Comparison of citrate-dependent respiration in digitonin-treated and endogenous respiration in L10 cells co-cultivated with activated macrophages. To determine the consequences of inhibition of aconitase activity on mitochondrial respiration, we

Figure 5. Kinetics of cytoxic activated macrophage-induced inhibition of aconitase (A), complex I (B), and complex II (C) activity in L1210 target cells. Conditions for state 3 respiration measurements were the same as given in the legend to Fig. 3. ○, control L1210 cells; ●, co-cultivated L1210 cells.

compared exogenous citrate-dependent respiration to endogenous respiration in intact L10 cells after 6 h of co-cultivation with cytotoxic activated macrophages. Oxidation of citrate by L10 cells that were co-cultivated with activated macrophages for 6 h was completely inhibited, while endogenous coupled and uncoupled respiration was unchanged from that measured in control L10 cells (Table IV). However, after 22 h of co-cultivation of L10 cells, both endogenous coupled and endogenous uncoupled respiration were markedly inhibited (Table IV). These results suggest that citric acid cycle block at the level of aconitase, which occurs relatively early during the cocultivation period does not inhibit mitochondrial respiration. Indeed, as long as complex I and complex II are still functional, endogenous substrates are able to circumvent the aconitase block.

Bypass of the aconitase reaction (and acetyl coenzyme A

Table III. Aconitase Activity in L10 Cells Treated with Cycloheximide to Inhibit Protein Synthesis

Substrates and inhibitor	Oxygen consumption (percent control L10 cells) at various time intervals of cultivation with cycloheximide		
	10 h	20 h	40 h
	percent	percent	percent
Citrate (aconitase activity)	91±9	51±6	39±5
Isocitrate (complex I activity)	96±3	60±15	39±2
Succinate + rotenone (complex II activity)	92±8	70±13	49±8

L10 cells were cultured with 10 $\mu\text{g ml}^{-1}$ cycloheximide for the time interval indicated before state 3 respiration measurements were made using digitonin-treated L10 cells. Concentration of substrates and inhibitor added to the respiration medium: aconitase activity, 5 mM citrate; complex I activity, 5 mM isocitrate; and complex II activity, 5 mM succinate + 100 nM rotenone. O₂ consumption was normalized to number of viable L10 cells and expressed as percent of control L10 cells not treated with cycloheximide. Values are mean±SD of four experiments.

Table IV. Exogenous Citrate-dependent State 3 Respiration and Endogenous Respiration in Control L10 Cells and L10 Cells Co-cultivated with Cytotoxic Activated Macrophages

	Oxygen consumption*			
	6 h		22 h	
	L10 cells alone	L10 cells + cytotoxic activated macrophages	L10 cells alone	L10 cells + cytotoxic activated macrophages
Citrate-dependent respiration	14	0	N.D.‡	N.D.
Endogenous respiration + 100 μ M 2,4 dinitrophenol	26	24	33	2

L10 cells were cultured alone or co-cultivated with cytotoxic activated macrophages for the time interval indicated before respiration measurements were made. 5 mM citrate was present in the respiration medium for measurement of citrate-dependent O₂ consumption in digitonin permeabilized L10 cells. Endogenous respiration was measured in parallel experiments in nonpermeabilized L10 cells in the presence or absence of 2,4 dinitrophenol.

* Units, ng atoms O · min⁻¹ · 10⁻⁶ L10 cells.

‡ N.D., not done.

