# New constructions of fundamental polyhedra in complex hyperbolic space 

by<br>MARTIN DERAUX<br>École Polytechnique<br>Palaiseau, France<br>ELISHA FALBEL<br>Université Pierre et Marie Curie and<br>JULIEN PAUPERT<br>Université Pierte et Marie Curie Paris, France Paris, France

## 1. Introduction

Construction of lattices in $\operatorname{PU}(n, 1)$ has been a major challenge in the last decades. In particular, in contrast with the situation in real hyperbolic space, non-arithmetic lattices have been found only in dimensions up to three (see [Mo1], [DM] and [Mo2]).

Mostow's first examples in $\operatorname{PU}(2,1)$ were constructed by giving explicit generators, and verifying that the corresponding groups are discrete by finding a fundamental domain for their action. In complex hyperbolic space, or in any space where sectional curvature is not constant, such an approach is bound to be at least somewhat difficult since there are no totally geodesic real hypersurfaces.

Other direct proofs of discreteness have led to domains bounded by various types of hypersurfaces, each of them adapted to the situation at hand (see the constructions in [FPk], [S1] and [S2]). There is a canonical construction due to Dirichlet, where the boundary of the domain is made up of bisectors, i.e. hypersurfaces equidistant from two given points. One chooses a point $p_{0}$, and considers the set $F$ of points closer to $p_{0}$ than to any other point in its orbit under the group. It is obvious that the group is discrete if and only if $F$ contains a neighborhood of $p_{0}$, but the set $F$ is in general very difficult to study or describe. Such a description amounts to solving a system of infinitely many quadratic inequalities in four variables (the real and imaginary part of the coordinates in the complex 2-ball). In particular, bisector intersections are neither transverse nor connected in general.

Nevertheless, this was the original approach taken by Mostow ([Mo1]) to study a remarkable class of groups, $\Gamma(p, t)$ (where $p=3,4,5$ and $t$ is a real parameter). Each of these is generated by three braiding complex reflections, $R_{1}, R_{2}$ and $R_{3}$, of order $p$; it is contained with finite index in the group $\widetilde{\Gamma}(p, t)$ generated by $R_{1}$ and the elliptic element $J$ which conjugates $R_{i}$ into $R_{i+1}$ (see $\S 2.2$ for further details).

There are very few values of the parameter $t$ for which $\Gamma(p, t)$ is discrete; for these values Mostow shows discreteness using Dirichlet domains, discovered by computer experimentation. They turn out to be the intersection of the three Dirichlet domains for the finite groups $\left\langle R_{i}, R_{j}\right\rangle$ generated by only two of the generators $R_{i}$. The advantage of working with a finite group is obvious, namely one needs to solve a finite set of inequalities. However, the fact that the inequalities are quadratic is still an important difficulty, and in fact using current computer technology, it is fairly easy to convince oneself that Mostow's domains for these finite groups (see [Mo1, p. 220]) are incorrect. The missing faces, most of which do not contain the common fixed point of the finite group, are described in [De] (it turns out that many of the extra faces disappear when taking the intersection of the three domains for different finite groups).

Part of Mostow's mistake comes from the assumption that the Dirichlet domain for each of the finite groups $\Gamma_{i j}$ is a cone with vertex given by its fixed point $p_{i j}$, which is far from being the case. Conical fundamental domains for finite subgroups of $\mathrm{U}(2)$ have been constructed in $[\mathrm{FP} p]$, but these are not Dirichlet domains. Our constructions also naturally yield cone fundamental domains for $\Gamma_{i j}$, having eight cone faces over the eight faces in Figure 5.

The fact that these mistakes are particularly difficult to notice in Mostow's paper, and that they seem quite difficult to fix, prompted us to write a detailed argument, using more geometric techniques. Another motivation for our work is to obtain simpler domains than the ones obtained by the Dirichlet construction, by allowing totally real 2-faces, which are necessarily excluded from Dirichlet domains (see Proposition 2.5).

The presence of totally real faces is related to the fact that Mostow's groups are index-2 subgroups of groups generated by three involutions fixing Lagrangian totally geodesic submanifolds (see $\S 2.2$ ). This observation makes them part of a large family containing infinite covolume groups (see [FK]) and all finite subgroups of $\mathrm{U}(2)$ (see [FPp]), among which one would expect to find other lattices as well.

We construct new fundamental polyhedra $\Pi=\Pi_{p, t}$ in $\mathbf{H}_{\mathbf{C}}^{2}$ for the action of $\widetilde{\Gamma}(p, t)$. Our fundamental domains have the same vertices as Mostow's domains, but their higherdimensional skeletons are simpler and more natural. All our 1 -faces are geodesic segments, and many (but not all) of our 2-faces are either real or complex totally geodesic submanifolds. The 3 -faces are either on bisectors, or on cones over totally geodesic submanifolds. Note that this construction is related to a fundamental domain for the Eisenstein-Picard group constructed in [FPk].

The main advantage, beyond the simplification of the combinatorics of the domains (see $\S 7$ ), is that most verifications can be phrased in concrete geometric terms and the arguments are often completely synthetic, i.e. very few calculations are needed.

In order to prove discreteness, we show that $\Pi$ and its images under the group tile complex hyperbolic space, by using the appropriate version of the Poincaré polyhedron theorem. In particular, to show that $\Pi$ and $\gamma \Pi$ have disjoint interior for every non-trivial group element $\gamma$, we are reduced to showing this for a finite set of group elements, provided that we can check some detailed compatibility conditions along the codimension- 2 faces of $\Pi$.

It turns out that only the cycles of complex geodesic faces impose conditions on the parameters, known as the Picard integrality conditions. The corresponding cycle transformations are simply complex reflections, whose angle of rotation is required to be an integer fraction of $\pi$, see Proposition 5.4. The heart of the proof consists of a careful justification (incomplete in $[\mathrm{P}]$, and not quite satisfactory in $[\mathrm{Mol}]$ ) that these are the only conditions. The main result is the following theorem (see $\S 2.2$ for the definition of the group, and $\S 3$ for the description of $\Pi$ ):

Theorem 1.1. The group $\widetilde{\Gamma}(p, t) \subset \mathrm{PU}(2,1)$, for $p=3,4,5$ and $|t|<1 / 2-1 / p$, is discrete if

$$
k=\left(\frac{1}{4}-\frac{1}{2 p}+\frac{t}{2}\right)^{-1} \quad \text { and } \quad l=\left(\frac{1}{4}-\frac{1}{2 p}-\frac{t}{2}\right)^{-1}
$$

are in $\mathbf{Z}$. In that case, $\Pi$ is a fundamental domain with side pairings given by $J, R_{1}$, $R_{2}, R_{2} R_{1}$ and $R_{1} R_{2}$, and the cycle relations give the following presentation of the group:

$$
\begin{aligned}
\widetilde{\Gamma}(p, t)=\left\langle J, R_{1}, R_{2}\right| J^{3} & =R_{1}^{p}=R_{2}^{p}=J^{-1} R_{2}^{-1} J R_{1}^{-1}=R_{1} R_{2} R_{1} R_{2}^{-1} R_{1}^{-1} R_{2}^{-1} \\
& \left.=\left(R_{2} R_{1} J\right)^{k}=\left(\left(R_{1} R_{2}\right)^{-1} J\right)^{l}=I\right\rangle
\end{aligned}
$$

The condition $|t|<1 / 2-1 / p$ shall be referred to as small phase shift, following Mostow. In fact, the conclusion of the theorem holds for large phase shift as well, but the combinatorics of the fundamental domains are then quite different. For the sake of brevity, we shall only sketch the corresponding changes in our fundamental domain, see $\S 6$.

There are finitely many values of $t$ for which the integrality conditions hold, and among the corresponding groups, seven are non-arithmetic. The list is given in Remark 5.2.

Our cone polyhedra turn out to be very convenient when proving that $\Pi$ and $\gamma \Pi$ have disjoint interiors. In most cases we find a bisector $B_{\gamma}$ that separates them (but these bisectors are certainly not all equidistant from a given point $p_{0}$, unlike in the Dirichlet construction). In order to verify that $\Pi$ or $\gamma \Pi$ lies entirely on one side of $B_{\gamma}$, we carefully argue that it is enough to verify this on the level of its 1 -skeleton. Note that verifications on the 0 -skeleton would quite clearly not be enough to prove that our polyhedron is on
one side of a bisector, since the two complementary components of a bisector are far from being convex.

Verifications on the 1 -skeleton become relatively easy, as they amount to analyzing the intersection of a bisector with geodesic segments (see Lemma 4.2). Note that the strength of the reduction is that we only need to check the position of a finite number of geodesic segments with respect to finitely many bisectors, which in turn amounts to checking finitely many inequalities. The verifications can be done very efficiently with the aid of a computer; however, our proofs are geometric and most of the time synthetic. For the case $p=3$, the small number of calculations could in principle even be done by hand.

Going from the 1 -skeleton to the 2 -skeleton involves geometric arguments of general interest about the projection of totally geodesic submanifolds onto a given complex geodesic, which is usually the complex spine of the relevant bisector (see Lemma 2.1). The main point is to analyze when a geodesic projects onto a geodesic, as in Lemma 4.1. Finally, passing to the 3 -skeleton is quite natural using the structure of our 3 -faces, either the slice decomposition of bisectors, or the cone structure of the other faces.

The paper is organized as follows. In $\S 2$ we review a number of geometric facts about complex hyperbolic space and bisectors, and give a description of the relevant groups. We construct our polyhedra $\Pi_{p, t}$ in $\S 3$, and $\S 4$ is devoted to a detailed verification that they have no self-intersection and are homeomorphic to a closed ball in complex hyperbolic space. In $\S 5$ we prove the main theorem by verifying the conditions of the Poincaré polyhedron theorem, following the strategy outlined above. $\S 6$ states the modifications needed in order to treat all the cases from [Mo1], allowing $|t| \geqslant 1 / 2-1 / p$. §7 contains a comparison with Mostow's original fundamental domains, including some difficulties encountered with the arguments in [Mo1]. For the reader's convenience, the last section lists the faces of our polyhedra and their lower-dimensional skeletons.

## 2. Complex hyperbolic space

We use [Go] as a general reference for this section. Let $\langle\cdot, \cdot\rangle$ be a Hermitian form of signature $(2,1)$ on $\mathbf{C}^{3}$. The set of complex lines in $\mathbf{C}^{3}$ on which the Hermitian form is negative definite is a model of complex hyperbolic space. One can write the distance between two points as

$$
\begin{equation*}
\cosh \left(\frac{1}{2} d([x],[y])\right)=\frac{|\langle x, y\rangle|}{\sqrt{\langle x, x\rangle\langle y, y\rangle}} \tag{2.1}
\end{equation*}
$$

The factor $\frac{1}{2}$ is chosen so as to get a metric with sectional curvature between -1 and $-\frac{1}{4}$.

More explicitly, we consider a Hermitian form $\langle z, w\rangle=z^{T} H \bar{w}$, where $H$ is a Hermitian matrix of signature $(2,1)$, and the following subsets of $\mathbf{C}^{3}$ :

$$
\begin{aligned}
& V_{0}=\left\{z \in \mathbf{C}^{3} \backslash\{0\}:\langle z, z\rangle=0\right\} \\
& V_{-}=\left\{z \in \mathbf{C}^{3} \backslash\{0\}:\langle z, z\rangle<0\right\}
\end{aligned}
$$

Let $\pi: \mathbf{C}^{3} \backslash\{0\} \rightarrow \mathbf{C} P^{2}$ be the canonical projection onto the complex projective space. Then $\mathbf{H}_{\mathbf{C}}^{2}=\pi\left(V_{-}\right)$is complex hyperbolic space. In the case where

$$
H=\left(\begin{array}{ccc}
1 & 0 & 0 \\
0 & 1 & 0 \\
0 & 0 & -1
\end{array}\right)
$$

we obtain in non-homogeneous coordinates the complex ball

$$
\mathbf{H}_{\mathbf{C}}^{2}=\left\{\left(z_{1}, z_{2}\right) \in \mathbf{C}^{2}:\left|z_{1}\right|^{2}+\left|z_{2}\right|^{2}<1\right\}
$$

The group of holomorphic isometries of $\mathbf{H}_{\mathbf{C}}^{2}$ is then $\operatorname{PU}(2,1)$ (the projectivization of the unitary group of the Hermitian form), and the full group of isometries of complex hyperbolic space, which we denote $\widehat{\mathrm{PU}}(2,1)$, is obtained by adjoining just one antiholomorphic involution.

Antiholomorphic involutions are also called real reflections ( $\mathbf{R}$-reflections) or Lagrangian reflections. In the ball coordinates as above an example of such a transformation is $\left(z_{1}, z_{2}\right) \mapsto\left(\bar{z}_{1}, \bar{z}_{2}\right)$. Their fixed-point set is a totally real totally geodesic submanifold which is a Lagrangian submanifold for the symplectic structure on $\mathbf{H}_{\mathbf{C}}^{2}$ defined by the imaginary part of the Hermitian metric.

Given a vector $v$ with $\langle v, v\rangle=1$, we consider the isometry of $\mathbf{C}^{3}$ given by

$$
\begin{equation*}
R_{v, \zeta}(x)=x+(\zeta-1)\langle x, v\rangle v \tag{2.2}
\end{equation*}
$$

where $\zeta$ is a complex number of absolute value one. The corresponding isometry of complex hyperbolic space is called a complex reflection; it fixes the totally geodesic subspace corresponding to the linear hyperplane $v^{\perp}$, and rotates in the normal direction by an angle $\theta$, where $\zeta=e^{i \theta}$.

Totally geodesic subspaces of complex hyperbolic space have the following natural description:

Proposition 2.1. The complete totally geodesic subspaces of $\mathbf{H}_{\mathbf{C}}^{2}$ are either geodesics, fixed subsets of complex reflections (complex lines, also called C-planes) or fixed subsets of Lagrangian reflections (Lagrangian planes, also called R-planes).

The following lemma describes the projection of geometrical objects into a complex line:

Lemma 2.1. Let $\pi_{C}$ be the orthogonal projection of complex hyperbolic space onto a complex line $C$.
(1) The image under $\pi_{C}$ of a polygon in a complex line is either a point or another polygon such that the angles at the vertices are preserved.
(2) The image under $\pi_{C}$ of a polygon in a Lagrangian plane is either contained in a geodesic, or a polygon or the union of two polygons with a common vertex.

Proof. The first item follows from the fact that the projection is holomorphic. For the second item, suppose that the image of the projection is not contained in a geodesic. The projection is either a diffeomorphism, and in that case the image is another polygon, or the projection is singular at a point. That means that the differential of the projection has a non-trivial kernel. Every vector in the kernel generates a geodesic which projects to a point; in fact, such a geodesic is contained in the Lagrangian and in the complex line tangent to the vector. We then claim that there is at most one of these geodesics: if there are two of them then clearly they are ultraparallel, and the common orthogonal geodesic is contained in $C$, which therefore intersects the Lagrangian in a geodesic. This would mean that the Lagrangian projects to that geodesic, which we have ruled out. Then the singular geodesic separates the Lagrangian in two, and in each half the projection is a diffeomorphism.

Remark 2.1. One can easily show, by using coordinates with center at the intersection, that if the Lagrangian intersects the complex line, its projection is either a geodesic (and in that case that geodesic is precisely the intersection) or a geodesic cone in the complex line at the intersection point.

