Non-cirrhotic portal fibrosis: Current concepts and management

SK SARIN AND D KAPOOR

Department of Gastroenterology, GB Pant Hospital, New Delhi, India

Abstract Non-cirrhotic portal hypertension (NCPH) comprises diseases having an increase in portal pressure (PP) due to intrahepatic or prehepatic lesions, in the absence of cirrhosis. The lesions are generally vascular, either in the portal vein, its branches or in the perisinusoidal area. Because the wedged hepatic venous pressure is near normal, measurement of intravariceal or intrasplenic pressure is needed to assess PP. The majority of diseases included in the category of NCPH are well-characterized disease entities where portal hypertension (PHT) is a late manifestation and, hence, these are not discussed. Two diseases that present only with features of PHT and are common in developing countries are non-cirrhotic portal fibrosis (NCPF) and extrahepatic portal vein obstruction (EHPVO). Non-cirrhotic portal fibrosis is a syndrome of obscure etiology, characterized by ‘obliterative portovenopathy’ leading to PHT, massive splenomegaly and well-tolerated episodes of variceal bleeding in young adults from low socioeconomic backgrounds, having near normal hepatic functions. In some parts of the world, NCPF is called idiopathic portal hypertension (IPH) or ‘hepatoportal sclerosis’. Because 85–95% of patients with NCPF and EHPVO present with variceal bleeding, treatment involves management with endoscopic sclerotherapy (EST) or variceal ligation (EVL). These therapies are effective in approximately 90–95% of patients. Gastric varices are another common cause of upper gastrointestinal bleeding in these patients and these can be managed with cyanoacrylate glue injection or surgery. Other indications for surgery include failure of EST/EVL, and symptomatic hypersplenism. The prognosis of patients with NCPF is good and 5 years survival in patients in whom variceal bleeding can be controlled has been reported to be approximately 95–100%.

INTRODUCTION

Non-cirrhotic portal hypertension (NCPH) comprises a group of diseases that are characterized by an increase in portal pressure due to intrahepatic or prehepatic lesions, in the absence of cirrhosis of the liver. It is not merely absence of cirrhosis, but also of hepatic venous outflow obstruction, such as veno-occlusive disease and Budd–Chiari syndrome. The lesion in NCPH is generally vascular, present in the portal vein, its branches or in the perisinusoidal area of the liver. Wedged hepatic venous pressure (WHVP) is near normal or mildly elevated in these patients and is significantly lower than portal vein pressure.^{1,2}

The majority of diseases that are grouped under this category of NCPH (Table 1) have portal hypertension (PTH) as a late manifestation of the disease. Two diseases, which are very common in developing countries

and almost always present only with features of PTH, include non-cirrhotic portal fibrosis (NCPF) and extrahepatic portal vein obstruction (EHPVO; Fig. 1).

The present review describes our existing knowledge of NCPF. The topic of EHPVO has been recently reviewed by us elsewhere.³

HISTORICAL PERSPECTIVE

Attention was drawn to a condition characterized by congestive splenomegaly, anemia, with or without gastrointestinal bleeding and ascites as early as the late 19th century.⁴ Awareness about this condition as being distinct from cirrhotic causes of PHT emerged in the Indian subcontinent in the late 1950s. In 1962, Indian scientists drew attention to splenomegaly with non-

cirrhotic liver disease in North Indian patients.⁵ Soon after, Boyer *et al.*, while working in Calcutta, reported a series of similar patients but used the term idiopathic portal hypertension (IPH).⁶ At the same time, Mikkelsen *et al.* described 36 patients with PHT without cirrhosis who had phlebosclerosis of intra- and extrahepatic portal veins and coined the term 'hepatoportal sclerosis'.⁷ In 1969, a workshop organized by the Indian Council of Medical Research (ICMR) reviewed all available information on this condition and christened this distinct clinicopathological entity as 'non-cirrhotic portal fibrosis'.⁸ This condition was simultaneously reported from Japan, where the condition is known as IPH,^{9,10} and subsequently from Iran¹¹ and Pakistan.¹²