(CoA) and citrate as respiratory substrates) could occur if glutamate, after transamination to the citric acid cycle intermediate α -ketoglutarate, is utilized as an alternative respiratory substrate (see Fig. 1 for reference). The successive five reaction steps between α -ketoglutarate and oxaloacetate could continue to function as a shortened pathway if oxaloacetate were transaminated to aspartate. Aspartate could be transported from mitochondria in exchange for its transamination partner glutamate. Glutamate, after transamination to α -ketoglutarate, would be substrate for the first reaction in this shortened pathway. This possibility was examined in L10 cells that were co-cultivated with activated

Table V. Effect of Dithionite on Citrate Oxidation (Aconitase Activity) in L10 Cells Co-cultivated with Cytotoxic Activated Macrophages

L10 cells cultured with:	Oxygen consumption*
Cultured alone (control L10 cells)	11.0±2.5
Cytotoxic activated macrophages (BCG-activated)	2.3±1.7 (79)
Cytotoxic activated macrophages (BCG-activated) + 5 mM sodium dithionite	8.7±3.7 (21)‡

L10 cells were cultured alone or co-cultivated with cytotoxic activated macrophages at 37°C in humidified 95% air, 5% CO₂ atmosphere for 6.5 h in the presence or absence of 5 mM sodium dithionite, permeabilized with digitonin, and state 3 respiration was measured. Sodium dithionite had no effect on citrate oxidation in digitonin-permeabilized control L10 cells. Respiratory medium contained 5 mM citrate during measurement of oxygen consumption. Values are the mean±SD of five experiments. Numbers in parentheses are percent inhibition.

* Units, ng atoms O · min⁻¹ · 10⁻⁶ L10 cells.

‡ Difference between groups co-cultivated in the presence or absence of sodium dithionite; *P* < 0.001.

Table VI. Reconstitution of Citrate Oxidation (Aconitase Activity)

Additives present during 1-h second incubation of L10 cells	Experiments	Oxygen consumption	Percent recovery*
None	6	0.9±0.9	9
50 μ M FeSO ₄	3	5.7±0.4	59
1 mM L-cysteine	3	3.1±0.2	32
50 μ M FeSO ₄ + 1 mM L-cysteine	3	8.4±3.5	87
3 mM thiosulfate	3	1.8±0.9	19
50 μ M FeSO ₄ + 3 mM thiosulfate	3	9.0±3.1	94

L10 cells were cultured alone or co-cultivated with cytotoxic activated macrophages for 6.5 h. They were then removed from the macrophage monolayers, washed, and reincubated in a shaker (Lab-Line Instruments, Inc., Melrose Park, IL) (250 oscillations per minute) for 1 h at 37°C in DME plus 5% calf serum. The DME used for the 1-h second incubation was previously deaerated by saturation with N₂ and contained no additives or the additives indicated below. State 3 respiration measurements were made after the 1-h second incubation using digitonin-treated L10 cells in respiration medium containing 5 mM citrate. Citrate-dependent O₂ consumption is presented as ng atoms O · min⁻¹ · 10⁻⁶ L10 cells. Values are the mean±SD for the number of experiments shown.

* Recovery is expressed as percent of citrate dependent respiration by control L10 cells (9.6±1.1 ng atoms O · min⁻¹ · 10⁻⁶ cells, *n* = 6).

macrophages for 7 h and then permeabilized with digitonin. In these cells, 5 mM citrate no longer supported mitochondrial respiration but 5 mM α -ketoglutarate was as effective as 5 mM isocitrate as a respiratory substrate (both supported respiration at rates 80% of that measured in control L10 cells). These results show that endogenous respiration continues at a normal rate and that α -ketoglutarate is an effective respiratory substrate in injured L10 cells at a time when aconitase activity is blocked but complex I and complex II are still functional.

Dithionite partially prevents inhibition of aconitase activity in L10 cells by activated macrophages. It is known that the enzymatic activity of aconitase is inactivated by mild oxidation (20, 21). Therefore, we supplemented the culture medium with reductants and measured aconitase activity in L10 cells after 6.5 h of co-cultivation. 10 mM L-cysteine or 5 mM ascorbate had no consistent effect on aconitase inhibition (data not shown) but sodium dithionite partially prevented activated macrophage-induced inhibition of aconitase activity in L10 cells (Table V). These results suggest that dithionite or one of its products, e.g., thiosulfate, interfere with cytotoxic activated macrophage-mediated inhibition of aconitase activity in L10 target cells.