### 2.1. Bisectors

Recall that the bisector equidistant from two points $x_{1}, x_{2} \in \mathbf{H}_{\mathbf{C}}^{2}$ is given by

$$
\begin{equation*}
B\left(x_{1}, x_{2}\right)=\left\{x \in \mathbf{H}_{\mathbf{C}}^{2}: d\left(x, x_{1}\right)=d\left(x, x_{2}\right)\right\} . \tag{2.3}
\end{equation*}
$$

In what follows we will also denote by $x_{1}$ and $x_{2}$ lifts to $\mathbf{C}^{3}$, by a slight abuse of notation. In view of equation (2.1), if we normalize two vectors $x_{1}$ and $x_{2}$ to have equal norms, the bisector is simply the projectivization of the set of vectors $x$ that satisfy

$$
\begin{equation*}
\left|\left\langle x, x_{1}\right\rangle\right|=\left|\left\langle x, x_{2}\right\rangle\right| . \tag{2.4}
\end{equation*}
$$

An example in the ball model is the "standard" bisector

$$
B_{0}=\left\{(z, t) \in \mathbf{H}_{\mathbf{C}}^{2}: z \in \mathbf{C} \text { and } t \in \mathbf{R}\right\}
$$

which is equidistant from $x_{1}=\left(0, \frac{1}{2} i\right)$ and $x_{2}=\left(0,-\frac{1}{2} i\right)$, for instance.
A bisector is a smooth real hypersurface diffeomorphic to a ball, but it is not totally geodesic. The complex spine $\Sigma$ of $B\left(x_{1}, x_{2}\right)$ is by definition the complex geodesic that contains $x_{1}$ and $x_{2}$. The real spine $\sigma$ is the real geodesic in $\Sigma$ that is equidistant from $x_{1}$ and $x_{2}$.

Proposition 2.2. (1) (Mostow) $B$ is foliated by complex geodesics of the form $\pi_{\Sigma}^{-1}(\{p\})$ for $p \in \sigma$. These are called the complex slices of $B$.
(2) (Goldman) $B$ is the union of all the Lagrangian planes that contain its real spine $\sigma$. These are called the meridians of $B$.

The complex slice decomposition is quite easy to understand from equation (2.4), which is equivalent to saying that $x \in\left(x_{1}-\alpha x_{2}\right)^{\perp}$ for some complex number $\alpha$ with $|\alpha|=1$. The hyperplanes corresponding to the orthogonal complements of $x_{1}-\alpha x_{2}$ (whenever such a vector has positive norm) are precisely the complex slices of $B$.

Remark 2.2. (1) The complex slice decomposition makes it clear that a bisector is uniquely determined by its real spine.
(2) The Lagrangian reflection in any meridian of $B$ fixes its real spine, hence preserves its complex spine. It must then interchange the two points $x_{1}$ and $x_{2}$. In fact, if $x$ is on the complex spine (but not on the real spine), and $\mu$ is the Lagrangian reflection in any meridian of $B$, then $B$ is equidistant from $x$ and $\mu(x)$.

The following result gives a refinement of the statement that bisectors are not totally geodesic:

Proposition 2.3. (See [Go, Theorem 5.5.1].) Let $B$ be a bisector and $x, y \in B$. Then the real geodesic between $x$ and $y$ is contained in $B$ if and only if $x$ and $y$ are in either a complex slice or a meridian of $B$.
2.1.1. Intersection with complex lines. In view of the slice decomposition for bisectors, it is clear that the following result is important in order to understand bisector intersections.

Proposition 2.4. ([Mo1]) Let $C$ be a complex geodesic that is not a complex slice of a bisector $B$. Then $B \cap C$ is either empty or a hypercycle in the complex geodesic.

Recall that a hypercycle in $C$ is a curve at constant distance from a real geodesic. In particular, unless the two bisectors share a common slice, the proposition implies that their intersection is foliated by arcs of circles. Since the complex slices map into the real spine under projection onto the complex spine, one sees that each connected component of the intersection $B_{1} \cap B_{2}$ is a disk (indeed it fibers over an interval, with
intervals as fibers). It can be proven that there are at most two connected components. If the bisectors are coequidistant, more can be said:

Proposition 2.5. Let $B_{1}$ and $B_{2}$ be two coequidistant bisectors, i.e. such that their complex spines intersect outside their real spines. Then $B_{1} \cap B_{2}$ is diffeomorphic to a disk. If the disk is totally geodesic, then it is in a common complex slice.

A proof of this can be found in [Go]. When the intersection is not geodesic, we call it a Giraud disk (such surfaces were analyzed in [Gi]). Observe that, in particular, the intersection of two coequidistant bisectors cannot contain a meridian. The latter fact can be seen directly: if two equidistant bisectors $B_{1}=B\left(x_{0}, x_{1}\right)$ and $B_{2}=B\left(x_{0}, x_{2}\right)$ share a meridian with $\mathbf{R}$-reflection $\mu$, then as we have just seen, $\mu$ exchanges on one hand $x_{0}$ and $x_{1}$, and on the other $x_{0}$ and $x_{2}$, so that the bisectors are equal.

The following lemma characterizes complex lines intersecting a bisector in a geodesic:
Lemma 2.2. Let $C$ be a complex geodesic, and let $B$ be a bisector with real spine $\sigma$. Suppose that $C$ is not a complex slice of $B$, and $C \cap B$ is non-empty. Then $C \cap B$ is a geodesic if and only if the extensions to projective space of $C$ and $\sigma$ intersect.

Proof. Let $\Sigma$ be the complex spine of $B$, which is the complex geodesic containing the real geodesic $\sigma$.
(1) Suppose that $\Sigma$ and $C$ intersect in $\mathbf{H}_{\mathbf{C}}^{2}$. If the real spine goes through their intersection, then taking the origin of our ball coordinates to be that intersection point makes the equation of $B$ linear, and hence the intersection is a line through the origin, which is a geodesic.

Conversely, if $C$ intersects $\Sigma$ outside of $\sigma$, we still take coordinates centered on $\sigma$, so that the intersection is again given by a straight line. If this line were a geodesic, it would have to be contained in a meridian of $B$, but then it would intersect $\sigma$ in projective space (but two complex projective lines intersect in exactly one point).
(2) The case where $\Sigma$ and $C$ intersect on $\partial \mathbf{H}_{\mathbf{C}}^{2}$ is similar to the previous one.
(3) Suppose that $\Sigma$ and $C$ intersect outside of $\mathbf{H}_{\mathbf{C}}^{2} \cup \partial \mathbf{H}_{\mathbf{C}}^{2}$. Then these two complex geodesics have a common perpendicular complex geodesic $D$. We may assume that $\Sigma$ is given by $z_{2}=0$, that $C$ is $z_{2}=c, c \neq 0$, and that $D$ is $z_{1}=0$. The real spine is either a straight line or a circle, depending on whether or not it goes through the origin.

Note that the intersection $B \cap C$ is the intersection with $C$ of the inverse image of $\sigma$ under the linear projection $\left(z_{1}, z_{2}\right) \mapsto z_{1}$. Remembering that real geodesics in complex geodesics are orthogonal to the boundary, we see that $B \cap C$ is a geodesic if and only if $\sigma$ is a straight line. This in turn is equivalent to saying that $C$ and $\sigma$ intersect in projective space (since any intersection would have to take place at infinity in $\mathbf{C}^{2}$ ).
2.1.2. Intersection with Lagrangian planes. The intersections of Lagrangians with bisectors have the following general property (which expresses the fact that a suitable normalization of the coordinates gives a quadratic equation for such an intersection):

Proposition 2.6. Let $L$ be a Lagrangian which is not a meridian of the bisector $B$. Then $B \cap L$ is a conic in $L$.

Note that singular conics can occur (two intersection lines). We describe that situation more explicitly. Using the ball coordinates, the Hermitian metric is written at $p=(b, 0)$ with $b$ real as (see [Go])

$$
\left[\begin{array}{cc}
\frac{1}{\left(1-b^{2}\right)^{2}} & 0 \\
0 & \frac{1}{1-b^{2}}
\end{array}\right]
$$

LEmma 2.3. Consider coordinates of the standard bisector $\{(z, t): z \in \mathbf{C}$ and $t \in \mathbf{R}\}$ at a point $p=(b, 0)$ with $b \in \mathbf{R}$, and let two tangent vectors $v_{1}=\left(z_{1}, t_{1}\right)$ and $v_{2}=\left(z_{2}, t_{2}\right)$ be in $T_{p} B$. Then
(1) $v_{i}$ is tangent to a meridian if and only if $z_{i} \in \mathbf{R}$;
(2) $v_{1}$ and $v_{2}$ are tangent to a common Lagrangian if and only if $z_{1} \bar{z}_{2} \in \mathbf{R}$.

Proof. The first item is obvious. For the second, we need $i v_{1} \perp v_{2}$. Computing, using the form of the metric defined above at the point $(b, 0)$,

$$
g\left(i v_{1}, v_{2}\right)=\operatorname{Re}\left\langle i v_{1}, v_{2}\right\rangle=\operatorname{Re}\left\langle\left(i z_{1}, i t_{1}\right),\left(z_{2}, t_{2}\right)\right\rangle=\operatorname{Re}\left(i z_{1} \bar{z}_{2} \frac{1}{\left(1-b^{2}\right)^{2}}+i t_{1} t_{2} \frac{1}{1-b^{2}}\right),
$$

we see that the Hermitian product is purely imaginary if and only if $z_{1} \bar{z}_{2} \in \mathbf{R}$.
Proposition 2.7. Suppose that the tangent space to a Lagrangian $L$ is contained in the tangent space to a bisector $B$, i.e. $T_{p} L \subset T_{p} B$. Then
(1) $L \subset B$ is a meridian, or
(2) $L \cap B$ is the union of two geodesics passing through $p$, one being in a meridian and orthogonal to a slice which contains the other one.

Proof. It follows from the lemma and proposition above. If $L$ is not contained in $B$, we first observe that the tangent space $T_{p} L$ in the coordinates of the lemma contains the vector $(0, t)$ which is tangent to the meridian passing through $p=(b, 0)$. The geodesic along that vector is contained in both the meridian and $L$. Analogously, the vector $(z, 0)$ is tangent to the slice, and the geodesic defined by it belongs to the slice and to $L$. The above proposition implies that there can be no more intersection.

Lemma 2.4. Let $g$ be a geodesic in a meridian of a bisector $B$, ultraparallel to its real spine. Then there exists a unique slice of $B$ which is orthogonal to $g$; moreover, it is orthogonal to the complex geodesic containing $g$.

Proof. Observe that in the meridian there exists a unique geodesic orthogonal to the real spine which is also orthogonal to $g$. The lemma follows from the fact that orthogonal geodesics in a Lagrangian plane are contained in orthogonal complex geodesics.

Proposition 2.8. Let $B$ be a bisector with real spine $\sigma$, and $L$ a Lagrangian not contained in $B$. Suppose that $L \cap B$ contains a geodesic $g$ which is in a meridian of $B$ but not in a slice.
(1) If $g$ is ultraparallel to $\sigma$, then $L \cap B$ contains another geodesic which is in a complex slice of $B$.
(2) If $g$ intersects $\sigma$ in $\mathbf{H}_{\mathbf{C}}^{2} \cup \partial \mathbf{H}_{\mathbf{C}}^{2}$, then $L \cap B=g$.

Proof. In the first case, by the above lemma, there exists a unique slice of $B$ orthogonal to the complex geodesic containing $g$. This implies that $L$ also intersects that slice in a geodesic. In the second case, by Proposition 2.7 , we can exclude a singular intersection because $g$ is not orthogonal to any slice. To show that there is only one component in the intersection, in the case where $g$ intersects $\sigma$ in $\mathbf{H}_{\mathbf{C}}^{2}$ we can use ball coordinates such that both the bisector and the Lagrangian are linear. In the parallel case we observe that there is a point $p$ at infinity belonging to the boundary of both $\sigma$ and $L$. If $L \cap B$ were to contain a point outside of $g$, then the geodesic joining that point to $p$ would belong to $B$ and $L$; there would then exist a complex slice of $B$ having two points in $L$, and therefore $L \cap B$ would contain another geodesic intersecting $g$, which is a contradiction.

We also need the following corollary to Proposition 2.7:
Proposition 2.9. Fix four points in $\mathbf{H}_{\mathbf{C}}^{2}$. If three triples of these points are contained in Lagrangian planes, then the four are contained in a common Lagrangian plane.

Proof. First observe that the four triples are in fact contained in Lagrangians. Indeed, it can easily be seen (as in [Go, p. 219]) that the Cartan angular invariants of various triples among four points $x_{1}, x_{2}, x_{3}, x_{4} \in \mathbf{H}_{\mathrm{C}}^{2}$ satisfy the relation

$$
\mathbf{A}\left(x_{1}, x_{2}, x_{3}\right)+\mathbf{A}\left(x_{1}, x_{3}, x_{4}\right)=\mathbf{A}\left(x_{1}, x_{2}, x_{4}\right)+\mathbf{A}\left(x_{2}, x_{3}, x_{4}\right)
$$

Consider then the tetrahedron formed by the four points. Taking opposite edges as real spines of two bisectors we obtain that the intersection contains at least the other four edges. Using Proposition 2.7 we conclude that if the Lagrangians do not coincide, then there exists one of the faces with all its edges meeting at right angles, which is a contradiction.

### 2.2. The group $\Gamma(p, t)$

The most natural description of a complex reflection group is done by means of a Coxeter diagram, where the nodes correspond to generating reflections, and the edges translate into braiding relations between the generators. In the case of complex reflection groups, there is an extra parameter attached to each loop in the diagram, the so-called phase shift. More details on the general case can be found in [Mo1] or [C], but for the sake of brevity we only discuss the following special case.

Consider the groups with Coxeter diagrams of the form

for $p=3,4$ or 5 . Each such group is generated by three complex reflections $R_{1}, R_{2}$ and $R_{3}$ of order $p$, satisfying the braid relation

$$
\begin{equation*}
R_{i} R_{j} R_{i}=R_{j} R_{i} R_{j} \tag{2.5}
\end{equation*}
$$

We write the mirror of $R_{j}$ as $e_{j}^{\perp}$ (take $v=e_{j}$ and $\zeta=e^{2 \pi i / p}$ in equation (2.2)). We may assume after rescaling the vectors $e_{i}$ that $\left\langle e_{i}, e_{i}\right\rangle=1$ and $\left\langle e_{1}, e_{2}\right\rangle=\left\langle e_{2}, e_{3}\right\rangle=\left\langle e_{3}, e_{1}\right\rangle$. The braid relation imposes a condition on the angle between the mirrors of the generating reflections, which translates as

$$
\begin{equation*}
\left|\left\langle e_{i}, e_{j}\right\rangle\right|=\frac{1}{2 \sin (\pi / p)} \tag{2.6}
\end{equation*}
$$

In what follows we shall write $\alpha=1 / 2 \sin (\pi / p)$.
The phase shift $\varphi$ that appears in the above diagram corresponds to specifying the common value of the argument of the inner products $\left\langle e_{i}, e_{i+1}\right\rangle$; specifically we take

$$
\begin{equation*}
\left\langle e_{i}, e_{i+1}\right\rangle=-\alpha \varphi \tag{2.7}
\end{equation*}
$$

where $|\varphi|=1$. We follow Mostow's notation and write $\varphi^{3}=e^{\pi i t}$, and denote the corresponding group by $\Gamma(p, t)$.

In the basis $\left\{e_{1}, e_{2}, e_{3}\right\}$, the matrix for the Hermitian form is given by

$$
H=\left(\begin{array}{ccc}
1 & -\alpha \varphi & -\alpha \bar{\varphi}  \tag{2.8}\\
-\alpha \bar{\varphi} & 1 & -\alpha \varphi \\
-\alpha \varphi & -\alpha \bar{\varphi} & 1
\end{array}\right)
$$

The existence of a triple of positive vectors $e_{i}$ satisfying (2.7) is equivalent to the requirement that $H$ be of signature $(2,1)$, which in turn is equivalent to

$$
\begin{equation*}
|t|<3\left(\frac{1}{2}-\frac{1}{p}\right) . \tag{2.9}
\end{equation*}
$$

In what follows, we shall always use coordinates in this basis and the Hermitian form (2.8).
The linear transformation

$$
J=\left(\begin{array}{lll}
0 & 0 & 1  \tag{2.10}\\
1 & 0 & 0 \\
0 & 1 & 0
\end{array}\right)
$$

is clearly an isometry, which is a regular elliptic element fixing $p_{0}=[1,1,1]^{T}$. Moreover, there are three natural antiholomorphic isometric involutions $\sigma_{i j}$, given by complex conjugation of the coordinates followed by exchanging two of the standard basis vectors. For instance,

$$
\begin{equation*}
\sigma_{12}:\left[x_{1}, x_{2}, x_{3}\right]^{T} \longmapsto\left[\bar{x}_{2}, \bar{x}_{1}, \bar{x}_{3}\right]^{T} . \tag{2.11}
\end{equation*}
$$

We will denote by $L_{i j}$ the fixed-point set of $\sigma_{i j}$, which is a Lagrangian plane by Proposition 2.1.