EPIDEMIOLOGY

Non-cirrhotic portal fibrosis has been reported from all over the Indian continent.^{5,12-14} It is believed to account for nearly one-sixth to one-quarter of all causes of PTH seeking medical attention. The condition has been commonly seen in people who are socioeconomically disadvantaged, not only in India, but also in Iran.¹¹ Improved hygiene and standards of living could explain the relative rarity of the disease in the West and its declining incidence in Japan. While in 1985 the reported inci-

dence of IPH in Japan was 0.75/10⁵ population, in 1992 only an average of 11 new patients were reported.¹⁵ The incidence of IPH has not been prospectively studied in India. Except for an occasional report, most studies indicate a male predominance.^{13,14} This is in contrast to IPH in Japan, Europe and the USA, where the disease is more common in females (Table 2). The mean age of NCPF patients varies from 25 to 35 years, which is much younger than for IPH patients.

ETIOLOGY

The etiopathogenesis of NCPF is poorly understood. A number of hypotheses have been proposed.

Infective hypothesis

Non-cirrhotic portal fibrosis has been commonly seen in patients from a low socioeconomic background. Abdominal infection at birth or in early childhood has been alleged to play an important role.¹⁴ Umbilical sepsis, bacterial infections and diarrheal episodes in infancy and in early childhood are likely to lead to por-

Table 1 Common causes of non-cirrhotic portal hypertension†

Extrahepatic portal venous obstruction*
Non-cirrhotic portal fibrosis or idiopathic portal hypertension
Schistosomiasis
Primary or secondary biliary cirrhosis (pre-cirrhotic stage)
Congenital hepatic fibrosis
Veno-occlusive disease*
Nodular regenerative hyperplasia
Partial nodular transformation
Hepatoportal sclerosis
Peliosis hepatitis

*May present acutely.

†Most causes are chronic conditions.

NCPF, non-cirrhotic portal fibrosis; IPH, idiopathic portal hypertension; LUQ, left upper quadrant.

tal pyemia, pylephlebitis, resulting in thrombosis, sclerosis and obstruction of small- and medium-sized portal vein radicals.

Experimental studies

Idiopathic portal hypertension like changes in the liver and the development of PTH, has been reported after injecting dead non-pathogenic colon bacilli into the portal vein of rabbits and dogs.^{16,17} In another model of indwelling cannulation of the gastrosplenic vein, repeated injections of *Escherichia coli* resulted in the development of splenomegaly and an increase in portal pressure at 3 months.¹⁸

Exposure to trace metals and chemicals

Prolonged ingestion of arsenic has been incriminated in the causation of NCPF.¹⁹ Liver histology in patients with chronic arsenic ingestion reveals periportal fibrosis, incomplete septal cirrhosis, with or without development of neovascularization within the expanded portal zones suggestive of NCPF or IPH. In a Belgian study, a previous intake of arsenic as Fowler's solution for the treatment of psoriasis was reported in eight of 47 NCPH patients.²⁰ Interestingly, these patients had florid skin stigmata of arsenicosis, something not commonly experienced by us. From our center, seven patients diagnosed as NCPF did not have elevated arsenic content in the liver, as assayed by electron probe microanalysis. In patients from Iran, a history of pica was obtained in nearly half the patients.¹¹

A histological picture resembling NCPF has been observed following chronic exposure to vinyl chloride monomers, copper sulfate (vineyard sprayers), protracted treatment with methotrexate, hypervitaminosis A and in renal allograft recipients receiving treatment with 6-mercaptopurine, azathioprine and corticosteroids.

Experimental studies

To investigate whether chronic arsenic exposure could produce NCPF, we undertook studies in albino mice with chronic oral arsenic feeding. While arsenic was found to induce a four- to 14-fold increase in hepatic hydroxyproline and hepatic collagen compared with control mice, features of NCPF or PTH did not develop in any animal.²¹ These observations suggest that although arsenic ingestion could induce hepatic fibrogenesis, it cannot be directly incriminated in the causation of NCPF.

