# Overview

There is a need for safer and improved methods for non-invasive imaging of the gastrointestinal tract. Modalities based on X-ray radiation, magnetic resonance and ultrasound suffer from limitations with respect to safety, accessibility or lack of adequate contrast. Functional intestinal imaging of dynamic gut processes has not been practical using existing approaches. Here, we report the development of a family of nanoparticles that can withstand the harsh conditions of the stomach and intestine, avoid systemic absorption, and give rise to good optical contrast for photoacoustic imaging. The hydrophobicity of naphthalocyanine dyes was exploited to generate purified ~20 nm frozen micelles, which we call nanonaps, with tunable and large near-infrared absorption values (>1000). Unlike conventional chromophores, nanonaps exhibited non-shifting spectra at ultrahigh optical densities and, following oral administration in mice, passed safely

through the gastrointestinal tract. Non-invasive, non-ionizing photoacoustic techniques were used to visualize nanonap intestinal distribution with low background and remarkable resolution with 0.5 cm depth, and enabled real-time intestinal functional imaging with ultrasound co-registration. Positron emission tomography following seamless nanonap radiolabelling allowed complementary whole body imaging.

### Introduction

In the United States, digestive diseases are implicated in upwards of 100 million ambulatory care visits annually<sup>1</sup> and improved imaging approaches could offer significant benefit. Capsule endoscopy, enteroscopy, magnetic resonance imaging, computed tomography, X-rays and ultrasound are presently used for assessing gastrointestinal (GI) conditions.<sup>2</sup> Functional imaging of intestinal motor patterns such as peristalsis and segmentation is not usually performed due to lack of accessible, effective, and non-invasive methods. Intestinal motility dysfunction is implicated in diseases such as small bowel bacterial overgrowth<sup>3</sup>, irritable bowel syndrome<sup>4</sup>, inflammatory bowel disease<sup>5</sup>, and constipation<sup>6</sup>. Motility disorders present serious side effects in numerous diseases including thyroid disorders<sup>7</sup>, diabetes<sup>8</sup> and Parkinson's<sup>9</sup>. In order to provide appropriate treatment and to evaluate effectiveness, the existence of and nature of motor disturbances should be known; but current approaches are by trial and error. In preclinical studies, motility and peristalsis are conventionally assessed by ex-vivo measurements. New imaging techniques that safely and non-invasively assess anatomic and functional imaging will lead to better diagnosis and treatment of gut diseases.

Photoacoustic (PA) imaging is a non-ionizing modality with deeper penetration than other optical methods.<sup>10–13</sup> Instrumentation costs are low and the systems are small and modular with potential to become widely accessible for routine clinical probing of chronic and acute GI conditions. PA imaging is a data-rich, inherently real-time modality suitable for imaging dynamic intestinal processes such as peristalsis and segmentation without spatial resolution sacrifice. Additionally, PA imaging is a safe, non-invasive and non-ionizing modality, which matches the preferred characteristics of GI imaging, especially in the case of paediatric patients.<sup>14</sup> PA techniques are particularly useful for imaging exogenous near-infrared (NIR, 650–1000 nm) contrast agents.<sup>15,16</sup> Any luminal GI contrast agent should avoid systemic absorption into the body, since the subsequent loss of contrast agent from the intestine would lead to signal reduction, interfere with quantitative measurements and introduce toxicity concerns. Finally, a contrast agent should not degrade in the harsh chemical and digestive environments of the stomach and intestine.

# Formation of frozen naphthalocyanine micelles

Chromophores of varying hydrophobicity were examined to determine whether they spontaneously assembled into stable nanoparticles following dilution into a biocompatible surfactant. Pluronic (poly(oxyethylene)-poly(oxypropylene)-poly(oxyethylene); PEO-PPO-PEO) F127 was selected because it is approved by the United States Food and Drug Administration (FDA) for oral consumption.<sup>17</sup> To examine chromophore-F127 complex stability, the solutions were then dialyzed against the bile surfactant sodium cholate, which