One checks that $R_{1}$ is given in the basis $\left\{e_{1}, e_{2}, e_{3}\right\}$ by the matrix

$$
R_{1}=\left(\begin{array}{ccc}
\eta^{2} & -\eta i \bar{\varphi} & -\eta i \varphi  \tag{2.12}\\
0 & 1 & 0 \\
0 & 0 & 1
\end{array}\right)
$$

where $\eta=e^{\pi i / p}$. Note that $J$ conjugates $R_{i}$ into $R_{i+1}$, where indices are taken modulo 3 , so that the matrices for $R_{2}$ and $R_{3}$ are easily deduced from the matrix above.

The condition that $p<6$ is equivalent to requiring that the mirrors of two reflections $R_{i}$ and $R_{j}$ intersect in the ball, in a point denoted by $p_{i j}$. The common fixed point of $R_{1}$ and $R_{2}$ can be written as

$$
p_{12}=\left[\begin{array}{c}
\alpha \varphi+\alpha^{2} \bar{\varphi}^{2}  \tag{2.13}\\
\alpha \bar{\varphi}+\alpha^{2} \varphi^{2} \\
1-\alpha^{2}
\end{array}\right],
$$

and the other $p_{i j}$ are deduced by applying the isometry $J$.
We study the group $\widetilde{\Gamma}(p, t)$ generated by $J$ and $R_{1}$. It is instructive to decompose these generators as a product of antiholomorphic involutions

$$
\begin{equation*}
J=\sigma_{12} \sigma_{23} \quad \text { and } \quad R_{1}=\sigma_{23} \tau \tag{2.14}
\end{equation*}
$$

where the $\sigma_{i j}$ are as in (2.11), and $\tau$ is by definition $\sigma_{23} R_{1}$. We shall write $\widehat{\Gamma}(p, t)$ for the group generated by $\sigma_{12}, \sigma_{23}$ and $\tau$. Note that the subgroup $\widetilde{\Gamma}(p, t) \subset \widehat{\Gamma}(p, t)$ is the index-2 subgroup of holomorphic elements.

We write $L_{i j}$ and $L_{\tau}$ for the fixed-point set of $\sigma_{i j}$ and $\tau$, respectively.

Proposition 2.10. The Lagrangians fixed by the generating antiholomorphic involutions intersect as follows:
(1) $L_{12} \cap L_{23}$ is the isolated fixed point $p_{0}$ of $J$;
(2) $L_{12} \cap L_{\tau}$ is the isolated fixed point $p_{1}$ of $J R_{1}$;
(3) $L_{23} \cap L_{\tau}$ is a geodesic $g_{1}$, contained in the mirror of $R_{1}$.

Proof. The first part follows from the definition of $J$. In order to get the second part, note that $J R_{1}$ has three distinct eigenvalues, its characteristic polynomial being given by $-(\lambda+\eta i \bar{\varphi})\left(\lambda^{2}+\eta i \varphi\right)$. The eigenvector with negative norm is the one corresponding to $\sqrt{-\eta i \varphi}=e^{\pi i(1 / 4-1 / 2 p-t / 6)}$ for $t>-(1 / 2-1 / p)$, and corresponding to $-\eta i \bar{\varphi}$ otherwise.

We now prove part (3). Since $\sigma_{23} e_{1}=e_{1}, \sigma_{23}$ preserves the mirror of $R_{1}$, and this implies that $L_{23}$ intersects the mirror in a geodesic (cf. [FPp]).

We wish to use these three Lagrangians and their intersections, of dimension 0,1 and 2, as building blocks for a fundamental polyhedron. The first observation is that these objects define a 3-dimensional object, namely the bisector $B_{1}$ having $g_{1}$ as its real spine. This bisector then has $\operatorname{Fix}\left(R_{1}\right)$ as complex spine, $L_{23}$ and $L_{\tau}$ as meridians, and contains the points $p_{0}$ and $p_{1}$, so it is indeed well adapted to our configuration.

In the following definition, we collect the groups introduced above:
Definition 2.1. For any integer $p$ and $|t|<3(1 / 2-1 / p)$ define
(1) $\widehat{\Gamma}(p, t)=\left\langle\sigma_{12}, \sigma_{23}, \tau\right\rangle$;
(2) $\widetilde{\Gamma}(p, t)=\left\langle R_{1}, J\right\rangle \subset \widehat{\Gamma}(p, t)$ of index 2 ;
(3) $\Gamma(p, t)=\left\langle R_{1}, R_{2}, R_{3}\right\rangle \subset \widetilde{\Gamma}(p, t)$,
where $R_{1}=\sigma_{23} \tau, J=\sigma_{12} \sigma_{23}, R_{2}=J R_{1} J^{-1}$ and $R_{3}=J^{2} R_{1} J^{-2}$.
Note that the index of $\Gamma(p, t)$ in $\widetilde{\Gamma}(p, t)$ could be 1 or 3 . Although we are not going to use the next proposition, we observe that using the main theorem we can decide, in certain cases, what the index is.

Proposition 2.11. (Cf. [Mo1, Lemma 16.1].) Let $p$ and $t$ in Theorem 1.1 be such that

$$
k=\left(\frac{1}{4}-\frac{1}{2 p}+\frac{t}{2}\right)^{-1} \quad \text { and } \quad l=\left(\frac{1}{4}-\frac{1}{2 p}-\frac{t}{2}\right)^{-1}
$$

are in $\mathbf{Z}$. Then $\Gamma(p, t) \subset \widetilde{\Gamma}(p, t)$ is an index-3 subgroup if $k$ and $l$ are both divisible by 3, and otherwise the groups are equal.

Proof. Clearly, the quotient $\widetilde{\Gamma}(p, t) / \Gamma(p, t)$ is represented by the class of $J$. From the main theorem we obtain the presentation with relation $\left(R_{2} R_{1} J\right)^{k}=I$, so
(1) $\left(R_{2} R_{1} J\right)^{k}=\left(R_{2} R_{1} R_{3}\right)^{2 m}$ if $k=3 m ;$
(2) $\left(R_{2} R_{1} J\right)^{k}=\left(R_{2} R_{1} R_{3}\right)^{2 m} R_{2} R_{1} J$ if $k=3 m+1$;
(3) $\left(R_{2} R_{1} J\right)^{k}=\left(R_{2} R_{1} R_{3}\right)^{2 m+1} R_{2} J^{2}$ if $k=3 m+2$.

Therefore $J$ is generated by $R_{1}, R_{2}$ and $R_{3}$ if 3 does not divide $k$. Using the relation $\left(\left(R_{1} R_{2}\right)^{-1} J\right)^{l}=I$ we obtain an analogous result for $l$.

### 2.3. A canonical hexagon

Let $B_{1}$ be the bisector with real spine $g_{1}$, the geodesic where $L_{23}$ and $L_{\tau}$ intersect. Note that its complex spine is by construction the mirror of the complex reflection $R_{1}$, and the Lagrangians $L_{23}$ and $L_{\tau}$ are two of its meridians. In particular, it also contains the points $\left\{p_{0}\right\}=L_{12} \cap L_{23}$ and $\left\{p_{1}\right\}=L_{12} \cap L_{\tau}$ (see Proposition 2.10).

The bisector $B_{1}$ can also be described as being equidistant from two understood points. Indeed, the isometry $\sigma_{23}$, which is the involution in a meridian of $B_{1}$, sends $p_{12}$ to $p_{31}$. This implies that $B_{1}$ is equidistant from $p_{12}$ and $p_{31}$ (see Remark 2.2).

Recall that we would like to construct a 3 -face of a fundamental domain on $B_{1}$. We need this face to intersect "well" with its neighbors, i.e. its images under short words in the group. This leads us to explore the intersection of the whole bisector $B_{1}$ with some of its images. Now $R_{1}$ stabilizes $B_{1}$ (in fact, each slice is stabilized), and $J$ cyclically permutes

$$
B_{1}, \quad B_{2}:=J\left(B_{1}\right) \quad \text { and } \quad B_{3}:=J^{2}\left(B_{1}\right)
$$

We thus study the intersection $S_{\eta}=B_{1} \cap J\left(B_{1}\right)$.
The surface $S_{\eta}$ is by construction equidistant from the three fixed points $p_{12}$, $p_{23}=J p_{12}$ and $p_{31}=J^{2} p_{12}$. This also makes it apparent that $S_{\eta}$ is the intersection of any two among the three bisectors $B_{1}, B_{2}$ and $B_{3}$.

Proposition 2.12. (1) $S_{\eta}$ is a smooth non-totally geodesic disk.
(2) $S_{\eta}$ contains six geodesics, arranged in a hexagon with right angles.

The extension to projective space of the hexagon $S_{\eta}$ is shown in Figure 1. Note that the hexagon appears already in Mostow [Mo1, Figure 14.1], but not as a face. In his notation the six vertices are $s_{12}, \tilde{s}_{13}, s_{23}, \tilde{s}_{21}, s_{31}$ and $\tilde{s}_{32}$, and are given by

$$
s_{12}=\left[\begin{array}{c}
\tilde{\eta} i \varphi  \tag{2.15}\\
\bar{\eta} i \bar{\varphi} \\
1
\end{array}\right], \quad \tilde{s}_{21}=\left[\begin{array}{c}
-\eta i \varphi \\
-\eta i \bar{\varphi} \\
1
\end{array}\right]
$$

$s_{23}=J s_{12}, s_{31}=J s_{23}, \tilde{s}_{32}=J \tilde{s}_{21}$ and $\tilde{s}_{13}=J \tilde{s}_{32}$.
The next section, which provides a proof of Proposition 2.12, is devoted to a more detailed analysis of this situation. It is somewhat technical and can be skipped during a first reading; the reader can simply assume Proposition 2.12 and refer to Figure 1.

Fig. 1. A right-angled geodesic hexagon on the Giraud disk $B_{1} \cap B_{2} \cap B_{3}$, for $t=\frac{1}{18}$. The figure shows a neighborhood of the disk in its torus extension to projective space.

### 2.4. Computing the vertices of the hexagon

We now prove Proposition 2.12. The first part follows from Proposition 2.5. Indeed, the bisectors $B_{i}$ and $B_{j}$ are co-equidistant, since their complex spines intersect at the point $p_{i j}$.

In the following arguments, we shall often refer to intersections taking place in complex projective space rather than hyperbolic space. We denote by $\widetilde{S}_{\eta}$ the extension to projective space of $S_{\eta}$, which is the set of lines $[x]$ (not necessarily negative definite with respect to the Hermitian form) such that

$$
\begin{equation*}
\left|\left\langle x, p_{12}\right\rangle\right|=\left|\left\langle x, p_{23}\right\rangle\right|=\left|\left\langle x, p_{31}\right\rangle\right| \tag{2.16}
\end{equation*}
$$

It is readily checked that $\widetilde{S}_{\eta}$ is a torus in projective space (cf. [Go, Lemma 8.3.4]). Similarly, $\tilde{\sigma}_{j}$ denotes the extension to projective space of the real spine $\sigma_{j}$. It is simply the circle parameterized by $p_{i j}-\alpha p_{j k},|\alpha|=1$. It is clear from the definitions that $[x] \in \widetilde{S}_{\eta}$ is equivalent to saying that $x$ is orthogonal to two vectors of the form $p_{i j}-\alpha_{i} p_{k i}$ and $p_{i j}-\alpha_{j} p_{j k},\left|\alpha_{i}\right|=\left|\alpha_{j}\right|=1$.

The second statement follows from the following observations:

Proposition 2.13. (1) For each $i$, there are precisely two complex slices of $B_{i}$ that intersect $S_{\eta}$ in a geodesic. We choose vectors $v_{j i k}$ and $v_{k i j}$ polar to these two complex slices.
(2) The vectors $v_{j i k}$ and $v_{k i j}$ correspond to the two intersection points of $\tilde{\sigma}_{i}$ and $\widetilde{S}_{\eta}$ in projective space.
(3) $v_{i j k} \perp v_{j i k}$ and $v_{i j k} \perp v_{i k j}$.
(4) The union of any two adjacent sides of the hexagon is the intersection with $S_{\eta}$ of a meridian of one of the three bisectors $B_{i}$.

The reader should keep Figure 1 at hand when reading the proof of the proposition. The picture of $\widetilde{S}_{\eta}$ is drawn using spinal coordinates on $B_{1} \cap B_{2}$, so that the complex slices of $B_{1}, B_{2}$ and $B_{3}$ intersect $\widetilde{S}_{\eta}$ in vertical, horizontal and slope-1 lines, respectively.

Proof. Lemma 2.2 implies that any slice of $B_{i}$ that intersects $S_{\eta}$ in a geodesic must intersect both $\tilde{\sigma}_{j}$ and $\tilde{\sigma}_{k}$ in projective space. By the slice decomposition, their points of intersection with the slice are orthogonal to some vector $z \in \tilde{\sigma}_{i}$. Such a $z$ is clearly contained in $\widetilde{S}_{\eta}$, since it is orthogonal to two points from two different extended real spines.

Hence the slices $C_{i}$ of $B_{i}$ that intersect $S_{\eta}$ in a geodesic are polar to points of intersection $\tilde{\sigma}_{i} \cap \widetilde{S}_{i}$. Now $\sigma_{i}$ is not contained in $B_{j}$ for $j \neq i$, and it intersects (the extension) of $B_{j}$ (hence $\widetilde{S}_{j}$ ) in at most two points.

We now describe the intersection points $\tilde{\sigma}_{j} \cap \widetilde{S}_{\eta}$. The corresponding six points appear already in [Mo1], and are denoted $v_{i j k}$ (where all indices are distinct among 1,2 and 3 ). We give the coordinates of two of them, the other ones being deduced by applying $J$ and the according cycle in the indices:

$$
v_{123}=\left[\begin{array}{c}
-\eta i \bar{\varphi}  \tag{2.17}\\
1 \\
\bar{\eta} i \varphi
\end{array}\right] \quad \text { and } \quad v_{321}=\left[\begin{array}{c}
\bar{\eta} i \bar{\varphi} \\
1 \\
-\eta i \varphi
\end{array}\right]
$$

These vectors have geometric meaning, namely $v_{i j k}$ can be checked to be orthogonal to the mirrors of a complex reflection given by $J^{ \pm 1} R_{j} R_{k}$, where the power is 1 if $k=j+1$ and -1 if $k=j-1$.

Using (2.13), one verifies that

$$
\begin{align*}
& p_{12}+\eta i \varphi p_{23}=\alpha^{2}\left(\eta^{2} \varphi^{2}+\bar{\eta} i \bar{\varphi}\right) v_{123}  \tag{2.18}\\
& p_{12}-\bar{\eta} i \varphi p_{23}=\alpha^{2}\left(\bar{\eta}^{2} \varphi^{2}-\eta i \bar{\varphi}\right) v_{321} \tag{2.19}
\end{align*}
$$

which implies that $v_{123}$ and $v_{321}$ are indeed on the extended real spine of $B_{2}$. Similarly, applying $J$, we see that $v_{i j k}$ is on the extended real spine of $B_{j}$. Another unenlightening
computation yields

$$
\begin{align*}
& \left\langle v_{123}, p_{12}\right\rangle=\bar{\eta} i \varphi \varkappa,  \tag{2.20}\\
& \left\langle v_{123}, p_{23}\right\rangle=-\eta i \bar{\varphi} \varkappa,  \tag{2.21}\\
& \left\langle v_{123}, p_{31}\right\rangle=\varkappa,  \tag{2.22}\\
& \left\langle v_{321}, p_{12}\right\rangle=-\eta i \varphi \varkappa,  \tag{2.23}\\
& \left\langle v_{321}, p_{23}\right\rangle=\bar{\eta} i \bar{\varphi} \varkappa,  \tag{2.24}\\
& \left\langle v_{321}, p_{31}\right\rangle=\varkappa, \tag{2.25}
\end{align*}
$$

where $\varkappa=\operatorname{det}(H)=1-3 \alpha^{2}-\alpha^{3}\left(\varphi^{3}+\bar{\varphi}^{3}\right)$. Note that all the complex numbers in equations (2.20)-(2.25) have the same absolute value, so $v_{123}$ and $v_{321}$ are in $\widetilde{S}_{\eta}$, see (2.16). The above result remains true for any $v_{i j k}$ simply by applying the 3 -cycle $J$.

