(Received April 6, 2004)

Phosphate deposits are generally characterized by enhanced radionuclide concentrations compared to natural levels. The mining and processing of this phosphate ore redistribute radionuclides throughout the environment and introduce them into phosphoric acid and phosphogypsum. Phosphoric acid is the starting material for triple superphosphate (TSP), single superphosphate (SSP), monoammonium phosphate (MAP), diammonium phosphate (DAP), NPK fertilizers and di-calcium phosphate (DCP). Contents of natural radionuclides from thorium and uranium series, ^{226}Ra, ^{210}Pb and ^{228}Ra, were measured in Brazilian igneous phosphate rock, phosphoric acid, phosphogypsum and phosphate fertilizer samples, using high-resolution gamma-spectrometry. Neutron activation analysis was used for the determination of U and Th in the same samples. The fertilizers samples which are derived directly from phosphoric acid, MAP and DAP, presented activity concentrations around the detection limits of the counting system for ^{226}Ra (<5.0 Bq·kg^{-1}), for ^{228}Ra (<3.0 Bq·kg^{-1}) and for ^{210}Pb (<19 Bq·kg^{-1}). As for U and Th, the concentrations found in MAP and DAP are more significant, up to 374 and 250 Bq·kg^{-1}, respectively. SSP, TSP and NPK, which are obtained by mixing phosphoric acid with different amounts of phosphate rock and NH_3, presented higher concentrations of radionuclides, up to 871 Bq·kg^{-1} for ^{226}Ra, 283 Bq·kg^{-1} for ^{228}Ra, 1255 Bq·kg^{-1} for ^{210}Pb, 413 Bq·kg^{-1} for U and 538 Bq·kg^{-1} for Th.

Introduction

Phosphate rock is used worldwide for manufacturing phosphoric acid and various brands of chemical fertilizers. It is known that the phosphate rock contains radionuclides of the U and Th natural decay series. The mining and processing of this phosphate rock redistributes radionuclides throughout the environment and introduce them into the final products and by-products. It has been reported by MAZZILLI et al.[1] that the phosphate rock used as raw material in the Brazilian phosphate industry presents concentration of radionuclides of the U and Th series ranging from 10 to 1200 Bq·kg^{-1}. It is important to measure natural radioactivity, not only in the phosphate rock, but also in different types of fertilizers and by-products, because the high radioactive content may lead to significant exposure of miners, manufacturers and end users. Furthermore, such measurements provide basic data for the estimation of the amount of radioactivity spread on agricultural land along with fertilizers. Since no regulation in terms of radiation protection principles has been applied to industries containing technologically enhanced naturally occurring radioactive materials (TENORM) so far, members of the public or occupationally exposed may incur undue exposures. The Brazilian phosphate fertilizer is obtained by wet reaction of igneous phosphate rock with concentrated sulphuric acid, giving as final product phosphoric acid, and calcium sulphate dihydrate (i.e., phosphogypsum) as by-product. This by-product is disposed in stacks and no application has been proposed for this waste so far, mainly due to elevated levels of impurities. Phosphoric acid is the starting material for triple superphosphate (TSP), single superphosphate (SSP), ammonium phosphate fertilizers (DAP and MAP), NPK fertilizers and di-calcium phosphate (DCP), a mineral complements for animal feeding. MAP and DAP are obtained by reacting directly phosphoric acid with different amounts of NH_3. TSP, SSP and NPK are obtained by reacting phosphoric acid with phosphate rock and NH_3. During the reaction of phosphate rock with sulphuric acid, the radioactive equilibrium between U, Th and their decay products is disrupted and the radionuclides migrate according to their solubility. Uranium isotopes form highly soluble compounds with phosphate ions, while Ra isotopes, ^{210}Pb and ^{210}Po concentrate in phosphogypsum.[1–3] MAZZILLI et al.[1] found percentages (phosphogypsum to ore rocks) of 90% for ^{226}Ra, 100% for ^{210}Pb and 78% for ^{210}Po. Several papers have been also published concerning the radiological and elemental characteristics of the stockpiled Brazilian phosphogypsum[4–6] and its environmental radiological impact.[7] SANTOS[5] reported that the Brazilian phosphogypsum is enriched in the rare earth elements, Ce, Eu, La, Nd, Sm, Tb, Yb, and Ba and Th. The results obtained so far show that the stacks are quite homogeneous and its composition is mainly dependent upon the phosphate rock used as raw material.[5]