can pass through dialysis tubing due to its small micelle size. As shown in Fig. 1a, dyes that were very hydrophobic based on the octanol-water partition coefficient (LogP values, predicted with the ALOGPS algorithm<sup>18</sup>) exhibited high retention after dialysis so did not readily exchange with the large excess of cholate micelles. Of the dyes evaluated, phthalocyanine (Pc) and naphthalocyanine (Nc) derivatives (Fig. 1b), which are characterized by their tetrapyrrole structure and extreme hydrophobicity, were nearly fully retained. The presence of a strongly colourful supernatant after centrifugation to remove any aggregates implied the formation of soluble nanoformulated naphthalocyanines (nanonaps). The yield of nanonaps increased with increasing F127 concentrations (Supplementary Fig. 1). No sharp increase in nanonap yield was observed above the critical micelle concentration (CMC) of F127 (~1 % at room temperature),<sup>19</sup> implying a nanonap formation mechanism unrelated to unimer-micelle equilibrium.

Because F127 has a temperature-sensitive CMC,<sup>20</sup> we examined the effects of lowering the solution temperature to convert micelles to F127 unimers. Reducing the temperature to 4 °C did not result in any Nc aggregation, which can be explained by the formation of the frozen micelles. This enabled a novel strategy for the removal of all excess F127 (Fig. 2a). As shown in Fig. 2b, centrifugal filtration removed all free F127 at 4 °C, but the process was ineffective at 25 °C, as detected using a previously reported colourimetric assay (Supplementary Fig. 2)<sup>21</sup>. CMC switching did not affect the self-assembly of nanonaps, which were quantitatively retained during the 4 °C washing process (Fig. 2c). All free surfactant was removed from the nanonaps with 3 low temperature wash cycles and no further change in contact angle was observed with additional washing (Supplementary Fig. 3). Unlike nanonaps, methylene blue (MB), a dye employed for PA applications, was completely removed from the retentate following 3 centrifugal filtration washes.

The nanoparticles formed 20 nm spheres (Fig. 2d, 2e). Because the CMC switching process removed all excess F127, the well-dispersed nanonaps could be concentrated to high dye to F127 molar ratios (>3:1 dye:F127, see Supplementary Table 1). We prepared 2 mg of Nc dye either in a nanonap or a liposomal formulation, using dimyristoylphosphatidylcholine (DMPC) in a 19:1 lipid:dye molar ratio. Following initial solubilization, the solutions were freeze-dried and reconstituted in a minimal volume of water (50  $\mu$ L). As shown in Fig. 2f, concentrated nanonaps dissolved in water, as evidenced by the extreme Nc NIR absorption of approximately 1000. However, after the freeze-dried liposomes were reconstituted, some Nc re-solubilization was observed but it was orders of magnitude lower than the nanonap formulation. Since CMC switching dramatically reduces the total amount of F127 surfactant present, nanonaps could be reconstituted at a much higher concentration. The phospholipid amounts required for Nc solubilization could not analogously be decreased via CMC switching, and following freeze-drying and further concentration during reconstitution, the phospholipid concentration was above the solubility limit. Difficulty in encapsulation could be further impacted by amorphous precipitation of the Nc during solvent removal.

Since nanonaps could be generated from a range of hydrophobic Pc and Nc chromophores (Fig. 1a), we set out to identify a subset with spectral properties spanning the NIR window. Different commercially available Pc and Nc dyes were screened using the CMC switching method to generate pure nanonaps (Supplementary Fig. 4). Dye extinction coefficients