This proves parts (1) and (2) of the proposition. We now check the orthogonality claim, namely that two successive spikes of the star of Figure 1 are represented by orthogonal vectors. We only check that $v_{321}$ and $v_{312}$ are orthogonal (the other orthogonality properties are easily deduced from this one). This follows at once from direct calculation, but a better interpretation is that the group contains a number of pairs of commuting complex reflections. Namely, $v_{312}^{\perp}$ is the mirror of $J^{-1} R_{1} R_{2}$, and $v_{321}^{\perp}$ is the mirror of $J R_{2} R_{1}$. Now these two mirrors are orthogonal, since

$$
\begin{align*}
& \left(J^{-1} R_{1} R_{2}\right)\left(J R_{2} R_{1}\right)=J^{-1} R_{1} J J^{-1} R_{2} J R_{2} R_{1}=R_{3} R_{1} R_{2} R_{1},  \tag{2.26}\\
& \left(J R_{2} R_{1}\right)\left(J^{-1} R_{1} R_{2}\right)=J R_{2} J^{-1} J R_{1} J^{-1} R_{1} R_{2}=R_{3} R_{2} R_{1} R_{2}, \tag{2.27}
\end{align*}
$$

and these two are equal because of the braiding relation (these commutation relations become more transparent in the description of the groups given in [ DM$]$ ).

It can be checked that, for $|t|<1 / 2-1 / p$, all $v_{i j k}$ are positive vectors, so that $v_{312}^{\perp} \cap v_{321}^{\perp}$ is a negative line. The corresponding point in complex hyperbolic space is denoted by $s_{12}$ in [Mo1]. Similarly, there is a point $\tilde{s}_{21}$ which can be described as $v_{123}^{\perp} \cap v_{213}^{\frac{1}{2}}$.

One can compute explicit homogeneous coordinates for these points, and obtain expression (2.15). Coordinates for the other four vertices of the hexagon are easily obtained from $s_{12}$ and $\tilde{s}_{21}$ by applying the symmetry $J$, namely $s_{23}=J s_{12}, s_{31}=J s_{23}$, $\tilde{s}_{32}=J \tilde{s}_{21}$ and $\tilde{s}_{13}=J \tilde{S}_{32}$.

It follows from the above orthogonality property that the complex geodesics that contain two successive sides of the hexagon are orthogonal, and hence the real geodesics themselves must be orthogonal. The orthogonality of the complex geodesics also implies that two successive sides of the hexagon are contained in a totally real 2-plane, which must then be a meridian of one of the three bisectors intersecting in the Giraud disk (indeed, it contains two points of its extended real spine). This gives part (4).

Fig. 2. A schematic view of the fundamental domain. The two 3 -faces $H$ and $H^{\prime}$ intersect in a 2 -face (a hexagon) $\eta$. The domain is a geodesic cone from $p_{12}$.

Fig. 3. The boundary of the fundamental domain is a sphere divided into 10 cells. The cone point $p_{12}$ is represented at infinity and only two of the 3 -cells are finite. They correspond to $H$ and $H^{\prime}$ and intersect in a hexagon. There are 4 pentagonal prisms and 4 tetrahedra containing $p_{12}$ as a vertex. The 1 -cells are all geodesics.

## 3. Description of a fundamental polyhedron $\Pi$ in $\mathbf{H}_{\mathrm{C}}^{\mathbf{2}}$

Our fundamental domain is a polyhedron $\Pi$ constructed as a cone at a point $p_{12}$ over the union of two 3-cells named $H$ and $H^{\prime}$ intersecting in a hexagonal 2-cell $\eta$.

Fig. 4. The 3-face $H$ in the bisector $B_{1}$. One of its 2-faces is the hexagon $\eta$ contained in the intersection $B_{1} \cap J\left(B_{1}\right)$.

### 3.1. The core hexagon

In order to construct the first 3-faces of the fundamental domain we recall that the intersection $S_{\eta}=B_{1} \cap J\left(B_{1}\right)$ is a topological disc which contains six geodesics, arranged along a hexagon with right angles, see Proposition 2.12. We thus define a 2 -face $\eta$ of our polyhedron to be the part of the surface $S_{\eta}$ bounded by the hexagon; this 2-face is contained in two 3 -faces, $H$ in $B_{1}$ and $H^{\prime}$ in $B_{1}^{\prime}=J\left(B_{1}\right)$, which we define below. Here and in what follows, we write

$$
B_{1}, \quad B_{1}^{\prime}:=J\left(B_{1}\right) \quad \text { and } \quad B_{1}^{\prime \prime}:=J^{2}\left(B_{1}\right)
$$

### 3.2. The 3-faces $\boldsymbol{H}$ and $\boldsymbol{H}^{\prime}$

We first take a closer look at the position of the hexagon in the first bisector $B_{1}$. We have that
(1) $s_{12}, s_{31}$ and $\tilde{s}_{32}$ are in the meridian $L_{\tau}$;
(2) $\tilde{s}_{13}, s_{23}$ and $\tilde{s}_{21}$ are in the meridian $R_{1}\left(L_{\tau}\right)$;
(3) $s_{31}$ and $\tilde{s}_{21}$ are in a common slice;
(4) $s_{12}$ and $\tilde{s}_{13}$ are in a common slice.

The situation can be seen in Figure 4, where we use coordinates on $B_{1}$ adapted to the bisector structure, in the sense that the (real) spine is the vertical axis, slices are horizontal planes and meridians are vertical planes containing the axis. We call such coordinates spinal coordinates on $B_{1}$.

We are now ready to complete the 3 -face $H$ by adding two vertices, $t_{23}$ and $t_{32}$ in Mostow's notation. They are given by the projection onto the spine of $B_{1}$ of the two slices containing the pairs $\left(s_{31}, \tilde{s}_{21}\right)$ and $\left(s_{12}, \tilde{s}_{13}\right)$, respectively. An elementary computation gives the formulas

$$
t_{23}=\left[\begin{array}{c}
\alpha\left|\varphi-\eta i \bar{\varphi}^{2}\right|^{2}  \tag{3.1}\\
\varphi-\eta i \bar{\varphi}^{2} \\
\bar{\varphi}+\bar{\eta} i \varphi^{2}
\end{array}\right] \quad \text { and } \quad t_{32}=\left[\begin{array}{c}
\alpha\left|\bar{\varphi}-\eta i \varphi^{2}\right|^{2} \\
\varphi+\bar{\eta} i \bar{\varphi}^{2} \\
\bar{\varphi}-\eta i \varphi^{2}
\end{array}\right]
$$

We then enclose $H$ by adding four 2 -faces:
(1) two C-planar geodesic triangles, $\tau_{11}=\left(t_{23}, s_{31}, \tilde{s}_{21}\right)$ in the "top" slice and $\tau_{21}=$ $\left(t_{32}, s_{12}, \tilde{s}_{13}\right)$ in the "bottom" slice;
(2) two $\mathbf{R}$-planar geodesic right-angled pentagons, $\pi_{1}=\left(t_{23}, s_{31}, \tilde{s}_{32}, s_{12}, t_{32}\right)$ in the meridian $L_{\tau}$, and $\pi_{2}=\left(t_{23}, \tilde{s}_{21}, s_{23}, \tilde{s}_{13}, t_{32}\right)$ in the meridian $R_{1}\left(L_{\tau}\right)$.

It is natural to construct this wedge from the spine $g_{1}$ because $R_{1}$ acts on the bisector $B_{1}$ by rotation around its spine. These five 2 -faces enclose a region in $B_{1}$ which is our first 3-face $H$.

Now the next face $H^{\prime}$ is easily derived: we simply consider $H^{\prime}=J(H)$ in $B_{1}^{\prime}=J\left(B_{1}\right)$. This new face, isometric to $H$, is glued to $H$ along the 2 -face $\eta$ (with a rotation of $\frac{2}{3} \pi$ in the orientation of the picture), and it only has two new vertices $t_{31}=J\left(t_{23}\right)$ and $t_{13}=J\left(t_{32}\right)$ which are on the spine of $B_{1}^{\prime}$.

We have thus closed the 2 -face $\eta$ in the sense that it belongs to two 3 -faces; we eventually want to close all the 2 -faces we have introduced, which is what we now do.

### 3.3. The whole polyhedron $\Pi$

Recall from $\S 2.2$ that $p_{12}$ is the intersection of the mirrors of $R_{1}$ and $R_{2}$ (see equation (2.13)). Alternatively, it can be seen as the intersection of the complex spines of the two bisectors we have used so far, $B_{1}$ and $B_{1}^{\prime}$.

We then construct our polyhedron $\Pi$ as the geodesic cone over the "core" part $H \cup H^{\prime}$ from the point $p_{12}$. We use the notation

$$
\operatorname{Cone}(\alpha)=\bigcup_{q \in \alpha}\left[p_{12} q\right],
$$

where $[p q]$ denotes the geodesic segment from $p$ to $q$, so that

$$
\Pi:=\operatorname{Cone}\left(H \cup H^{\prime}\right)
$$

Fig. 5. The core part $H \cup H^{\prime}$ in $B_{1} \cup B_{1}^{\prime}$. The pentagonal 2-cells $\pi_{1}$ and $\pi_{2}$ contain the spine $g_{1}$, and $\pi_{1}^{\prime}$ and $\pi_{2}^{\prime}$ contain the spine $g_{2}$. The side-pairing transformation which interchanges $H$ and $H^{\prime}$ is $J$.

This is analogous to the construction in [FPk] for the Eisenstein-Picard modular group, where the cone vertex was at infinity.

With this construction, the interior of $\Pi$ is the cone over the interior of $H \cup H^{\prime}$, and its boundary is the cone over the boundary of $H \cup H^{\prime}$, together with $H \cup H^{\prime}$. Thus the boundary of $\Pi$ consists of ten 3 -faces: $H, H^{\prime}$ and eight faces of two combinatorial types, tetrahedra (cones over a triangle) and pentagonal pyramids (cones over a pentagon). We will see, in fact, that these two types are also geometrically different, because the tetrahedra live in bisectors whereas the pentagonal pyramids do not.

What is less obvious, and which we leave to the next section, is that this construction does not yield any unwanted intersection between the faces. We first describe the remaining 3 -faces.

### 3.4. The remaining 3 -faces

3.4.1. Description of a tetrahedron. The "top" and "bottom" triangles $\tau_{11}$ and $\tau_{21}$ are not isometric (unless $t=0$ ); however, the tetrahedra based on them have the same structure, so we need only describe the tetrahedron $T_{1}$ based on $\tau_{11}$.

Recall that $\tau_{11}=\left(t_{23}, s_{31}, \tilde{s}_{21}\right)$ is C-planar. Now when we add the point $p_{12}$, we

Fig. 6. The four tetrahedra in the boundary of the polyhedron $\Pi$ actually have the common vertex $p_{12}$. Shown are the corresponding side-pairing transformations.

Fig. 7. The four pentagonal pyramids in the boundary of $\Pi I$ and their side-pairing transformations. Again, they are defined as cones to the common vertex $p_{12}$.
obtain a special configuration:
Lemma 3.1. The triangles $\tau_{12}=\left(t_{23}, s_{31}, p_{12}\right)$ and $\tau_{13}=\left(t_{23}, \tilde{s}_{21}, p_{12}\right)$ are R-planar.
Proof. This can be seen by computing the two Hermitian triple products. Another proof is obtained by observing that the complex geodesics containing $\left[t_{23}, s_{31}\right]$ and $\left[t_{23}, p_{12}\right]$, respectively, are orthogonal. Indeed, by construction, the first one is a slice of $B_{1}$ and the second is the complex spine of $B_{1}$.

This shows that three faces of the tetrahedron are naturally reconstructed from its vertices; there remains some flexibility in the choice of the fourth face, and we have chosen the union of geodesics from $p_{12}$ to the opposite edge (this ensures that this face is also a face of the neighboring pentagonal pyramid). We can moreover see the following result:

Lemma 3.2. The tetrahedron $T_{1}$ is contained in a (unique) bisector.
Proof. We need to find a bisector $B$ such that the $\mathbf{R}$-planar triangles $\tau_{12}$ and $\tau_{13}$ are each in a meridian of $B$ and such that the $\mathbf{C}$-planar triangle $\tau_{11}$ is in a slice. This is possible because the geodesic $\left(t_{23} p_{12}\right)$ common to both $\mathbf{R}$-planes (which is the only possible spine) lives in a $\mathbf{C}$-plane orthogonal to the possible slice.
3.4.2. Description of a pentagonal pyramid. We also have a priori two isometry classes of pentagonal pyramids. They share, however, the same structure, and we only describe the pyramid $P_{1}$ based on the $\mathbf{R}$-planar pentagon $\pi_{1}$. What happens now is that when we add the point $p_{12}$, we obtain five triangular 2 -faces, one of which is $\mathbf{C}$-planar $\left(\left(t_{23} t_{32} p_{12}\right)\right.$ is contained in $\left.\operatorname{Fix}\left(R_{1}\right)\right)$, the two adjacent faces $\left(t_{23} s_{31} p_{12}\right)$ and $\left(t_{32} s_{12} p_{12}\right)$ are R-planar (they are also faces of the tetrahedra $T_{1}$ and $T_{2}$, respectively), and the two remaining faces are not geodesic. In particular, we have the following lemma:

Lemma 3.3. The pentagonal pyramid $P_{1}$ is not contained in a bisector.
Proof. Indeed, three of its faces are R-planar, intersecting in two distinct geodesics, whereas any three (or more) $\mathbf{R}$-planes contained in a bisector intersect in a common geodesic (the real spine).

## 4. Topology and combinatorial structure of $\Pi$

The reader can skip this section if he assumes Proposition 4.1. We will now show how the combinatorial structure of $\Pi$ ensures that its topology is reasonable, in the following sense:

Fig. 8. Generic intersection of a geodesic and a bisector.
Proposition 4.1. Topologically, the boundary polyhedron $\partial \Pi$ is a sphere $S^{3}$, and the whole polyhedron $\Pi$ is a ball $B^{4}$.

Proof. We show that $\partial \Pi$ is homeomorphic to $S^{3}$. The technical aspect is to show that the 3 -faces as we have defined them intersect only where we expect them to, i.e. in common 2 -faces or unions of 1 -faces; this will be seen below and follows from the structure of the bisector faces and the special position of our cone point $p_{12}$. Assuming this, the fact that every 2 -face belongs exactly to two 3 -faces ensures that $\partial \Pi$ is a 3 manifold; in fact, we have a realization of $\partial \Pi$ in $S^{3}$ by considering the core part $H \cup H^{\prime}$ (a topological $B^{3}$ ) in $\mathbf{R}^{3}$ and setting the point $p_{12}$ at infinity. The boundary polyhedron $\partial \Pi$ is then the union of $H \cup H^{\prime}$ with the cone from $p_{12}$ over $\partial\left(H \cup H^{\prime}\right)$, which is the exterior of this ball; the verifications below ensure that this is an embedding.

We now want to check that the different 3 -faces that we have defined intersect pairwise as expected (in 2-faces or unions of 1-faces), i.e. that there is no unwanted extra intersection. A real difficulty resides in the fact that bisectors are not geodesically convex and that, more precisely, the generic intersection between a geodesic and a bisector is empty or a pair of points. This is a problem for us as we have defined our polyhedron as a geodesic cone over certain objects living in bisectors. For instance, it is possible that a geodesic between $p_{12}$ and a point $q \in H$ meets $H^{\prime}$ before reaching $q$. We will see that this does not happen, the key point being that $p_{12}$ is on the complex spines of both $B_{1}$ and $B_{1}^{\prime}$.