Immunologic and immunogenetic hypotheses

Evidence supporting these hypotheses includes: (i) a reduction in the suppressor/cytotoxic T lymphocytes

(T8) in NCPF patients and a decreased T4/T8 lymphocyte ratio;²² (ii) a reduction in the cell-mediated immune status in NCPF patients; and (iii) a poor autologous mixed lymphocyte reaction (MLR).²³

In Japan, IPH is frequently associated with autoimmune disorders such as systemic lupus erythematosus (SLE), progressive systemic sclerosis (PSS), thyroiditis and mixed connective tissue disease (MCTD).²⁴ Nearly two-thirds of Japanese female patients with IPH test positive for anti-ds DNA antibody and one-quarter test positive for antinuclear antibody.²⁵ Such a high prevalence of associated autoimmune conditions has not been the experience in the Indian subcontinent. However, familial aggregation and a high frequency of HLA-DR3 has been found in our patients.²⁶

Experimental studies

Repeated injections of splenic extract, Freund's adjuvant and egg albumin have been shown to produce splenomegaly and histological lesions similar to IPH in rabbits.²⁷ In a recent study, injection of splenic extract in presensitized rabbits resulted in the development of an NCPF-like picture, with splenomegaly and an increase in portal pressure with negligible parenchymal injury.¹⁸

Proposed hypothesis

Based on the available information, we propose a hypothesis for the development of NCPF and EHPVO. Both these venous inflow tract diseases could develop in a genetically predisposed individual when infection or a prothrombotic event could precipitate thrombosis in the portal vein or its radicals. If it is a major thrombotic event, occurring at an early age in life, the main portal vein becomes occluded, leading to the development of EHPVO (Fig. 2). However, in the event of repeated microthrombotic events, the small or medium branches of the portal vein are affected, leading to the development of NCPF in a young adult.

PATHOLOGY

When NCPF was first recognized, salient histological features characteristic of this condition were described. In fact, NCPF was termed as a distinct clinicopathological entity.

Gross pathology

Early experience was derived from systematic study of wedge hepatic specimens, obtained from patients undergoing surgery. In patients with NCPF, the liver may be normal to markedly nodular. This nodularity,

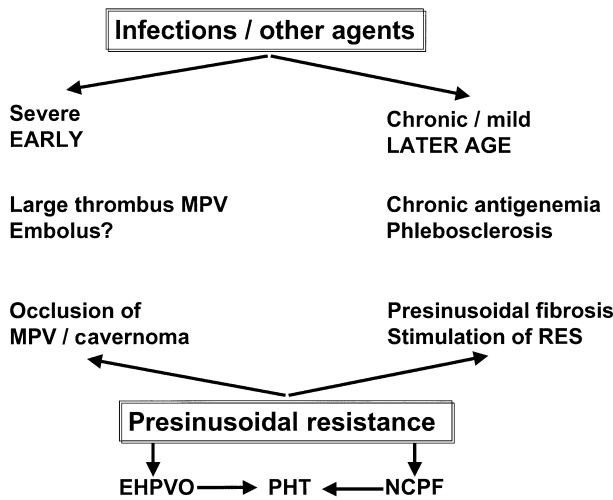

Figure 2 A proposed hypothesis for the pathogenesis of non-cirrhotic portal fibrosis (NCPF) and extrahepatic portal vein obstruction (EHPVO). MPV, main portal vein; RES, reticuloendothelial system.

seen in 10–15% of cases, is confined to the liver surface. The portal vein and its branches are prominent and have sclerosed walls. Autopsy series commonly show thrombosis in the medium and small (diameter < 300 µm) portal vein branches.^{23,24}

Histopathology

Histological changes in NCPF were aptly summarized by Nayak and Ramalingaswamy as ‘obliterative porto-venopathy of liver’.²⁸ Essentially, there is a marked but patchy and segmental subendothelial thickening of the large and medium-sized branches of the portal vein. These changes are summarized in an excellent review by Nakanuma *et al.* (Table 3).²⁹ The intimal thickening of intrahepatic portal venous channels, associated with obliteration of small portal venules and emergence of new aberrant portal channels, is quite characteristic of NCPF. Evidence of previous phlebothrombosis is suggested by the presence of old mural thrombi incorporated in the wall, mural thickening of the extrahepatic portal vein and coexistence of lesions characteristic of NCPF as well as EHPVO in the same patient.