ranged from  $1.0-2.2 \times 10^5 \text{ M}^{-1} \text{ cm}^{-1}$  in organic solvents, whereas in nanonap form these decreased to  $0.4-1.5\times 10^5 \text{ M}^{-1} \text{ cm}^{-1}$  (Supplementary Table 1). This suggests the dense arrangement of Ncs in nanonaps led to altered electronic properties and intermolecular interaction, which was further supported by full fluorescence self-quenching of aqueous nanonaps (Supplementary Fig. 5). Powder diffraction analysis of freeze dried samples did not reveal any presence of crystalline Nc within the nanonaps, showing the dyes were probably embedded with F127 without organized stacking (Supplementary Fig. 6). It is assumed that the nanonap interior is an amorphous blend of the dyes and hydrophobic F127 PPO blocks. However, since structural studies have shown the gyration radius of F127 PPO blocks is only 1.6 nm<sup>22</sup>, and given the contiguous nature of PEO-PPO-PEO blocks, the interior of the nanonaps may also contain a small portion of hydrophilic PEO, which would segregate from the more hydrophobic Nc and PPO. The aqueous-facing shell of nanonaps is presumed to be composed exclusively of PEO. Further studies are required to gain deeper insight into the nanonap formation mechanism.

1 Pc and 3 Nc dyes were identified that gave rise to nanonaps with peaks at 600, 707, 793 and 863 nm (Fig. 3a, b). The nanonaps generated absorption spanning the NIR spectrum while maintaining reasonably narrow full-width half-maxima (50-100 nm). Since PA imaging can resolve multiple absorption wavelengths<sup>23</sup>, multi-wavelength classes of nanoparticles are desirable.<sup>24</sup> The PA spectral response of nanonaps aligned with their absorption spectra (Supplementary Fig 7). The nanoparticles could be concentrated into fully soluble solutions with absorptions of greater than 1000. One advantage of nanonaps compared to free dyes was that upon concentration, absorption peak positions displayed negligible shifting (Fig. 3c). This was assessed by measuring absorption of a concentrated solution (~1000 optical densities (OD)/mL) in a 10 µm path length, and then measuring a 1000 fold dilution of the same solution in a 1 cm path length. The commonly used PA dyes MB and indocyanine green exhibited large absorption shifts in concentrated solutions, as a result of modulated electronic properties induced by self-interaction encountered at high concentration. On the other hand, Ncs co-assembled with F127 in the nanonap matrix exhibited no modified peak absorption shifts, demonstrating that nanonaps prevented concentration-dependent dye interaction that would otherwise affect absorption at higher concentrations. Although concentration-dependent absorption shifts can be useful in PA imaging<sup>25</sup>, concentration-independent optical parameters lead to simplified analysis of contrast movement, as would be the case for GI-photoacoustic tomography (PAT). Based on zeta potential measurements, nanonaps maintained a nearly neutral surface charge over a broad range of pH values (Supplementary Fig. 8).

Absorbance, as measured on a spectrophotometer, includes effects of both absorption and scattering. However, only absorption contributes to the photoacoustic effect. Resonance light scattering was used to estimate scattering. Compared to extinction-matched gold nanorods, nanonaps exhibited negligible scattering (Supplementary Fig. 9). This is in accordance with previous reports of tetrapyrrole-based nanoparticle scattering.<sup>26</sup> Since the reference nanorods had a low scattering component. Based on the molar ratio of Nc to F127 in the purified nanonaps and geometric calculations, we estimated that each 5,9,14,18,23,27,32,36-Octabutoxy-2,3-naphthalocyanine (ONc) nanonap contains 501

molecules of Nc and 155 molecules of F127, with an optical cross section of  $2.9 \times 10^{-17}$  m<sup>2</sup>. Additional optical parameters are reported in Supporting Table 1. Although this cross section is two orders of magnitude lower than that of nanorods, the unique dispersibility of nanonaps enables them to be concentrated to orders-of-magnitude higher particle density while maintaining solubility. As a result, stable nanoparticle solutions are achievable with overall absorptions greater than 1000.