Lemma 4.1. Let $C$ be a complex line and $\pi_{C}$ be the orthogonal projection onto it. If $\gamma$ is a geodesic intersecting $C$ then $\pi_{C}(\gamma)$ is a geodesic in $C$.

Note that this is not true in general, $\pi_{C}(\gamma)$ being an arc of a Euclidean circle (see Figure 8).

Proof. Normalize the coordinates in the ball model so that $C=\left\{\left(z_{1}, 0\right) \in \mathbf{B}_{\mathbf{C}}^{2}\right\}$ and $C \cap \gamma=\{(0,0)\}$. Then the projection is simply $\left(z_{1}, z_{2}\right) \mapsto\left(z_{1}, 0\right)$, and the result is obvious knowing that the geodesics through the origin are the Euclidean segments.

We apply this simple fact to the context of bisectors. Recall the slice decomposition of a bisector: if $B$ is a bisector with (real) spine $g$ and complex spine $C$, and if as above $\pi_{C}$ is the orthogonal projection onto $C$, then $B=\pi_{C}^{-1}(g)$, where the fibers $\pi_{C}^{-1}(\{p\})$ for $p \in g$ are the slices of $B$. The above lemma has the following consequences:

Lemma 4.2. Let $B$ be a bisector with (real) spine $g$ and complex spine $C$, and let $p \in C$. Then the geodesics through $p$
(1) intersect $B$ in $\{p\}$ or are contained in $B$ if $p \in g$;
(2) intersect $B$ in at most one point if $p \notin g$.

Proof. The first part comes from the fact that the (real) spine is contained in all meridians. For the second part, the preceding lemma shows that if $\gamma$ is a geodesic through $p$, then $\pi_{C}(\gamma)$ intersects $g$ in at most one point $q$. Then $B \cap \gamma$ is contained in the slice $\pi_{C}^{-1}(\{q\})$. The slice being totally geodesic, this shows that $B \cap \gamma$ contains only one point.

We are now ready to analyze the different intersections of 3-faces.
4.0.1. Intersection of the pentagonal pyramids with $H$ and $H^{\prime}$. There are two types of intersection between a pentagonal pyramid and a core face $H$ or $H^{\prime}$, as follows:

Proposition 4.2. (1) $P_{1}$ intersects $H$ in the pentagon $\pi_{1}$.
(2) $P_{1}$ intersects $H^{\prime}$ in two geodesic segments, $\left[\tilde{s}_{32} s_{31}\right]$ and $\left[\tilde{s}_{32} s_{12}\right]$.

Proof. We prove the stronger statement that

$$
P_{1} \cap B_{1}=\pi_{1} \quad \text { and } \quad P_{1} \cap B_{1}^{\prime}=\left[\tilde{s}_{32} s_{31}\right] \cup\left[\tilde{s}_{32} s_{12}\right]
$$

by projecting to the $\mathbf{C}$-spine of the appropriate bisector and using the above lemma. Let $\pi_{C_{1}}$ (resp. $\pi_{C_{1}^{\prime}}$ ) denote the orthogonal projection to the $\mathbf{C}$-spine of $B_{1}$ (resp. $B_{1}^{\prime}$ ).

For the first point: since $\pi_{1} \subset B_{1}, \pi_{C_{1}}\left(\pi_{1}\right)$ is contained in the (real) spine of $B_{1}$, so that the preceding lemma implies that each geodesic from $p_{12}$ to a point $q$ of $\pi_{1}$ intersects $B_{1}$ only in $q$.

It remains to see how $P_{1}$ intersects $H^{\prime}$. We start off by showing that the pentagon $\pi_{1}$ is entirely contained in the half-space bounded by $B_{1}^{\prime}$ and containing $p_{12}$. Recall that $\pi_{1}$ is contained in the $\mathbf{R}$-plane $L_{\tau}$ (see Proposition 2.10). Now $L_{\tau}$ has singular intersection with $B_{1}^{\prime}$, consisting in the two orthogonal geodesics $\left(\tilde{s}_{32} s_{31}\right)$ and ( $\left.\tilde{s}_{32} s_{12}\right)$ which separate $L_{\tau}$ into four regions as in Figure 9 (where + and - indicate the half-spaces bounded

Fig. 9. The trace of $B_{1}^{\prime}$ on the R-plane $L_{\tau}$.
by $B_{1}^{\prime}$ ). Thus $\pi_{1}$ (which is convex) is entirely contained in one of these half-spaces, which contains the vertices $t_{23}$ and $t_{32}$. Now we can check, using two points from which $B_{1}^{\prime}$ is equidistant, such as $p_{12}$ and $p_{23}$, that $t_{23}$ and $t_{32}$ are on the same side of $B_{1}^{\prime}$ as the point $p_{12}$. (Figure 10 illustrates the difference $\cosh \varrho\left(t_{23}, p_{23}\right)-\cosh \varrho\left(t_{23}, p_{12}\right)$ as a function of the phase shift $t$, the point being that it remains positive for $|t|<1 / 2-1 / p$.) We can then conclude, by projecting to the $\mathbf{C}$-spine of $B_{1}^{\prime}$ and using the lemma, that the whole cone $P_{1}$ is on the same side of $B_{1}^{\prime}$ as $p_{12}$, which implies that $P_{1}$ and $B_{1}^{\prime}$ have the desired intersection, which is the pair of edges $\left[\tilde{s}_{32} s_{31}\right]$ and $\left[\tilde{s}_{32} s_{12}\right]$.

The same argument applies to the other pentagonal pyramids, knowing that $t_{13}$ and $t_{31}$ are on the same side of $B_{1}$ as the point $p_{12}$.
4.0.2. Intersection of the tetrahedra with $H$ and $H^{\prime}$. These intersections are exactly as above, replacing the pentagons with triangles. We have in this case:

Proposition 4.3. (1) $T_{1}$ intersects $H$ in the triangle $\tau_{11}$.
(2) $T_{1}$ intersects $H^{\prime}$ in the geodesic segment $\left[\tilde{s}_{21} s_{31}\right]$.
4.0.3. Intersection of two cone faces. The intersection of two faces which are unions of geodesics from $p_{12}$ is not much of a problem.

LEmma 4.3. If $\alpha$ and $\beta$ are subsets of $\partial\left(H \cup H^{\prime}\right)$, then

$$
\operatorname{Cone}(\alpha) \cap \operatorname{Cone}(\beta)=\operatorname{Cone}(\alpha \cap \beta)
$$

Proof. It is obvious that $\operatorname{Cone}(\alpha \cap \beta) \subset \operatorname{Cone}(\alpha) \cap \operatorname{Cone}(\beta)$. That there is no extra intersection follows from what we have seen on the other faces.

Fig. 10. $t_{23}$ is on the same side of $B_{1}^{\prime}$ as $p_{12}$.
4.0.4. Intersection of the two core faces $H$ and $H^{\prime}$. This is the easiest case because we have defined the 2-face $\eta$ so that $H \cap H^{\prime}=\eta$. Note that $H$ (resp. $H^{\prime}$ ) lies entirely on one side of the bisector $B_{1}^{\prime}$ (resp. $B_{1}$ ), which is the same side as $p_{12}$ as we have seen by testing the vertices.

## 5. Using Poincaré's polyhedron theorem

In this section we review Poincaré's polyhedron theorem. We will follow the general
 proof (see also $[\mathrm{FPk}]$ and [ Ma$]$ ). We define a polyhedron as a cellular space homeomorphic to a compact polytope. In particular, each codimension-2 cell is contained in exactly two codimension- 1 cells. Its realization as a cell complex in a manifold $X$ is also referred to as a polyhedron. We will say that a polyhedron is smooth if its faces are smooth.

Definition 5.1. A Poincaré polyhedron is a smooth polyhedron $D$ in $X$ with co-dimension-1 faces $T_{i}$ such that
(1) the codimension- 1 faces are paired by a set $\Delta$ of homeomorphisms of $X$ which respect the cell structure (the side-pairing transformations); we assume that if $\gamma \in \Delta$ then $\gamma^{-1} \in \Delta$;
(2) for every $\gamma_{i j} \in \Delta$ such that $T_{i}=\gamma_{i j} T_{j}$, we have $\gamma_{i j} D \cap D=T_{i}$.

Remark 5.1. If $T_{i}=T_{j}$, i.e. if a side pairing maps one side to itself, then we impose, moreover, that $\gamma_{i j}$ be of order 2 and call it a reflection. We refer to the relation $\gamma_{i j}^{2}=1$ as a reflection relation.

Let $T_{1}$ be an ( $n-1$ )-face and $F_{1}$ be an ( $n-2$ )-face contained in $T_{1}$. Let $T_{1}^{\prime}$ be the other $(n-1)$-face containing $F_{1}$. Let $T_{2}$ be the ( $n-1$ )-face paired to $T_{1}^{\prime}$ by $g_{1} \in \Delta$ and $F_{2}=g_{1}\left(F_{1}\right)$. Again, there exists only one ( $n-1$ )-face containing $F_{2}$, which we call $T_{2}^{\prime}$. We define recursively $g_{i}$ and $F_{i}$ so that $g_{i-1} \circ \ldots \circ g_{1}\left(F_{1}\right)=F_{i}$.

Definition 5.2. Cyclic is the condition that for each pair ( $F_{1}, T_{1}$ ) (an ( $n-2$ )-face contained in an ( $n-1$ )-face), there exists $r \geqslant 1$ such that, in the construction above, $g_{r} \circ \ldots \circ g_{1}\left(T_{1}\right)=T_{1}$ and $g_{r} \circ \ldots \circ g_{1}$ restricted to $F_{1}$ is the identity. Moreover, calling $g=$ $g_{r} \circ \ldots \circ g_{1}$, there exists a positive integer $m$ such that

$$
g_{1}^{-1}(P) \cup\left(g_{2} \circ g_{1}\right)^{-1}(P) \cup \ldots \cup g^{-1}(P) \cup\left(g_{1} \circ g\right)^{-1}(P) \cup\left(g_{2} \circ g_{1^{\circ}} g\right)^{-1}(P) \cup \ldots \cup\left(g^{m}\right)^{-1}(P)
$$

is a cover of a closed neighborhood of the interior of $F_{1}$ by polyhedra with disjoint interiors.

The relation $g^{m}=\left(g_{r} \circ \ldots \circ g_{1}\right)^{m}=\mathrm{Id}$ is called a cycle relation.
Theorem 5.1. Let $D$ be a compact Poincaré polyhedron with side-pairing transformations $\Delta \subset \operatorname{Isom}\left(\mathbf{H}_{\mathbf{C}}^{2}\right)$ in $\mathbf{H}_{\mathbf{C}}^{2}$ satisfying the cyclic condition. Let $\Gamma$ be the group generated by $\Delta$. Then $\Gamma$ is a discrete subgroup of $\operatorname{Isom}\left(\mathbf{H}_{\mathbf{C}}^{2}\right)$, and $D$ is a fundamental domain. A presentation is given by

$$
\Gamma=\langle\Delta| \text { cycle relations, reflection relations }\rangle .
$$

### 5.1. Side pairings

The side pairings of our polyhedron $\Pi$ are, writing $R_{2}=J R_{1} J^{-1}$,

$$
\begin{gathered}
H \xrightarrow{J} H^{\prime}, \\
P_{1} \xrightarrow{R_{1}} P_{2}, \quad P_{1}^{\prime} \xrightarrow{R_{2}} P_{2}^{\prime}, \\
T_{1} \xrightarrow{\left(R_{2} R_{1}\right)^{-1}} T_{1}^{\prime}, \quad T_{2} \xrightarrow{R_{1} R_{2}} T_{2}^{\prime} .
\end{gathered}
$$

### 5.2. Cycles and orbits of faces

We now write the cycles of 2 -faces induced by the side pairings, according to the type of 2-face.
(1) The hexagon cycle

$$
\eta \xrightarrow{J} \eta \xrightarrow{J} \eta \xrightarrow{J} \eta .
$$

(2) The pentagon cycle

$$
\pi_{1} \xrightarrow{R_{1}} \pi_{2} \xrightarrow{J} \pi_{2}^{\prime} \xrightarrow{R_{2}^{-1}} \pi_{1}^{\prime} \xrightarrow{J^{-1}} \pi_{1}
$$

(3) The C-planar triangle cycles

$$
\begin{aligned}
& \tau_{11} \xrightarrow{\left(R_{2} R_{1}\right)^{-1}} \tau_{11}^{\prime} \xrightarrow{J^{-1}} \tau_{11} \\
& \tau_{21} \xrightarrow{R_{1} R_{2}} \tau_{21}^{\prime} \xrightarrow{J^{-1}} \tau_{21} \\
& \tau_{c 1} \xrightarrow{R_{1}} \tau_{c 1} \\
& \tau_{c 2} \xrightarrow{R_{2}} \tau_{c 2}
\end{aligned}
$$

(4) The $\mathbf{R}$-planar triangle cycles

$$
\begin{aligned}
& \tau_{12} \xrightarrow{R_{1}} \tau_{13} \xrightarrow{\left(R_{2} R_{1}\right)^{-1}} \tau_{13}^{\prime} \xrightarrow{R_{2}^{-1}} \tau_{12}^{\prime} \xrightarrow{R_{2} R_{1}} \tau_{12} \\
& \tau_{22} \xrightarrow{R_{1}} \tau_{23} \xrightarrow{R_{1} R_{2}} \tau_{23}^{\prime} \xrightarrow{R_{2}^{-1}} \tau_{22}^{\prime} \xrightarrow{\left(R_{1} R_{2}\right)^{-1}} \tau_{22}
\end{aligned}
$$

(5) The generic triangle cycles

$$
\begin{aligned}
& \tau_{14} \xrightarrow{\left(R_{2} R_{1}\right)^{-1}} \tau_{14}^{\prime} \xrightarrow{R_{1}} \tau_{g 2} \xrightarrow{R_{2}} \tau_{14} \\
& \tau_{24} \xrightarrow{R_{1} R_{2}} \tau_{24}^{\prime} \xrightarrow{R_{1}^{-1}} \tau_{g 1} \xrightarrow{R_{2}^{-1}} \tau_{24}
\end{aligned}
$$

### 5.3. Verifying the tessellation conditions

5.3.1. First step: the side pairings send $\Pi$ II off itself. We show in this section that each side pairing $g$ of $\Pi$ satisfies

$$
\stackrel{\circ}{\Pi} \cap g(\Pi)=\varnothing
$$

This is more easily seen in the case where the faces corresponding to the side pairing live in a bisector, because the bisector in question separates $\Pi$ and its image, and hence the intersection of these polyhedra has dimension at most 3, and their interiors are disjoint. We now verify this claim.

- Side pairing $J . J$ maps $H$ to $H^{\prime}$, which lives in the bisector $B_{1}^{\prime}$. We have the following result:

Proposition 5.1. $B_{1}^{\prime}$ separates $\Pi$ and $J(\Pi)$.
Proof. We first see this for the core parts $H \cup H^{\prime}$ and $J\left(H \cup H^{\prime}\right)=H^{\prime} \cup H^{\prime \prime}$. Now $H^{\prime}$ is in $B_{1}^{\prime}$, so we only need to check that $H$ is on one side of $B_{1}^{\prime}$ and $H^{\prime \prime}$ on the other. We already know that $H$ is on the same side of $B_{1}^{\prime}$ as $p_{12}$ (see §4.0.4), and the second part follows, knowing that the $\mathbf{R}$-reflection $\sigma_{13}$ (in the meridian $L_{13}$ of $B_{1}^{\prime}$ ) exchanges $H$ and $H^{\prime \prime}$, as can be checked on the vertices.

The cone parts are then easily seen to be on the appropriate sides of $B_{1}^{\prime}$, because the cone points $p_{12}$ and $p_{23}=J\left(p_{12}\right)$ are in the $\mathbf{C}$-spine of $B_{1}^{\prime}$, each on the same side as the base of its cone.