Reconstitution of aconitase activity. Early studies showed that ferrous ion and cysteine activate and stabilize highly purified aconitase preparations (22). Subsequent findings demonstrated that aconitase is reversibly inactivated by mild oxidative conditions (20, 21, 23). Therefore, experiments were carried out to investigate whether ferrous ion alone, or ferrous ion in combination with cysteine or thiosulfate, could restore aconitase activity in L10 cells that previously had been co-cultivated with cytotoxic activated macrophages for 6.5 h (Table VI). A 1-h incubation of injured L10 cells in DME with 50 μ M FeSO₄ resulted in a restoration of aconitase activity to 59% of that in control L10 cells. When 1 mM cysteine or 3 mM thiosulfate were also present during the 1-h incubation of injured L10 cells with 50 μ M FeSO₄, the activity of aconitase was restored to 87 and 94%, respectively, of that in control L10 cells. Cysteine or

thiosulfate induced some recovery of aconitase activity when added alone but we cannot exclude the possibility that this effect could be due to trace amounts of contaminating iron.

It is possible that further degradation of the iron-sulfur cluster occurs in injured target cells as the co-cultivation continues beyond 6–8 h. We were unable to reconstitute aconitase, complex I, and complex II activities by adding 50 μ M FeSO₄ and 1 mM L-cysteine to L10 cells (conditions described in the legend to Table VI) that had been co-cultivated with cytotoxic activated macrophages for 24 h. Aconitase activity was measured polarographically as well as spectrophotometrically. Complex I and complex II activity was measured polarographically.

Discussion

We recently showed that L10 cells and L1210 cells co-cultivated with cytotoxic activated macrophages lose intracellular iron while remaining viable and growth inhibited (8). In the present study we show that loss of intracellular iron is associated with inhibition of the citric acid cycle enzyme aconitase and that the iron-sulfur prosthetic group of aconitase plays an essential role in the enzymatic inhibition. These results are the first evidence that mobilization of intracellular iron in target cells by a cytotoxic activated macrophage-mediated mechanism is causally related to inhibition of an enzyme with an iron-sulfur cluster.

When aconitase is isolated from cells it can be reversibly inactivated by mild oxidative conditions. Recent studies using Mössbauer spectroscopy showed that oxidative stress results in conversion of the [4Fe-4S] cluster of the active enzyme to a [3Fe-4S] cluster of the inactive enzyme by loss of an iron atom (20, 21, 23). Upon incubation of the inactive enzyme in the presence of ferrous ion, or ferrous ion plus a reducing agent, the [3Fe-4S] cluster is converted to the active [4Fe-4S] cluster (20, 23, 24). These results suggest ferrous ion is used to rebuild the active [4Fe-4S] cluster from the inactive [3Fe-4S] cluster.

The findings reported here have implications for iron-sulfur cluster interconversion in regulation of the *in vivo* catalytic activity of aconitase. Aconitase activity falls precipitously in L10 and L1210 target cells between 4 and 6 h of co-cultivation with cytotoxic activated macrophages and is undetectable by 8 h of co-cultivation. The loss of catalytic activity is not due to cytotoxic activated macrophage-induced inhibition of protein synthesis in L10 target cells. Rather than loss of or damage to the apoenzyme, the results observed are explained by cytotoxic activated macrophage induced removal of iron from the iron-sulfur prosthetic group of target cell aconitase. Dithionite, a reducing agent, largely prevents aconitase inhibition in L10 target cells. This is evidence that oxidative degradation of the [4Fe-4S] cluster correlates with aconitase inactivation. Furthermore, incubation of injured L10 cells with ferrous ion and thiosulfate or cysteine after 6.5 h of co-cultivation with cytotoxic activated macrophages causes virtual complete restoration of aconitase activity. These findings provide strong evidence that cytotoxic activated macrophage-induced inhibition of aconitase in L10 target cells is submolecular and mediated by iron removal from that enzyme's iron-sulfur center. The results are compatible with the possibility that aconitase, that has been inhibited in injured L10 cells by the activated macrophage cytotoxic mechanism, contains an inactive [3Fe-4S] cluster which is readily restored to an active [4Fe-4S] cluster by incorporation of a ferrous ion. Thus, the [4Fe-4S] \rightleftharpoons [3Fe-4S] interconversion of the cluster could represent a regulatory function for the iron-sulfur center of aconitase

that is modulated by an activated macrophage mediated mechanism.