# Photoacoustic gut imaging

To assess the suitability of nanonaps for use as an orally administered PA agent, we determined if nanonaps could withstand the harsh conditions of the stomach and intestine, which often pose hurdles for nanoparticles.<sup>28</sup> When nanonaps were dialyzed in simulated gastric fluid (SGF) or simulated intestinal fluid (SIF) at 37 °C, no appreciable loss of absorption was observed, demonstrating stability in harsh dialysis conditions (Fig. 4a). In contrast, wavelength-matched gold nanoparticles stabilized by either residual cetrimonium bromide (CTAB) or by thiolated polyethylene glycol (PEG) did not withstand the same dialysis conditions and rapidly aggregated (Supplementary Fig. 10). In water, 1.2 mg/mL ONc nanonaps generated over one hundred time greater photoacoustic signal than concentration-matched and wavelength-matched gold nanorods (Supplementary Fig. 11). Semiconducting organic nanoparticles also have been reported to generate more photoacoustic contrast than gold at matching mass concentrations.<sup>29</sup>

The cellular toxicity of ONc nanonaps was assessed using Caco-2 cells. Whereas MB induced toxicity when incubated in cell media with absorbance greater than 1, nanonaps did not exhibit any toxicity up to absorbance of 100, the highest value tested (Supplementary Fig. 12). Encouraged by these results, we administered 100 ODs of ONc nanonaps via gavage to mice. Nanonaps were completely excreted in the faeces (Fig. 4b). The lack of intestinal absorption likely stemmed from both the 20 nm size of the nanonaps which prevents passive diffusion through membranes, and the PEO character of F127, which prevents bioadsorption<sup>30</sup>. For comparison, 100 ODs of MB was administered in the same manner. MB was systemically absorbed and was detectable in urine, with most of the MB remaining in the body or getting metabolized (Fig. 4c).

The effect of nanonaps on intestinal tissues was examined using histology (Fig 4d). No noticeable inflammatory response or damaging effects were induced and intestinal villi and crypts appeared healthy. Given the safety of nanonaps predicted by their quantitative excretion and lack of systemic absorption, we next assessed the acute toxicity of nanonaps using an oral dose of 50,000  $OD_{860}$ /kg. This represents a 10 fold excess of the functional nanonap dose used for imaging applications. There were no adverse behavioural or weight changes in male or female mice over the two week study (Supplementary Fig. 13a). Histology revealed no systemic (Supplementary Fig. 13b) or gastrointestinal (Supplementary Fig. 13c) toxicity.

We next examined the utility of nanonaps for non-invasive PAT of the intestine in vivo. As shown in Fig. 5a, PA imaging using a custom-built single-element scanning system revealed the biodistribution of nanonaps in the GI tract with 100 µm axial resolution. Progression of

Zinc-2,11,20,29-Tetra-tert-butyl-2,3-naphthalocyanine (ZnBNc) nanonaps through the intestine was clearly observed. Negligible background was detected, enabling clear resolution of intestinal features and individual small bowel diverticula were distinguishable. Depth encoding analysis revealed further spatial details of intestinal distribution with depth mapping to 5 mm (Fig. 5b). Strong isoflurane anesthetization (3% v/v) halted intestinal motility (Supplementary Fig. 14). This was fortuitous since each high-resolution, whole-abdomen scan took upwards of 30 minutes to perform. Although lower resolution and smaller scanning areas would reduce scan times, single element transducer approaches are not ideal for data-rich functional imaging of dynamic intestinal processes.

For dynamic imaging, a Vevo LAZR transducer array system was used. 100 ODs of ONc nanonaps were administered via gavage. As shown in the transverse slice in Fig. 5c, PA (colour) overlaid perfectly with US (grey) to reveal nanonap distribution in intestine below the stomach surface with minimal background. The 5 frames per second scanning speed enabled detailed tracking of nanonap movement in the intestine. Rapid changes in nanonap flow were readily apparent (Fig. 5d) and detailed peristaltic movements were clear (Supplementary Movie 1). By selecting a region of interest that displayed undulating nanonap content, segmentation or peristaltic flow was quantified. Flow of nanonaps into a representative region of interest occurred periodically with distinct inflow and outflow movements (Fig. 5e). Calculation of the rate of peristaltic intestinal flow shown in Fig. 5f demonstrated contractions close to 30 per minute, which is consistent with values reported in mice.<sup>31</sup>

By examining US co-registration, intestinal nanonap distribution was mapped to anatomical features. As shown in Fig. 5g, bladder and kidneys were identified with US and the relative position of adjacent intestinal nanonaps changed over time. Two US/PA maximum intensity projection (MIPs) were generated from a stack of scans that trace the movement of nanonaps through the intestine over a 30 minute period (Fig. 5h). The MIP is useful to provide intestinal orientation in any given individual transverse slice. The indicated regions of interest showed, in real time, the out-of-plane passing of nanonaps through a transverse slice of the intestine. Compared to control regions "B" and "C", containing relatively constant nanonap volumes, nanonaps quantitatively exited from region "A" over one minute and exhibited peristaltic contractions in the process.