- Side pairings $R_{1} R_{2}$ and $R_{2} R_{1}$. We treat the case of $R_{1} R_{2}$, the other being completely analogous. The side pairing $R_{1} R_{2}$ maps $T_{2}$ to $T_{2}^{\prime}$, which is contained in the bisector $B_{T_{2}^{\prime}}$, having as real spine the geodesic ( $t_{13} p_{12}$ ). We have the following result:

Proposition 5.2. $B_{T_{2}^{\prime}}$ separates $\Pi$ and $R_{1} R_{2}(\Pi)$.
Proof. It suffices to show that $\Pi$ is entirely on one side of $B_{T_{2}^{\prime}}$. Indeed, $\Pi$ is then analogously entirely on one side of $B_{T_{2}}$, so that by the side pairing $R_{1} R_{2}, R_{1} R_{2}(\Pi)$ is entirely on one side of $B_{T_{2}^{\prime}}=R_{1} R_{2}\left(B_{T_{2}}\right)$. We then check one point in each polyhedron to see that they are indeed on opposite sides.

The fact that $\Pi$ is entirely on one side of $B_{T_{2}^{\prime}}$ can be seen by projecting to the C-spine of $B_{T_{2}^{\prime}}$ (the mirror of $R_{2}$ ), which contains the points $p_{12}, t_{13}$ and $t_{31}$.

- Position of $H^{\prime} . H^{\prime}$ lives in the bisector $B_{1}^{\prime}$, which has the same $\mathbf{C}$-spine as $B_{T_{2}^{\prime}}$; its projection is thus contained in the geodesic $\left(t_{13} t_{31}\right)$ (the real spine of $\left.B_{1}^{\prime}\right)$, and in light of the foliation of $H^{\prime}$ by complex triangles it is in fact inside the segment $\left[t_{13} t_{31}\right]$.
- Position of $H$. Recall that the 2 -skeleton of $H$ consists of $\eta, \pi_{1}, \pi_{2}, \tau_{11}$ and $\tau_{21}$.

The 2 -face $\eta$ is also in $H^{\prime}$, so it projects in the segment $\left[t_{13} t_{31}\right]$. For the pentagons we need the following lemma:

LEMMA 5.1. The four points $p_{12}, \tilde{s}_{21}, t_{13}$ and $t_{23}$ (resp. $p_{12}, s_{12}, t_{31}$ and $t_{32}$ ) lie in a common R-plane.

Proof. Indeed, as we have seen earlier, the triples $\left(p_{12}, \tilde{s}_{21}, t_{13}\right),\left(p_{12}, \tilde{s}_{21}, t_{23}\right)$ and $\left(\tilde{s}_{21}, t_{13}, t_{23}\right)$ each lie in an $\mathbf{R}$-plane because the pairs of geodesics $\left(p_{12} t_{13}\right)$ and ( $\left.\tilde{s}_{21} t_{13}\right)$, $\left(p_{12} t_{23}\right)$ and $\left(\tilde{s}_{21} t_{23}\right),\left(\tilde{s}_{21} t_{13}\right)$ and $\left(\tilde{s}_{21} t_{23}\right)$ lie in pairwise orthogonal complex lines. Thus we have a tetrahedron of which three faces are R-planar; by Proposition 2.9 this is possible only if the four points lie in the same $\mathbf{R}$-plane.

We can now analyze the position of $\pi_{2}$. As we have just seen, the geodesic $\left(\tilde{s}_{21} t_{23}\right)$ is contained in (a meridian of) $B_{T_{2}^{\prime}}$, which also contains ( $\tilde{s}_{21} s_{23}$ ) in a complex slice. Thus

Fig. 11. Projection of $H$ to the $\mathbf{C}$-spine of $B_{T_{2}^{\prime}}$.
the intersection of the $\mathbf{R}$-plane containing $\pi_{2}$ with $B_{T_{2}^{\prime}}$ is exactly a pair of geodesics, which are two sides of $\pi_{2}$, so that $\pi_{2}$ lies entirely on one side of $B_{T_{2}^{\prime}}$, as in Figure 9.

We now use the other quadruple of points of the lemma: these lie on an $\mathbf{R}$-plane which is, for instance, a meridian of the bisector $B_{T_{1}^{\prime}}$ having ( $p_{12} t_{31}$ ) as real spine (and having the same $\mathbf{C}$-spine as $B_{T_{2}^{\prime}}$ ). Thus the entire quadrilateral projects into the segment [ $p_{12} t_{31}$ ]. We now know that the 1-skeleton of $H$ projects to the appropriate side of $B_{T_{2}^{\prime}}$, except maybe for the edge $\left[s_{31} t_{23}\right]$. This is the third side of the $\mathbf{C}$-planar triangle $\tau_{11}$, whose two other sides, $\left[\tilde{s}_{21} t_{23}\right]$ and $\left(\tilde{s}_{21} s_{31}\right)$, project, as we have seen, into the segments $\left[t_{13} p_{12}\right]$ and $\left[t_{13} t_{31}\right]$, respectively (see Figure 11). This gives us sufficient control over the third side. Indeed, the projection restricted to a complex face is holomorphic, thus an open and angle-preserving map. This rules out the possibility that the image of the edge [ $s_{31} t_{23}$ ] (which is an arc of hypercycle in the $\mathbf{C}$-spine of $B_{T_{2}^{\prime}}$ ) would pass through the real spine $\left(t_{13} p_{12}\right)$ (see Figure 12; the first case is ruled out by "angle-preserving" and the second by "open"). We then conclude by saying that the image of $H$ is bounded by the image of its boundary, using, for instance, the foliation of $H$ by complex triangles.

- Position of the cone faces. As earlier, the geodesics through $p_{12}$ project to geodesics because $p_{12}$ is in the complex line onto which we are projecting; moreover, $p_{12}$ is in the real spine of $B_{T_{2}^{\prime}}$, so that the cone on an object is entirely on the same side of $B_{T_{2}^{\prime}}$ as that object.
- Side pairings $R_{1}$ and $R_{2}$. This is the most delicate case because $\Pi$ and its image cannot be separated by a bisector (or else this bisector would contain one of the pentagonal pyramids, which we have seen to be impossible).

To prove that $R_{1}(\Pi)$ and $\Pi$ have disjoint interiors, a possible approach would be to show that $\Pi$ is contained in a fundamental domain for $R_{1}$ (as suggested to us by the

Fig. 12. Non-admissible projections of a complex triangle.
referee). In fact, $R_{1}$ acts on complex lines orthogonal to its mirror as a rotation. Therefore, the choice of a wedge (of angle $2 \pi / p$ ) in each of these lines defines a fundamental domain for $R_{1}$. Unfortunately, there does not seem to be a simple global choice of such wedges.

Instead we have to consider separately the core faces and the cone faces, and use the fact that if the interiors of the polyhedra were to meet, then so would the interiors of some of their 3-faces.

Proposition 5.3.

$$
\stackrel{\circ}{\Pi} \cap R_{1}(\Pi I)=\varnothing .
$$

Proof. We follow the lines given above, first separating the core faces ( $H$ and $H^{\prime}$, $R_{1}(H)$ and $\left.R_{1}\left(H^{\prime}\right)\right)$. The only obvious intersection between these faces is that of $H$ and $R_{1}(H)$ (namely $P_{2}$ ), which live in the same bisector $B_{1}$.

We first prove the following lemma:
Lemma 5.2. There exists a bisector $B_{R_{1}}$ which separates $H \cup H^{\prime}$ and $R_{1}\left(H \cup H^{\prime}\right)$. In particular, these two objects have disjoint interiors.

Observe that the four faces in question all have the edges $\left[\tilde{s}_{13} s_{23}\right]$ and $\left[s_{23} \tilde{s}_{21}\right]$ in common, so that a suitable bisector must contain these edges. In fact, our bisector will contain the whole $\mathbf{R}$-plane $R_{1}\left(L_{\tau}\right)$ as a meridian.

The most natural idea is to use one of the complex slices of $B_{1}$ as a $\mathbf{C}$-spine for our bisector (the $\mathbf{C}$-plane onto which we will project). For practical reasons we use the slice containing $s_{23}$ and $\tilde{s}_{32}$ (this is the slice containing the largest section of $H$ ). We thus define $B_{R_{1}}$ by its real spine, which is the geodesic joining $s_{23}$ and its projection to the vertical axis $\left(t_{23} t_{32}\right)$. The first thing to say is stated in the next lemma:

Lemma 5.3. The bisectors $B_{1}$ and $B_{R_{1}}$ intersect only along the common meridian $R_{1}\left(L_{\tau}\right)$.

Proof. It is clear that $B_{1}$ and $B_{R_{1}}$ share this meridian, because it contains both real spines. One can then invoke [Go, p. 174], or use Proposition 2.9 on R-planar tetrahedra to conclude.

Fig. 13. Projection of $H$ and $H^{\prime}$ to the $\mathbf{C}$-spine of $B_{R_{1}}$.
This shows that $H$ is entirely on one side of $B_{R_{1}}$ (and $R_{1}(H)$ on the other). Consider now $H^{\prime}$; we examine each 2 -face separately.

- The most obvious is the hexagon $\eta$, which also belongs to $H$.
- The C-planar triangle $\tau_{21}^{\prime}$ has an edge, $\left[s_{23} \tilde{s}_{21}\right]$, which is in $B_{R_{1}}$. That geodesic can be the only intersection between $B_{R_{1}}$ and the $\mathbf{C}$-plane containing $\tau_{21}^{\prime}$, so that $\tau_{21}^{\prime}$ is entirely on one side of $B_{R_{1}}$.
- The R-planar pentagon $\pi_{1}^{\prime}$ also has an edge which is in $B_{R_{1}}$, namely [ $\left.s_{23} \tilde{s}_{13}\right]$. Now this geodesic meets the $\mathbf{R}$-spine of $B_{R_{1}}$, in $s_{23}$, so that by Proposition 2.8 it can be the only intersection between the $\mathbf{R}$-plane $R_{1}\left(L_{\tau}\right)$ and $B_{R_{1}}$. Thus the whole pentagon is on one side of $B_{R_{1}}$.

So far, we know that the entire 1-skeleton of $H^{\prime}$ is on one side of $B_{R_{1}}$, except maybe for the edge $\left[\tilde{s}_{32} t_{31}\right]$. Now this edge meets the $\mathbf{C}$-spine of $B_{R_{1}}$ (in $\tilde{s}_{32}$ ), so it projects to a geodesic and stays on the same side of $B_{R_{1}}$ as its endpoints. Having the 1 -skeleton, we extend the result to the 2 -skeleton: the only non-obvious faces are a $\mathbf{C}$-planar triangle and an R-planar pentagon of $H^{\prime}$, which are handled by Lemma 2.1. Finally, we get the corresponding result for all of $H^{\prime}$ by using the foliation of $H^{\prime}$ into $\mathbf{C}$-planar triangles.

Thus $H \cup H^{\prime}$ is entirely on one side of $B_{R_{1}}$; the same arguments (replacing the Rplane $R_{1}\left(L_{\tau}\right)$ by $L_{\tau}$ ) prove that $H \cup H^{\prime}$ is entirely on one side of $B_{R_{1}^{-1}}$ (the bisector analogous to $B_{R_{1}}$, but containing $L_{\tau}$ ), so that in fact $H \cup H$ ' is entirely in the "wedge" of angle $2 \pi / p$ between $B_{R_{1}}$ and $B_{R_{1}^{-1}}$ (see Figure 13).

We conclude by noting that $R_{1}$ rotates the $\mathbf{C}$-spine of $B_{R_{1}}$ by an angle $2 \pi / p$ (around the point image of $t_{23}, t_{32}$ and $p_{12}$ ), sending the wedge off itself.

To conclude the proof of the proposition, it remains to see what happens with the

Fig. 14. View of a complex slice of $B_{1}$ (for $p=4$ ).
cone faces: we have already seen, when describing the self-intersection of $\Pi$, that the cones from $p_{12}$ on $H$ and $H^{\prime}$ have no other intersection than the cone on their intersection. There remain three intersecting pairs to analyze:

Lemma 5.4. (1) Cone $\left(H^{\prime}\right) \cap \operatorname{Cone}\left(R_{1}(H)\right)=\operatorname{Cone}\left(H^{\prime} \cap R_{1}(H)\right)$.
(2) $\operatorname{Cone}(H) \cap \operatorname{Cone}\left(R_{1}\left(H^{\prime}\right)\right)=\operatorname{Cone}\left(H \cap R_{1}\left(H^{\prime}\right)\right)$.

Proof. We start with the first item. We project the cones to both complex spines of $B_{1}$ and $B_{1}^{\prime}$. If a geodesic containing $p_{12}$ is in the intersection of the cones, it projects onto a geodesic under both projections by Lemma 4.1. Such a geodesic will meet either $H^{\prime}$ or $R_{1}(H)$ first. The lemma is proven if we show that the geodesic meets $H^{\prime}$ and $R_{1}(H)$ at the same time. To see this, recall from $\S 4.0 .1$ that the projection of $H^{\prime}$ in the complex spine of $B_{1}$ is on the same side as $p_{12}$ with respect to the real spine (which contains the projection of $R_{1}(H)$ ).

This shows that the geodesic meets $H^{\prime}$ first. Projecting to the complex spine of $B_{1}^{\prime}$ shows analogously that the same geodesic meets $R_{1}(H)$ first. Indeed, $R_{1}(H)$ is contained in $B_{1}$, on the same side of the surface $S_{\eta}$ as $H$, as can be seen slice by slice (if $C$ is a slice of $B_{1}, S_{\eta} \cap C$ is a hypercycle, i.e. an arc of a Euclidean circle meeting twice the boundary circle, bounding $C \cap H$, and $C \cap R_{1}(H)$ is on the same side of this arc as that of $C \cap H$, see Figure 14); thus $R_{1}(H)$ is on the same side of $B_{1}^{\prime}$ as $H$ and $p_{12}$.

The second item is proven analogously, noting that in a slice $C$ of $B_{1}, C \cap H$ is on the same side of the hypercycle $C \cap R_{1}\left(S_{\eta}\right)$ as $C \cap R_{1}(H)$.

Lemma 5.5. Cone $\left(H^{\prime}\right) \cap \operatorname{Cone}\left(R_{1}\left(H^{\prime}\right)\right)=\operatorname{Cone}\left(H^{\prime} \cap R_{1}\left(H^{\prime}\right)\right)$.
Proof. We project the cones on the complex spines of $B_{1}^{\prime}$ (which contains $H^{\prime}$ ) and $R_{1}\left(B_{1}^{\prime}\right)$ (which contains $R_{1}\left(H^{\prime}\right)$ ). Since $p_{12}$ is in both complex spines, as in the previous lemma, the projections of the cones are cones over the projection by Lemma 4.1. The same argument as above will hold if we show that each projection is on the same side as $p_{12}$ with respect to the corresponding real spine; we will refer to that side as the good side.