Ultrastructure

A widening of the space of Disse with haphazardly arranged collagen bands in the perisinusoidal space leading to capillarization of sinusoids may be seen. Whether these electron microscopic changes correlate with the severity of PHT or occurrence of ascites, which is seen in a small proportion of NCPF patients, has not been determined.

Table 3 Histological findings in idiopathic portal hypertension

	Frequency (%)
Dense portal fibrosis and portal venous obliteration	
Mild	48
Moderate to severe	52
Portal inflammation	47
Irregular intimal thickening of portal veins	75–100*
Organizing thrombotic and/or recanalization of portal veins	20–100*
Nodular hyperplasia of the parenchyma	40
Abnormal blood vessels in the lobules	75
Intralobular fibrous septa	95
Subcapsular atrophy	70
Periductal fibrosis of interlobular bile ducts	50

Modified from Nakanuma *et al.*²⁹ based on a study of 66 patients with idiopathic portal hypertension.

*100% abnormalities were observed only in autopsy specimens.

Figure 3 The pathoanatomic sites of resistance to portal blood flow in patients with non-cirrhotic portal fibrosis (NCPF), namely presinusoidal and perisinusoidal, caused by thickening and obstruction to the medium-sized and small branches of portal veins and the collagenization of the space of Disse, respectively.

HEMODYNAMICS

The intrasplenic and portal vein pressures are markedly elevated in patients with NCPF. The WHVP may be normal or slightly elevated in approximately half the patients. Two pathoanatomic sites of obstruction (Fig. 3) have been identified: a pressure gradient between the spleen (intrasplenic pressure; ISP) and the liver (intrahepatic pressure; IHP) and another between the liver (IHP) and the WHVP (Fig. 4).³⁰ Variceal pressure has also been studied in these patients and found comparable to that in cirrhotic PHT.^{30,31} Splenic and

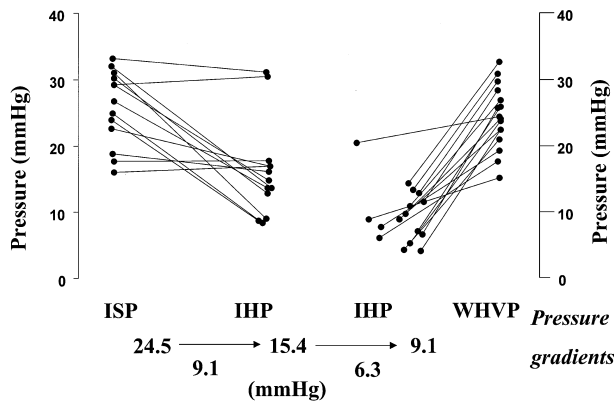

Figure 4 Two pressure gradients, between the spleen and liver (intrasplenic pressure (ISP)–intrahepatic pressure (IHP)) and between the liver and the wedged hepatic venous pressure (IHP–WHVP) are observed in patients with non-cirrhotic portal fibrosis (NCPF). In effect, they represent presinusoidal and perisinusoidal resistance to portal blood flow.

portal vein blood flow are known to be markedly increased in IPH patients from Japan, suggestive of a hyperdynamic circulatory state. Pulmonary hemodynamics in patients with NCPF have also been reported.³² Two of 22 patients in that study had features of primary pulmonary hypertension (PPH). Pulmonary angiography was reported normal in the single patient in whom it was performed.

CLINICAL PROFILE

Non-cirrhotic portal fibrosis is a disease of young patients coming from a low socioeconomic background. Most studies quote a slight male preponderance (male : female ratio 2 : 1).^{13,14} The patients may present with one or more well-tolerated episodes of gastrointestinal hemorrhage, long-standing mass in the left upper quadrant (splenomegaly) and consequences of hypersplenism. Development of ascites, jaundice and hepatic encephalopathy is uncommon and are only seen after an episode of gastrointestinal hemorrhage. Of all the causes of PHT, a massive and disproportionately large spleen is most commonly seen in NCPF. It is not uncommon to see patients presenting with repeated attacks of left upper quadrant pain due to perisplenitis and splenic infarction.³³ The clinical presentation of NCPF is distinct from IPH in several regards (Table 2). Like cirrhosis, NCPF may also have odd presentations, such as glomerulonephritis^{34,35} or hypoxemia.³⁶

Over a 12-year period (1983–1995), we had seen 2137 patients with PTH; 1133 bleeders and 1004 non-bleeders. Non-cirrhotic portal fibrosis comprised 35.4% of all bleeders and 4.1% of non-bleeders. Non-cirrhotic portal fibrosis was diagnosed in 207 patients, while EHPVO was diagnosed in 236 patients. The clinical and laboratory profiles of these patients are shown in Table 4.