Although several publications have been concerned about the radioactivity of phosphate fertilizers throughout the world,[8–11] few papers were found about the characterization of the Brazilian phosphate

fertilizers. ARRUDA-NETO et al.[12] reported quite high concentrations of uranium in both animals and humans, which could be attributed to the substantial uranium content in di-calcium phosphate used as animal feeding supplement (up to 200 ppm).

In this work, contents of natural radionuclides from thorium and uranium series, ^{226}Ra, ^{210}Pb and ^{228}Ra, were measured in Brazilian igneous phosphate rock, phosphoric acid, phosphogypsum and phosphate fertilizers samples, using high-resolution gamma-spectrometry. Neutron activation analysis was used for the determination of U and Th in the same samples.

Experimental

Activity concentrations of ^{226}Ra, ^{228}Ra, ^{210}Pb and ^{40}K were measured in samples of phosphate rock, phosphoric acid, phosphogypsum and fertilizers by gamma-spectrometry with a hyper-pure germanium detector, GEM-15200, from EG&G Ortec. The detector was calibrated using natural soil "9809 SO", certified by Instituto de Radioproteção e Dosimetria (IRD-CNEN). The radionuclides used in the efficiency calibration were ^{40}K, ^{210}Pb, ^{214}Pb, ^{214}Bi, ^{212}Pb, ^{208}Tl and ^{228}Ac, the uncertainties in the efficiency ranged from 4.5 to 11%. Samples were packed in 100-cm^3 cans and sealed for about four weeks prior to the measurement in order to ensure that equilibrium has been reached between ^{226}Ra and its decay products of short half-life. The ^{226}Ra activities were determined by taking the mean activity of three separate photopeaks of its daughter nuclides: ^{214}Pb at 295 keV and 352 keV, and ^{214}Bi at 609 keV. The ^{228}Ra content of the samples was determined by measuring the intensities of the 911.07 keV and 968.90 keV gamma-ray peaks from ^{228}Ac. The concentration of ^{210}Pb and ^{40}K were carried out by measuring the activity of their energy peak, 46.5 keV and 1460.8 keV, respectively. Self-absorption correction was applied to ^{210}Pb since the attenuation for low energy gamma-rays is highly dependent upon sample composition. The approach used was modified from that suggested by CUTSHALL et al.[13] All the spectra obtained were analyzed by WinnerGamma Program.[14] Minimum detectable activity concentrations for gamma-spectrometry were obtained by measuring deionized water in the same geometry as the samples for 150,000 seconds. The results were 5.0 Bq·kg^{-1} for ^{226}Ra, 19 Bq·kg^{-1} for ^{210}Pb, 3.0 Bq·kg^{-1}for ^{228}Ra and 45 Bq·kg^{-1} for ^{40}K.

All samples except of phosphoric acid were analyzed by neutron activation analysis (NAA), for U and Th. The elements were determinated by irradiation of approximately 150 mg of each sample, during 16 hours at a neutron flux of 10^{12} n·cm^{-2}·s^{-1}, at Instituto de Pesquisas Energéticas e Nucleares (IPEN) research reactor IEA-R1. The induced radioactivity was measured with a Ge-hyperpure detector, Intertechnique, with 2.1 keV resolution for the 1332 keV ^{60}Co photopeak. The concentration of the analyzed elements was determined by comparing activities obtained in the samples with standard materials Buffalo River Sediment (NIST SRM 2704) and Soil-7 (IAEA). The precision and accuracy of the method were verified by measuring these reference materials, the results obtained are presented in Fig. 1. The concentration of ^{238}U and ^{232}Th were obtained by taking into account the results of NAA and the specific activities of these radionuclides.