To show this, let us first consider the projection of $R_{1}\left(H^{\prime}\right)$ on the complex spine of $B_{1}^{\prime}$. We check that the vertices of $R_{1}\left(H^{\prime}\right)$ are all on the same side of $B_{1}^{\prime}$ as $p_{12}$. That gives a hint that the whole 3-face $R_{1}\left(H^{\prime}\right)$ is on the good side. More precisely, we divide the proof in several steps:
(1) We check numerically that $R_{1}\left(t_{13}\right)$ and $R_{1}\left(t_{31}\right)$ are on the good side of $B_{1}^{\prime}$.
(2) From the knowledge of $S_{\eta}=B_{1} \cap B_{1}^{\prime}$, which is a union of hypercycles, one in each slice of $B_{1}$, we obtain that $R_{1}(\eta)$ intersects $S_{\eta}$ in precisely two geodesic segments, [ $\tilde{s}_{21} s_{23}$ ] and $\left[s_{23} \tilde{s}_{13}\right]$, and, moreover, is contained in the good side of $B_{1}^{\prime}$.
(3) As the intersection of $R_{1}\left(\tau_{11}^{\prime}\right)$ (a slice of $R_{1}\left(H^{\prime}\right)$ ) with $B_{1}^{\prime}$ is a hypercycle and contains the geodesic segment [ $s_{23} \tilde{s}_{13}$ ], we conclude that $R_{1}\left(\tau_{11}^{\prime}\right)$ is on the good side.
(4) We have to check that the pentagonal faces $R_{1}\left(\pi_{i}^{\prime}\right), i=1,2$, project on the good side. Observe that the Lagrangian pentagon $R_{1}\left(\pi_{2}^{\prime}\right)$ has a geodesic in common with the bisector $B_{1}^{\prime}$, namely $\left[\tilde{s}_{21} s_{23}\right]$. Now the intersection of the whole Lagrangian with the bisector could contain at most one more geodesic, orthogonal to the first (see Proposition 2.8). However, if such a second geodesic existed and met the pentagon $R_{1}\left(\pi_{2}^{\prime}\right)$, the vertices of $R_{1}\left(\pi_{2}^{\prime}\right)$ would lie on both sides of this geodesic (because the pentagon has only right angles), and thus on both sides of $B_{1}^{\prime}$. This is impossible since we have verified that all points are on the same side of $B_{1}^{\prime}$. We conclude that the whole pentagon is on the good side.

Concerning the other pentagon, $R_{1}\left(\pi_{1}^{\prime}\right)$, the same argument does not apply (because a priori it has no intersection with $B_{1}^{\prime}$ ), and it remains to check that one of its edges is on the good side, namely the edge $\left[R_{1}\left(t_{13}\right) R_{1}\left(s_{23}\right)\right]$. This is done in the next item.
(5) We need to prove the following statement, which seems quite obvious in Figure 15: the geodesic segment between $R_{1}\left(t_{13}\right)$ and $R_{1}\left(s_{23}\right)$ does not intersect the bisector $B_{1}^{\prime}$. Computer investigation shows that a stronger statement is true, namely that the entire geodesic (and not only the segment) does not intersect the relevant bisector. We shall explain how this can be done for the first case only, the second one being completely

Fig. 15. The straight line segments represent the spine of the relevant bisector, which we need to separate $H^{\prime}$ and $R_{1}\left(H^{\prime}\right)$. The thick segment is the only one that we need to check numerically. The pictures are drawn for $p=3$ and $t=\frac{1}{18}$.
analogous.
Let $\gamma$ be the geodesic segment between $p=R_{1}\left(t_{13}\right)$ and $q=R_{1}\left(s_{23}\right)$. We claim that it never intersects the bisector $B_{1}^{\prime}$ equidistant from $p_{12}$ and $p_{23}$.

We write $\gamma(x)=(1-x) p+x q /\langle q, p\rangle=v+x w$ (note that the geodesic is not parameterized with constant speed, so the parameter $x$ should range through some interval, whose endpoints are irrelevant to our computation).

Any possible intersection of $\gamma$ with $B_{1}^{\prime}$ would be found by solving the equation

$$
\begin{equation*}
\left|\left\langle v+x w, p_{12}\right\rangle\right|=\left|\left\langle v+x w, p_{23}\right\rangle\right| . \tag{5.1}
\end{equation*}
$$

Using the linearity of the Hermitian product and squaring both sides of the equation, we can rewrite it in the form of a quadratic equation

$$
\begin{equation*}
a x^{2}+b x+c=0 \tag{5.2}
\end{equation*}
$$

where

$$
\begin{align*}
a & =\left|\left\langle w, p_{12}\right\rangle\right|^{2}-\left|\left\langle w, p_{23}\right\rangle\right|^{2}  \tag{5.3}\\
b & =2 \operatorname{Re}\left(\left\langle v, p_{12}\right\rangle\left\langle p_{12}, w\right\rangle-\left\langle v, p_{23}\right\rangle\left\langle p_{23}, w\right\rangle\right)  \tag{5.4}\\
c & =\left|\left\langle v, p_{12}\right\rangle\right|^{2}-\left|\left\langle v, p_{23}\right\rangle\right|^{2} \tag{5.5}
\end{align*}
$$

It can easily be checked that the discriminant of this quadratic equation is negative for small phase shift. The values of $\Delta=b^{2}-4 a c$ for the values of $t$ corresponding to discrete

Fig. 16. The 3 -faces $H^{\prime}, R_{1}\left(H^{\prime}\right), H$ and $R_{1}(H)$. Note that $H$ and $R_{1}(H)$ are contained in the bisector $B_{1}$.
groups with $p=3$ are given in the following table:

| $t$ | $\Delta$ |
| :---: | :---: |
| 0 | $-0.2369 \ldots$ |
| $\frac{1}{30}$ | $-0.2465 \ldots$ |
| $\frac{1}{18}$ | $-0.2472 \ldots$ |
| $\frac{1}{12}$ | $-0.2414 \ldots$ |
| $\frac{5}{42}$ | $-0.2236 \ldots$ |

(6) The projection of the face $R_{1}\left(H^{\prime}\right)$ in the complex spine of $B_{1}^{\prime}$ is bounded by the image of its 2-skeleton, because $R_{1}\left(H^{\prime}\right)$ is foliated by triangles in slices and the image by the projection (a holomorphic map) of each triangle is a triangle in the complex spine of $B_{1}^{\prime}$. In fact, it is also bounded by the projection of the 1 -skeleton by Lemma 2.1. Using the items above we then conclude the proof that the projection of the face $R_{1}\left(H^{\prime}\right)$ in the complex spine of $B_{1}^{\prime}$ is on the good side.

The same argument shows that $H^{\prime}$ is on the good side of $R_{1}\left(B_{1}^{\prime}\right)$. In particular, a key step is to show that the geodesic segment between $t_{31}$ and $\tilde{s}_{32}$ does not intersect the bisector $R_{1}\left(B_{1}^{\prime}\right)$ (see again Figure 15).

To conclude the proof of the lemma we show as above, by projecting to both $\mathbf{C}$ spines, that the intersection on the cones over the bases has to contain a point of the
intersection of the bases.
The proposition follows from the three main lemmas.
5.3.2. Second step: further along the cycles. In this section we verify the cyclic condition of the Poincare theorem. Recall that for a cycle of codimension-2 faces $\phi_{i}$,

$$
\phi_{1} \xrightarrow{g_{1}} \phi_{2} \xrightarrow{g_{2}} \ldots \xrightarrow{g_{k-1}} \phi_{k} \xrightarrow{g_{k}} \phi_{1},
$$

the cycle transformation $g_{k}{ }^{\circ} g_{k-1}{ }^{\circ} \ldots \circ g_{1}$ has a certain finite order $m$ (this is one of the hypotheses we have to check; the side pairings $g_{i}$ are explicit in matrix form, which allows us to find $m$ ). We will call $k$ the length of the cycle, and $m k$ its total length. The cyclic condition ensures that the $m k$ images of $\Pi$

$$
g_{1}^{-1}(\Pi), \quad\left(g_{2} \circ g_{1}\right)^{-1}(\Pi), \quad \ldots, \quad\left(\left(g_{k} \circ g_{k-1} \circ \ldots \circ g_{1}\right)^{m}\right)^{-1}(\Pi)=\Pi
$$

tile a neighborhood of the face $\phi_{1}$. In fact, each of these polyhedra shares a codimension-1 face with its two closest neighbors, so that we only need to check that all of these polyhedra have pairwise disjoint interiors.

We have shown in the preceding section that this is true for all pairs of adjacent polyhedra (those differing by a side pairing). This settles the case of all cycles of maximum total length 3 ; for greater total length we must check that $\Pi$ and its non-adjacent images have disjoint interiors. We will start with the three cycles of total length 4 , where we only need to compare $\Pi$ with its "diagonal" image (see diagrams below). The cycles of total length 4 are as follows:

- The pentagon cycle

$$
\pi_{1} \xrightarrow{R_{1}} \pi_{2} \xrightarrow{J} \pi_{2}^{\prime} \xrightarrow{R_{2}^{-1}} \pi_{1}^{\prime} \xrightarrow{J^{-1}} \pi_{1} .
$$

A schematic picture of the tiling of a neighborhood of the 2 -face $\pi_{1}$ (represented by the central vertex) is

$$
\begin{array}{|c|c|}
\hline J^{-1}(\Pi)=R_{1}^{-1} J^{-1} R_{2}(\Pi) & \Pi \\
\hline J^{-1} R_{2}^{-1}(\Pi)=R_{1}^{-1} J^{-1}(\Pi) & R_{1}^{-1}(\Pi) \\
\hline
\end{array}
$$

The fact that $\Pi$ and its "diagonal" image $J^{-1} R_{2}^{-1}(\Pi)=R_{1}^{-1} J^{-1}(\Pi)$ have disjoint interiors follows easily from what we have already seen. Indeed, we know that the bisector $B_{1}$ separates $\Pi$ and $J^{-1}(\Pi)$. Now $R_{1}$ fixes pointwise the $\mathbf{C}$-spine of $B_{1}$ (which is its mirror) and commutes with the orthogonal projection onto it, so that it preserves each of the half-spaces bounded by $B_{1}$.

Thus, applying $R_{1}^{-1}$ to $J^{-1}(\Pi)$, we see that $B_{1}$ separates $\Pi$ from $R_{1}^{-1} J^{-1}(\Pi)$.

- The R-planar triangle cycles

$$
\begin{aligned}
& \tau_{12} \xrightarrow{R_{1}} \tau_{13} \xrightarrow{\left(R_{2} R_{1}\right)^{-1}} \tau_{13}^{\prime} \xrightarrow{R_{2}^{-1}} \tau_{12}^{\prime} \xrightarrow{R_{2} R_{1}} \tau_{12}, \\
& \tau_{22} \xrightarrow{R_{1}} \tau_{23} \xrightarrow{R_{1} R_{2}} \tau_{23}^{\prime} \xrightarrow{R_{2}^{-1}} \tau_{22}^{\prime} \xrightarrow{\left(R_{1} R_{2}\right)^{-1}} \tau_{22} .
\end{aligned}
$$

A diagram for the first cycle is

$$
\begin{array}{|c|c|}
\hline R_{2} R_{1}(\Pi)=R_{1}^{-1} R_{2} R_{1} R_{2}(\Pi) & \Pi \\
\hline R_{1}^{-1} R_{2} R_{1}(\Pi)=R_{2} R_{1} R_{2}^{-1}(\Pi) & R_{1}^{-1}(\Pi) \\
\hline
\end{array}
$$

As above, we can easily separate $\Pi$ and its diagonal image $R_{1}^{-1} R_{2} R_{1}(\Pi)=R_{2} R_{1} R_{2}^{-1}(\Pi)$, this time by the bisector $B_{T_{1}}$. Indeed, $B_{T_{1}}$ separates $\Pi$ and $R_{2} R_{1}(\Pi)$, as we have already seen, and as above, $R_{1}$ preserves the half-spaces bounded by $B_{T_{1}}$ (whose $\mathbf{C}$-spine is again the mirror of $R_{1}$ ), so that $B_{T_{1}}$ separates $\Pi$ and $R_{1}^{-1} R_{2} R_{1}(\Pi)$.

The second cycle is analogous.
Now the only other cycles with total length greater than 3 are the $\mathbf{C}$-planar triangle cycles

$$
\begin{aligned}
& \tau_{11} \xrightarrow{\left(R_{2} R_{1}\right)^{-1}} \tau_{11}^{\prime} \xrightarrow{J^{-1}} \tau_{11} \\
& \tau_{21} \xrightarrow{R_{1} R_{2}} \tau_{21}^{\prime} \xrightarrow{J^{-1}} \tau_{21}
\end{aligned}
$$

on one hand, which has length 2 but arbitrarily large total length, and

$$
\begin{aligned}
& \tau_{c 1} \xrightarrow{R_{1}} \tau_{c 1} \\
& \tau_{c 2} \xrightarrow{R_{2}} \tau_{c 2}
\end{aligned}
$$

on the other, of length 1 and of total length $p$ (in our cases, $p=3,4$ or 5 ).

- We start with the first pair of cycles. The cycle transformations are respectively $\left(R_{2} R_{1} J\right)^{-1}$ and $J^{-1} R_{1} R_{2}$; they both fix pointwise a $\mathbf{C}$-plane, namely the one containing the triangle $\tau_{11}$ (resp. $\tau_{21}$ ). Computing the eigenvalues of these two elements tells us that they act on C-planes orthogonal to their mirror by multiplication by $\bar{\eta} i \bar{\varphi}^{3}$ (resp. $-\eta i \bar{\varphi}^{3}$ ), corresponding to rotations of angle $\pi(1 / 2-1 / p \pm t)$. If the group is discrete, these elliptic elements are to have finite order. In fact, imposing the angles to be of the form $2 \pi / k$ and $2 \pi / l$ with $k, l \in \mathbf{Z} \cup\{\infty\}$ is sufficient to obtain the cyclic condition for these two cycles, and thus discreteness of our group. More precisely we have the following proposition:

Proposition 5.4. (1) If

$$
k=\left(\frac{1}{4}-\frac{1}{2 p}+\frac{t}{2}\right)^{-1} \in \mathbf{Z}
$$

then the polyhedra

$$
\Pi, \quad R_{2} R_{1}(\Pi), \quad R_{2} R_{1} J(\Pi), \quad \ldots, \quad\left(R_{2} R_{1} J\right)^{k}(\Pi), \quad\left(R_{2} R_{1} J\right)^{k} R_{2} R_{1}(\Pi)
$$

have disjoint interiors. In fact, two of these share a common 3-face if they are adjacent, or else they only have the 2-face $\tau_{11}$ in common.
(2) Analogously, if

$$
l=\left(\frac{1}{4}-\frac{1}{2 p}-\frac{t}{2}\right)^{-1} \in \mathbf{Z}
$$

then the polyhedra
$\Pi,\left(R_{1} R_{2}\right)^{-1}(\Pi),\left(R_{1} R_{2}\right)^{-1} J(\Pi), \quad \ldots, \quad\left(\left(R_{1} R_{2}\right)^{-1} J\right)^{l}(\Pi), \quad\left(\left(R_{1} R_{2}\right)^{-1} J\right)^{l}\left(R_{1} R_{2}\right)^{-1}(\Pi)$
have disjoint interiors, and two of them share a common 3-face if they are adjacent, or else they only have the 2-face $\tau_{21}$ in common.

Proof. We have just seen that the elements $\left(R_{2} R_{1} J\right)^{-1}$ and $J^{-1} R_{1} R_{2}$ act on $\mathbf{C}$ planes orthogonal to their mirror by certain rotations, the two integrality conditions saying that these are of angle $2 \pi / k$ and $2 \pi / l$. Now we know that the $\mathbf{C}$-plane containing the points $t_{23}, t_{32}$ and $p_{12}$ (which is the common spine of the bisectors $B_{1}, B_{T_{1}}$ and $B_{T_{2}}$ ) is orthogonal to the mirrors of $\left(R_{2} R_{1} J\right)^{-1}$ and $J^{-1} R_{1} R_{2}$, at points $t_{23}$ and $t_{32}$, respectively. We project to this C-plane, which contains the geodesic triangle ( $t_{23}, t_{32}, p_{12}$ ), each of the sides being the real spine of one of the bisectors $B_{1}, B_{T_{1}}$ and $B_{T_{2}}$. We have shown that the polyhedron $\Pi$ is entirely on one side of each of these bisectors, which means that its projection is entirely inside of the triangle $\left(t_{23}, t_{32}, p_{12}\right)$. This proves the proposition.