Table 4 Profile of non-cirrhotic portal fibrosis and extra-hepatic portal vein obstruction patients

	NCPF (n = 207)	EHPVO (n = 236)
Mean age (years)	30.7	13.9
Sex (males : females)	117 : 90	168 : 68
Hematemesis/melena (%)	84.5	94.5
Mass in LUQ (%)	13.5	3.5
Ascites (transient) (%)	10	12.7
Jaundice (%)	–	12.7
Liver functions tests	Near normal	Near normal
Esophageal varices (%)	92	94
Gastric varices (%)	22.3	40.7
Portal gastropathy		
Presclerotherapy (%)	1.6	0.5
Post-sclerotherapy (%)	17	15
Portal biliopathy (%)	40	90
Portal colopathy (%)	40	44

Data are based on the experience at the GB Pant Hospital, New Delhi, India.³⁷

NCPF, non-cirrhotic portal fibrosis; EHPVO, extrahepatic portal vein obstruction; LUQ, left upper quadrant.

LABORATORY FEATURES

Tests of liver function are, by and large, normal in NCPF patients. These include semiquantitative tests of liver function, such as monoethylglycineylidide (MEGX) extraction.³⁸ Biliary lipid composition is normal in NCPF patients.³⁹ The frequency of hepatitis B and C in non-transfused NCPF patients is approximately 5 and 3%, respectively (SK Sarin, unpubl. obs., 2000); similar to the figures in the general population.

Anemia is a common finding in the majority of NCPF patients. This may be microcytic, hypochromic (due to gastrointestinal blood loss) or normocytic, normochromic (hypersplenism). Leukopenia (<4000/mm³) and thrombocytopenia (<50 000/mm³) may also be present. These changes are due, in part, to an increase in plasma volume and splanchnic pooling of the blood. Bone marrow is hypercellular. While asymptomatic hypersplenism is common, symptomatic hypersplenism is rather rare in NCPF.⁴⁰ Coagulation and platelet function anomalies have been observed in NCPH patients (Table 5).⁴¹ A state of mild compensated disseminated intravascular coagulation secondary to endotoxemia or portosystemic collaterals has been reported in a fair proportion of these patients.^{41,42}

Autonomic dysfunction is increasingly being recognized in patients with cirrhosis. We have recently observed these anomalies in EHPVO patients, possibly because these patients do have some degree of hepatic dysfunction.⁴³ However, autonomic dysfunction does occur even in patients with NCPF, with near-normal liver function, suggesting some contribution of PTH *per se*.

Table 5 Coagulation and platelet function in non-cirrhotic portal hypertension³⁹

Parameter (normal range)	NCPF (n = 18)	EHPVO (n = 18)
INR	1.8 ± 0.68*	1.7 ± 0.4*
PTT (28–31 s)	29 ± 4.2	30 ± 4.2*
Fibrinogen (250–350 mg%)	196 ± 57**	199 ± 61**
Fibrinogen degradation products (< 8 µg/mL)	< 8	> 8**
Platelet aggregation (40–60%)	33 ± 16.5	22 ± 11.3**
Platelet MDA (6–12 nmol/mL)	9.0 ± 3.6	9.6 ± 3.8

* $P < 0.05$, ** $P < 0.001$ compared with controls.

* $P < 0.01$ between cirrhosis and non-cirrhotic portal fibrosis (NCPF).

EHPVO, extrahepatic portal vein obstruction; PHG, portal hypertensive gastropathy.