The kinetics of inhibition of complex I and complex II of the electron transport chain are slower than the kinetics of inhibition of aconitase activity. However, cytotoxic activated macrophage-mediated degradation of iron-sulfur clusters of complex I and complex II could explain the inhibition of their oxidoreductase activity and ultimately, inhibition of mitochondrial respiration. Complex I contains three [4Fe-4S] clusters (9). Whether or not redox-mediated interconversions of the [4Fe-4S] clusters in complex I occur is not known. Recent evidence shows that complex II contains a 3-iron cluster probably of the [3Fe-4S] type (25). The 3-iron cluster could arise by oxidative degradation of a [4Fe-4S] cluster in this enzyme complex. Therefore, both complex I and complex II, like aconitase, may contain [4Fe-4S] clusters and a similar mechanism could explain cytotoxic activated macrophage inhibition of their catalytic function.

The generalization that all enzymes containing iron-sulfur clusters are inhibited by the activated macrophage cytotoxic mechanism can not be made. Complex III of the mitochondrial electron transport system contains a [2Fe-2S] cluster that is essential for its electron transport function (9). Granger and Lehninger showed (7), and we confirmed in this study, that electron transfer can occur from ubiquinone through complex III to complex IV in mitochondria of injured target cells in which complex I and complex II are inhibited. However, because electron transport occurs at less than normal state 3 rates in both normal and injured target cells when α -glycerol phosphate is the electron donor, partial inhibition of complex III in mitochondria of injured target cells would not have been detected with the experimental method used. It is of interest that a similar pattern of loss of bioenergetic function was observed in mitochondria from severely iron-deficient rats (26). The Fe-S clusters of complex I and complex II were markedly decreased while the Fe-S cluster of complex III was only minimally affected.

Endogenous respiration continues at a normal rate and exogenous α -ketoglutarate is an effective respiratory substrate in injured L10 cells after 6 h of co-cultivation. At this time, aconitase activity is blocked but complex I and complex II are still functional. However, endogenous respiration is markedly inhibited after 22 h of co-cultivation, and NADH-linked substrates (including α -ketoglutarate) as well as succinate are not effectively oxidized. This suggests that endogenous respiration measured after inhibition of aconitase activity, but before significant inhibition of complex I and complex II, could be due to oxidation of α -ketoglutarate derived from the transamination of glutamate. It is also possible the malate-aspartate shuttle or the α -glycerol phosphate shuttle could transport reducing equivalents from extramitochondrial NADH into mitochondria and bypass aconitase block.

The kinetics of inhibition of aconitase activity in target cells of cytotoxic activated macrophages is exactly paralleled by the kinetics of inhibition of DNA synthesis as detected by [³H]thymidine uptake. Ribonucleotide reductase, the rate-limiting enzyme in DNA synthesis, contains non-heme iron essential for its catalytic activity (27). However, whether or not the mechanism of cytotoxic activated macrophage-mediated inhibition of DNA synthesis is similar to the mechanism of inhibition of aconitase activity is not known.

The biological significance of metabolic changes induced in target cells by cytotoxic activated macrophages has yet to be

determined with certainty. These metabolic changes are selective and highly reproducible. It is possible that cytotoxic activated macrophage-mediated regulation of a pool of intracellular iron available for participation in catalytic function, particularly in enzymes with iron-sulfur prosthetic groups, could be a mechanism involved in control of cellular proliferation.