Remark 5.2. There are finitely many values of $t$ for which the two numbers

$$
\left(\frac{1}{4}-\frac{1}{2 p} \pm \frac{t}{2}\right)^{-1}
$$

are integers; these are listed in the table

| $p$ | $\|t\|<1 / 2-1 / p$ | $\|t\|=1 / 2-1 / p$ | $\|t\|>1 / 2-1 / p$ |
| :---: | :---: | :---: | :---: |
| 3 | $0, \frac{1}{30}, \frac{1}{18}, \frac{1}{12}, \frac{5}{42}$ | $\frac{1}{6}$ | $\frac{7}{30}, \frac{1}{3}$ |
| 4 | $0, \frac{1}{12}, \frac{3}{20}$ | $\frac{1}{4}$ | $\frac{5}{12}$ |
| 5 | $\frac{1}{10}, \frac{1}{5}$ |  | $\frac{11}{30}, \frac{7}{10}$ |

Remark 5.3. It follows from what we have done that the group generated by $A=$ $\left(R_{2} R_{1} J\right)^{-1}$ and $B=J^{-1} R_{1} R_{2}$ is a C-Fuchsian triangle goup, preserving the mirror of $R_{1}$. Indeed, one checks that the product $A B$ acts on this complex geodesic as a rotation by an angle $2 \pi / N$, where $N=2 p /(6-p)$, fixing $p_{12}$ (a geometric reason for this value can be found in [Mo1, p. 243]). In particular, a fundamental domain for its action is given by the union of the triangle $\tau_{c 1}$ and its reflection about the geodesic $\left(t_{23} t_{32}\right)$.

- Now consider the last cycles, where the cycle transformations are $R_{1}$ and $R_{2}$, of order $p=3,4$ or 5 . For $p=3$ there is nothing to add, but for $p=4$ or 5 we must ensure that the non-adjacent polyhedra $\Pi$ and $R_{i}^{2}(\Pi)$ have disjoint interiors. We do this by following the lines of the analogous verification for $\Pi$ and $R_{i}(\Pi)$ (proof of Proposition 5.3); in principle, the two non-adjacent polyhedra are easier to separate because they have a smaller intersection; however, we lose some control over this intersection. Rather, we handle this by using the computer to check the position of the sixteen core edges (as opposed to just one previously).

The core faces are easily separated using the bisector $B_{R_{1}}$ which was introduced in the proof of Proposition 5.3:

Lemma 5.6. For $p=4$ and $p=5, B_{R_{1}}$ separates $H \cup H^{\prime}$ and $R_{1}^{2}\left(H \cup H^{\prime}\right)$.
Proof. This follows from what we have seen: we know that $H \cup H^{\prime}$ projects to the C-spine of $B_{R_{1}}$ inside a wedge of angle $2 \pi / p$ (see Figure 13) whose images under $R_{1}^{k}$ ( $k=0, \ldots, p-1$ ) tile this C-plane.

As before, two of the three cases of intersections of cones are easily described (using arguments of elementary plane geometry on hypercycles). However, the bases of the cones are now disjoint, so that the cones intersect only at the common apex $p_{12}$, as follows:

Lemma 5.7. (1) $\operatorname{Cone}\left(H^{\prime}\right) \cap \operatorname{Cone}\left(R_{1}^{2}(H)\right)=\left\{p_{12}\right\}$.
(2) Cone $(H) \cap \operatorname{Cone}\left(R_{1}^{2}\left(H^{\prime}\right)\right)=\left\{p_{12}\right\}$.

The last case, which requires some numerical verifications, is contained in the following lemma:

Lemma 5.8. Cone $\left(H^{\prime}\right) \cap \operatorname{Cone}\left(R_{1}^{2}\left(H^{\prime}\right)\right)=\left\{p_{12}\right\}$.
Proof. As before, we consider simultaneously the projections to both complex spines of the bisectors containing the bases of the cones, namely $B_{1}^{\prime}$ and $R_{1}^{2}\left(B_{1}^{\prime}\right)$. Both complex spines contain the cone point $p_{12}$, so that the cones will behave well provided that the bases $H^{\prime}$ and $R_{1}^{2}\left(H^{\prime}\right)$ are on the appropriate side of these bisectors. Using the same arguments as earlier, we reduce this to a verification on the 1 -skeleton of these 3 -faces.

Fig. 17. Cone $\left(H^{\prime}\right)$ and Cone $\left(R_{1}^{2}\left(H^{\prime}\right)\right)$ intersect only in the point $p_{12}$, as can be seen by projecting each one onto the complex spine of the other. The pictures are drawn for $p=5$ and $t=\frac{1}{5}$.

It then remains to check the position of sixteen edges for each face (thirty-two in all), for every value of $t$ where the integrality condition holds, listed in Remark 5.2. One way to do this is to plot the projection of these edges using a computer, as done in Figure 17. Note that the picture is fairly unambiguous in the sense that all edges are "very far" from the real spine, i.e. at a distance much larger than the implied precision. In principle, a detailed verification could also be written along the lines of part (5) of the proof of Lemma 5.5.

## 6. Beyond the critical phase shift

In this section we describe the modification of the combinatorics of our polyhedron for $|t| \geqslant 1 / 2-1 / p$.

For small phase shift, the starting point of our construction is the hexagon $\eta$ contained in the intersection of the two natural bisectors $B_{1}=B\left(p_{12}, p_{13}\right)$ and $B_{1}^{\prime}=J\left(B_{1}\right)$. Recall that the sides of the hexagon are contained in the complex geodesics polar to the points $v_{i j k}$ (see $\S 2.4$ ).

As already observed by Mostow, when $|t|=t_{c}:=1 / 2-1 / p$, the hexagon degenerates, three of its sides collapsing to points on the boundary (three of the $v_{i j k}$ ). After this critical value, the corresponding $v_{i j k}$ are inside the ball (see Figure 18), and they replace their polar triangles in the construction of our polyhedron. More precisely, for $t>t_{c}$, the 3 -face $H$ simplifies to a tetrahedron with vertices $v_{132}, v_{213}, v_{321}$ and $t_{32}$, having one C-planar and two R-planar faces (see Figure 19). The whole polyhedron $\Pi$ is then a

Fig. 18. For large phase shift, some edges of the hexagon $\eta$ are outside complex hyperbolic space. The corresponding face is a triangle, with vertices $v_{132}, v_{213}$ and $v_{321}$, if $t>0$.
cone over a union of two such tetrahedra, $H$ and $J(H)$. Note that $\Pi$ is non-compact only for the critical values where $|t|=t_{c}$.

The side pairings and cycles remain the same as earlier, removing those involving the 3-faces which have disappeared (namely $T_{1}$ and $T_{1}^{\prime}$ for $t>t_{c}$, and $T_{2}$ and $T_{2}^{\prime}$ for $t<-t_{c}$ ). In particular, there remains only one of the two integrality conditions from Proposition 5.4.

Keeping these changes in mind, the arguments given above for small phase shift go through without any major modification. The main difference occurs for critical phase shift, since the hypotheses of the Poincaré polyhedron theorem include an extra verification at the cusps (see $[F P k]$ ).

## 7. Comparison with Mostow's domains

In this section we comment on Mostow's fundamental domains for the groups $\Gamma(p, t)$ generated by $R_{1}, R_{2}$ and $R_{3}$ (for more details see [De]). The goal of his construction is to describe the Dirichlet fundamental domain centered at $p_{0}$. Mostow gives an explicit set of points in the orbit of $p_{0}$ that are supposed to describe all the faces of $F$, namely $R_{i}^{ \pm 1} p_{0},\left(R_{i} R_{j}\right)^{ \pm 1} p_{0},\left(R_{i} R_{j} R_{i}\right)^{ \pm 1} p_{0}$ (a total of twenty-four points).

One then needs to prove that the corresponding twenty-four inequalities suffice. As explained in [Mo1], this can be done by using the appropriate version of the Poincaré

Fig. 19. The core part $H \cup H^{\prime}$ for large phase shift.
polyhedron theorem, by verifying that the polyhedron bounded by the above twenty-four hypersurfaces has side pairings, compatible along the codimension-2 faces.

To explain what goes wrong in his agument, we observe that Mostow describes a polyhedron by giving each face of its $k$-skeleton, $0 \leqslant k \leqslant 3$, as the intersection of a number of bisectors (sometimes more than $4-k$ of them, some intersections not being transverse). Most of this skeleton is not geodesic, and in particular there are several instances of bigons, i.e. two different 1 -faces with the same endpoints.

Mostow's verification that there are side pairings between the 3-faces is correct, but it is relatively easy to check numerically that, for some specific values of the parameters $p$ and $t$, he missed some of the intersections between the 3 -faces. This means that the polyhedron he uses is not simple, which makes it doubtful that it could be used in the context of a Poincaré polyhedron theorem.

Moreover, some of the verifications on the cycles of non-totally geodesic 2-faces are incorrect, some of his 3 -faces having (very tiny) extra intersections, which are easy to miss at first glance with coarse numerical experiments.

It turns out that for two of the groups (the ones with $p=5$ and large phase shift, namely $\Gamma\left(5, \frac{11}{30}\right)$ and $\left.\Gamma\left(5, \frac{7}{10}\right)\right)$, there are more faces in the Dirichlet domain than expected, corresponding to $\left(R_{i} R_{j}\right)^{ \pm 2} p_{0}$ (see [De]). Although this might seem only like a minor correction, it illustrates the difficulty in using Dirichlet domains in complex hyperbolic geometry. Even though the construction is quite canonical (it depends only on the choice of the point $p_{0}$ ), bisector intersections are too complicated to be practical.

The complexity of Dirichlet domains is explained in part by the fact that none of its codimension-2 faces can ever be in a Lagrangian plane. Indeed, any two bisectors
bounding faces of a Dirichlet domain are coequidistant, since their complex spines all contain $p_{0}$ (see $\S 2.5$ ). If their intersection were to contain a Lagrangian plane $L$, the real reflection fixing $L$ would preserve both complex spines, and hence fix their intersection point, which is a contradiction.

In Mostow's Dirichlet domains, certain pairs of 2 -faces are close to a Lagrangian plane, in the sense that their vertices are all contained in such an $\mathbf{R}$-plane. These two non-totally geodesic faces wrap around a certain Lagrangian quadrilateral contained in the Dirichlet domain, forming some kind of droplet contained in a bisector having the Lagrangian as a meridian (see the pictures in [Mo1, Figure 14.4] and [De]). One expects this phenomenon to be due to the rigid nature of Dirichlet domains, and indeed we get rid of such faces in our fundamental domains.

## 8. Appendix: list of faces and combinatorial structure of $\Pi$

We will now list the (proper) faces of $\Pi$; the inclusions are obvious because the 1 - and 2 -faces are determined by their vertices. The 1 -faces are all geodesic segments, and the 2 -faces are either $\mathbf{R}$ - or $\mathbf{C}$-planar, or unions of geodesics from $p_{12}$ to a segment (except for the hexagon $\eta$ which lies on a Giraud disk).

This contrasts strongly with Mostow's Dirichlet domain, where faces shaped like "bubbles" occur, in the form of distinct 1-faces having the same endpoints and of distinct 2 -faces having the same boundary.

- The ten 3-faces. These are of three types (and five isometry classes): the core faces $H$ and $H^{\prime}$, the tetrahedra $T_{1}, T_{1}^{\prime}, T_{2}$ and $T_{2}^{\prime}$ (where $T_{i}^{(\prime)}$ is the cone based on the triangle $\tau_{i 1}^{(\prime)}$ ), and the pentagonal pyramids $P_{1}, P_{1}^{\prime}, P_{2}$ and $P_{2}^{\prime}$ (where $P_{i}^{(\prime)}$ is the cone based on the pentagon $\left.\pi_{i}^{(1)}\right)$.
- The twenty-five 2-faces. These are of three types (and ten isometry classes):
- the right-angled hexagon $\eta=\left(s_{12}, \tilde{s}_{13}, s_{23}, \tilde{s}_{21}, s_{31}, \tilde{s}_{32}\right)$ living in the intersection of bisectors $B_{1}$ and $B_{1}^{\prime}$;
- four $\mathbf{R}$-planar right-angled pentagons:

$$
\begin{aligned}
& \pi_{1}=\left(t_{23}, s_{31}, \tilde{s}_{32}, s_{12}, t_{32}\right), \\
& \pi_{2}=R_{1}\left(\pi_{1}\right)=\left(t_{23}, \tilde{s}_{21}, s_{23}, \tilde{s}_{13}, t_{32}\right), \\
& \pi_{1}^{\prime}=J\left(\pi_{1}\right)=\left(t_{31}, s_{12}, \tilde{s}_{13}, s_{23}, t_{13}\right), \\
& \pi_{2}^{\prime}=J\left(\pi_{2}\right)=\left(t_{31}, \tilde{s}_{32}, s_{31}, \tilde{s}_{21}, t_{13}\right)
\end{aligned}
$$

- twenty triangles:
the faces of $T_{1}$ :

$$
\begin{array}{ll}
\tau_{11}=\left(t_{23}, s_{31}, \tilde{s}_{21}\right) & \text { (C-planar) }, \\
\tau_{12}=\left(t_{23}, s_{31}, p_{12}\right) & (\text { R-planar }), \\
\tau_{13}=\left(t_{23}, \tilde{s}_{21}, p_{12}\right) & (\text { R-planar }), \\
\tau_{14}=\left(p_{12}, s_{31}, \tilde{s}_{21}\right) & \text { (generic) } ;
\end{array}
$$

the faces of $T_{2}$ :

$$
\begin{array}{ll}
\tau_{21}=\left(t_{32}, s_{12}, \tilde{s}_{13}\right) & (\mathbf{C} \text {-planar }), \\
\tau_{22}=\left(t_{32}, s_{12}, p_{12}\right) & (\mathbf{R} \text {-planar }), \\
\tau_{23}=\left(t_{32}, \tilde{s}_{13}, p_{12}\right) & (\mathbf{R} \text {-planar }), \\
\tau_{24}=\left(p_{12}, s_{12}, \tilde{s}_{13}\right) & \text { (generic }) ;
\end{array}
$$

the faces of $T_{1}^{\prime}$ :

$$
\begin{array}{ll}
\tau_{11}^{\prime}=\left(t_{31}, s_{12}, \tilde{s}_{32}\right) & (\text { C-planar }), \\
\tau_{12}^{\prime}=\left(t_{31}, s_{12}, p_{12}\right) & (\mathbf{R} \text {-planar }), \\
\tau_{13}^{\prime}=\left(t_{31}, \tilde{s}_{32}, p_{12}\right) & (\mathbf{R} \text {-planar }), \\
\tau_{14}^{\prime}=\left(p_{12}, s_{12}, \tilde{s}_{32}\right) & \text { (generic }) ;
\end{array}
$$

the faces of $T_{2}^{\prime}$ :

$$
\begin{array}{ll}
\tau_{21}^{\prime}=\left(t_{13}, s_{23}, \tilde{s}_{21}\right) & (\text { C-planar }), \\
\tau_{22}^{\prime}=\left(t_{13}, s_{23}, p_{12}\right) & (\text { R-planar }), \\
\tau_{23}^{\prime}=\left(t_{13}, \tilde{s}_{21}, p_{12}\right) & (\mathbf{R} \text {-planar }), \\
\tau_{24}^{\prime}=\left(p_{12}, s_{23}, \tilde{s}_{21}\right) & \text { (generic) } ;
\end{array}
$$

four triangles belonging to two pentagonal pyramids:

$$
\begin{aligned}
& \tau_{c 1}=\left(t_{23}, t_{32}, p_{12}\right) \quad \text { (C-planar) }, \\
& \tau_{c 2}=\left(t_{13}, t_{31}, p_{12}\right) \quad \text { (C-planar) }, \\
& \tau_{g 1}=\left(s_{31}, \tilde{s}_{32}, p_{12}\right) \quad \text { (generic) }, \\
& \tau_{g 2}=\left(s_{23}, \tilde{s}_{13}, p_{12}\right) \quad \text { (generic). }
\end{aligned}
$$

- The twenty-six edges (1-faces). These are the sixteen edges of the core part (six for the hexagon, adding five for each of $H$ and $H^{\prime}$ ) together with the ten edges joining the ten vertices of the core part to the cone point $p_{12}$.
- The eleven vertices ( 0 -faces). These are the vertices of the hexagon, $s_{12}, \tilde{s}_{13}, s_{23}$, $\tilde{s}_{21}, s_{31}$ and $\tilde{s}_{32}$, together with the vertices $t_{23}$ and $t_{32}$ of $H, t_{13}$ and $t_{31}$ of $H^{\prime}$, and the cone point $p_{12}$.