Results and discussion

Results obtained for radionuclides activity concentration in the phosphate rock, phosphoric acid, phosphogypsum and fertilizers are presented in Table 1. Radionuclide concentration in the phosphate rock varied from <19 to 1414 Bq·kg^{-1} for U decay series and from 56 to 310 Bq·kg^{-1} for Th decay series. The results are better understood if the origin of the phosphate rock (PR) used in industries A, B, C and D is taken into account. Industry A presents the higher concentration of radionuclides from the U and Th series, its PR comes from Catalão (GO); and industry D, which uses PR from Cajati (SP), presents lower activities for all radionuclides studied. Industries B and C present the same pattern of activity concentration for radionuclides of the U and Th series, PR of industry B comes from Tapira (MG) and that of industry C comes from Catalão. In all cases, the radionuclides ^{226}Ra, ^{210}Pb, ^{232}Th and ^{228}Ra migrate predominantly to phosphogypsum.

The fertilizers samples which are derived directly from phosphoric acid, MAP and DAP, presented in their composition activity concentrations around the detection limits of the counting system for ^{226}Ra, ^{228}Ra and ^{210}Pb. As for U and Th, the concentrations found in MAP and DAP are more significant, up to 374 and 250 Bq·kg^{-1}, respectively. Such results indicate that in the processing of the phosphate rock, a significant amount of U and Th is migrating to phosphoric acid. SSP, TSP and NPK, which are obtained by mixing phosphoric acid with different amounts of phosphate rock and NH_3, presented higher concentrations of radionuclides, up to 871 Bq·kg^{-1} for ^{226}Ra, 283 Bq·kg^{-1} for ^{228}Ra, 1255 Bq·kg^{-1} for ^{210}Pb, 413 Bq·kg^{-1} for U and 538 Bq·kg^{-1} for Th. No activity was found in di-calcium phosphate, which is used for feeding animals.

From the radiation protection point of view the high radium content of fertilizers is significant in two ways. First, the accumulation of large quantities of phosphate fertilizers in warehouses increases the radon concentration in the surrounding air. The radium equivalent, Ra(eq) is a common index required to compare the specific activities of samples containing ^{226}Ra, ^{232}Th and ^{40}K, that takes into account the radiation hazards associated with them. The Ra(eq) is defined as:[15]

$$\mathrm{Ra(eq)} = C(^{226}\mathrm{Ra}) + 1.43\, C(^{232}\mathrm{Th}) + 0.077\, C(^{40}\mathrm{K})$$

where $C(^{226}\mathrm{Ra})$, $C(^{232}\mathrm{Th})$ and $C(^{40}\mathrm{K})$ are the activities of ^{226}Ra, ^{232}Th and ^{40}K in Bq·kg^{-1}. This formula is based on the estimation that 1 Bq·kg^{-1} of ^{226}Ra, 0.7 Bq·kg^{-1} of ^{232}Th and 13 Bq·kg^{-1} of ^{40}K produce the same gamma dose rate. The Ra(eq) is related to the external gamma dose rate and the internal dose due to radon and its daughters. The Ra(eq) values of the phosphate rock, phosphogypsum and fertilizer samples are given in Table 1. The highest Ra(eq) activity among the analyzed samples was found in phosphate rock, phosphogypsum, SSP and TSP from industries A, B and C.

The contribution of radioactivity to agricultural lands due to the application of phosphate fertilizers is the second concern for radiation protection point of view. However, this contribution is not easily quantified, since the quantity of radioactivity spread along with fertilizers in the agricultural fields depends upon the quantity of fertilizers used, the type of crop and area of its cultivation. As diet is the main source of intake and human exposure, ^{40}K should be neglected, since its content in the body is under homeostatic control and its radiation dose is not affected by variations in the environmental levels. The data presented here will be used for a future study of the application of Brazilian phosphate fertilizers.