IMAGING

Splenoportovenography, often used in the past, shows a dilated and thickened vein with venous collaterals.⁴⁴ On ultrasonography, the portosplenic axis is seen to be dilated and patent. Occasionally, thrombus is seen in the intrahepatic branch of the portal vein. We have observed the wall thickness (echogenic boundary of portal vein) of the main portal vein (at hilum) to be significantly more in NCPF than for other etiologies of PHT. Spontaneous lienorenal shunts are also seen more frequently in NCPF patients than in patients with cirrhosis.

Hepatic venography and radionuclide scintigraphy (using ^{99m}Tc phytate or sulfur colloid) have been used to distinguish between NCPF and cirrhosis.^{12,45,46} High marrow uptake on scintigraphy is almost pathognomonic of cirrhosis. Some Japanese workers have used computed tomography (CT) portography and CT hepatic angiography to show aberrant vessels in the periphery of hepatic parenchyma in these patients.²³

Portal biliopathy, defined as anomalies of the biliary system and gallbladder in patients with PTH, is commonly seen in patients with EHPVO. It is also not uncommon in NCPF patients.⁴⁷ However, because tests of liver function are generally normal, endoscopic retrograde cholangiopancreatography (ERCP) is not routinely recommended in NCPF patients.

ENDOSCOPY

Esophagogastric varices have been reported in 85–95% of patients with NCPF.³⁷ In a series from North India, large varices were far more common in NCPH (90%)

than in patients with cirrhosis (70%).⁴⁸ Similarly, anorectal varices were also more commonly reported in NCPH than in cirrhosis (90 vs 56%) and were likely to be larger in the former condition.⁴⁸ El Atti *et al.* found variceal pressure (using a pressure gauge) to be similar in NCPH and cirrhosis but, for any given variceal pressure, cirrhotic patients are more likely to bleed.³¹ El Atti *et al.* found the prevalence of red signs and the NIEC (North Italian Endoscopy Club) index to be similar in the two groups of portal hypertensive patients.

We had also reported that variceal pressure in patients with NCPF and cirrhosis is comparable. Similar findings were reported by El Atti *et al.*³¹ Portal hypertensive gastropathy is uncommon in NCPF patients and is a rare cause of upper gastrointestinal bleeding at the initial presentation.⁴⁹ Gastropathy, however, develops after endoscopic sclerotherapy or variceal ligation in a fair proportion of patients. Post-variceal obliteration gastropathy is often transitory or non-progressive in NCPF patients (Table 6).

DIFFERENTIAL DIAGNOSIS

For most physicians and gastroenterologists practising in India, NCPF is a distinct and easily identifiable disease. While NCPF can be easily differentiated from EHPVO (Table 7), it may be difficult to diagnose when there is coexisting thrombosis of one of the main branches of the portal vein. Non-cirrhotic portal fibrosis generally develops insidiously, while portal vein thrombosis may have an acute presentation (sudden increase in variceal size, development of an upper gastrointestinal bleed, abdominal pain and ascites).

Table 7 Differentiating features between extrahepatic portal vein obstruction, non-cirrhotic portal fibrosis and cirrhosis of liver

Parameter	EHPVO	NCPF	Cirrhosis
Mean age (years)	10	28	40
Ascites	Absent/transient after bleed	Absent/transient after bleed	+ to +++
Encephalopathy	–	–	+
Jaundice/signs of liver failure	–	–	+
Liver function tests	Normal*	Normal	Deranged
Liver			
Gross	Normal/small	Normal, rarely irregular	Shrunken, nodular
Microscopic	Normal	Normal/portal fibrosis	Necrosis, regeneration
Splenoportovenography/US	Portal/splenic vein block	Normal splenoportal axis, 'withered tree' appearance, periportal fibrosis	Dilated, patent portal and splenic vein

*Occasional impairment may be observed.

NCPF, non-cirrhotic portal fibrosis; EHPVO, extrahepatic portal vein obstruction; US, ultrasound.

Child's A cirrhosis may mimic NCPF, but tests of liver function, viral serology and histology (lobular disarray, pseudolobule formation) can distinguish between the two. Moreover, a disproportionately large spleen with a dilated and thickened portal vein favors the diagnosis of NCPF.

Tropical splenomegaly syndrome (TSS) is another condition sometimes seen in the tropics, which presents with massive splenomegaly. However, PHT is uncommon in patients with TSS and the WHVP is within normal limits.⁵⁰ Moreover, elevated serum IgM levels and high malarial antibody titers are common in TSS patients.

Histologically, NCPF needs to be distinguished from conditions like nodular regenerative hyperplasia, partial nodular transformation and incomplete septal cirrhosis.

MANAGEMENT

The key management issues in patients with NCPF are gastrointestinal hemorrhage and hypersplenism. For acutely bleeding patients, endoscopic variceal ligation (EVL) and endoscopic sclerotherapy (EST) are equally efficacious (95% success in the control of an acute bleed).⁵¹ Emergency shunt surgery is required in less than 5% of cases.⁵² Selective shunts, like a distal lienorenal shunt, are preferred because they have a lower incidence of post-shunt encephalopathy. The number of sessions of sclerotherapy required for obliteration of varices is similar in patients with cirrhosis and NCPF.⁵³ Variceal recurrence has been reported in approximately 20% of cases, but recurrent bleed is quite uncommon (approximately 3%).^{52,53} Prevention of rebleeding has been reported in patients with schistosomiasis in an isolated study using non-selective beta-blockers.⁵⁴ These data have not been confirmed in NCPF patients. In our recently reported experience of primary prophylaxis using beta-blockers or EVL, both modalities were found to be comparable and efficacious, even in non-cirrhotic patients, although the number of NCPF patients in each group was small.⁵⁵ Gastric varices are seen in nearly one-quarter of NCPF patients, more often than

that seen in cirrhotic patients.⁵⁶ These varices can often be managed with cyanoacrylate glue injection and rarely require surgical intervention.⁵⁷

Interventional radiological procedures have been reported to be effective in IPH patients. These include splenic embolization, percutaneous transhepatic obliteration and transjugular intrahepatic portosystemic shunt (TIPS) procedure.⁵⁸ We have also performed a TIPS in three NCPF patients with gastric varices and the shunt remained patent at 12 months post-procedure.

Surgery has been reported to be an effective alternative to endoscopic therapy, especially in patients who fail to respond to endoscopic therapy.⁵⁹ Surgery is also indicated for patients with symptomatic hypersplenism–spontaneous bleeding episodes or severe anemia requiring transfusion or repeated splenic infarcts. In those patients who hail from far-flung areas or who desire one-time treatment, elective shunt surgery is a reasonable option. The most important cause of death in NCPF or IPH patients is exsanguinating hemorrhage. Prophylactic devascularization has been advocated by certain Japanese workers.²³

Surgical mortality after emergency shunts is approximately 10%. Shunt occlusion, overt chronic portosystemic encephalopathy and rebleeding after elective shunt surgery are seen in approximately 10% of patients.^{60,61} The morbidity and mortality after shunt surgery and the limited expertise available to perform these procedures have restricted the use of surgery in the management of patients with NCPF. Recently, development of membranoproliferative glomerulonephritis and other renal anomalies have been reported following shunt surgery in NCPF patients.³⁴

PROGNOSIS

The prognosis for patients with NCPF is excellent. The mortality from an acute bleed in NCPF is significantly lower than that observed in cirrhotic patients.²³ After successful eradication of esophagogastric varices, a 2- and 5-year survival of nearly 100% has been observed in

these patients. If these patients are managed with selective shunt surgery, shunt occlusion and post-shunt encephalopathy may cause some morbidity, but dietary manipulations (protein restriction) can ameliorate the symptoms to a large extent.

CONCLUDING REMARKS

Non-cirrhotic portal fibrosis continues to be a common cause of PHT in selected geographic areas of the world, especially in socially disadvantaged people. The etio-pathogenesis of this condition is possibly multifactorial. The clinical presentation of patients is with splenomegaly and/or complications of PTH. The patients have a relatively well-preserved liver function. The diagnosis is based on clinical and endoscopic evidence of PHT, as well as radiological and histological features. If managed suitably, these patients have a life expectancy similar to that of the population at large. Future research should aim to elucidate pathogenetic mechanisms so that the condition can be effectively prevented.