Small bowel obstructions cause 300,000 operations annually in the United States.<sup>32</sup> To determine whether US/PA imaging could be useful for detecting intestinal obstructions, we used a surgically-induced duodenal ligation mouse model.<sup>32</sup> Following duodenal ligation or sham treatment (opening the abdomen but omitting the ligation), the abdomen was sutured closed. The mice were then administered a 100  $OD_{860}$  dose of ONc nanonaps and imaged one hour post-gavage. The stomachs of the mice with obstructions visibly swelled to a large volume. US transverse slices showed a prominent void stomach volume in the ligated mice, but not the sham-treated ones (Fig. 5i, top). Although US could distinguish the bloated stomach of the obstructed mice, the PA signal was barely detectable. The enlarged stomachs of the obstructed mice contained large pockets of air that may have caused PA attenuation and further investigation into this phenomenon is required. In the obstructed mice, barely any PA signal was detected over the entire intestinal area (Fig 5i, bottom) However, sham-

treated mice displayed a strong PA signal, demonstrating that nanonaps progressed uninhibited through the intestine. Thus, nanonaps may be useful as a diagnostic tool for detection of small bowel obstructions.

Based on their high absorption, both ZnBNc (707 nm) and ONc nanonaps (860 nm) were suitable for low-background GI PA imaging. The selection of optimal nanonap wavelength is case-dependent. For example, many tunable lasers currently used in photoacoustic instrumentation generate higher laser output at 707 nm, whereas 860 nm may have less intrinsic biological background and scattering. In chicken breast tissue, absorbance-matched ONc and ZnBNc nanonaps could both easily be detected up to 2.5 cm in depth, with similar photoacoustic signal-to-noise ratios (Supplementary Fig. 15). The pulse energies used were only 2 and 1.5 mJ/cm<sup>2</sup>, corresponding to only ~1/10 and ~1/30 of the laser safety limits for ZnBNc and ONc nanonaps wavelengths respectively.

# Positron emission tomography

Although PA technology is rapidly improving, deep tissue (>5 cm) PA imaging is yet to be reported in humans. Since positron emission tomography (PET) is clinically used for non-invasive whole body imaging, we examined nanonap-based PET imaging as a complementary technique. The 4 pyrrole nitrogens within the Nc macrocycle can coordinate with copper to serve as a chelator<sup>33</sup> and it has been shown that the positron emitter <sup>64</sup>Cu can be used to conveniently label intact tetrapyrrole-based nanoparticles.<sup>34</sup> Because nanonaps are formed from Ncs themselves, no additional steps of chelator conjugation are required.

When nanonaps were incubated with  $^{64}$ Cu in aqueous solution, labelling was achieved in just 30 minutes with over 65 % radiolabelling yield (Fig. 6a and Supplementary Table 2). Size and zeta potential were unaffected (Supplementary Fig. 16). Following the removal of free copper, when  $^{64}$ Cu-nanonaps were incubated in SIF and SGF at 37 °C, the chelation was stable in vitro (Fig. 6b). A 100 OD<sub>860</sub> dose of radiolabelled ONc nanonaps was then gavaged (7.4 MBq per mouse). Gamma counting validated that faecal clearance of  $^{64}$ Cu-nanonaps followed the same kinetics as the unlabelled ones (Supplementary Fig. 17). 99% of nanonaps were excreted in faeces, compared to 85% of the  $^{64}$ Cu radiolabel (Fig. 6c). This discrepancy was likely due to the displacement of some of the copper from the Nc chelate in the harsh GI environment. Minimal radioactivity remained in any part of the mouse, with all organs retaining less than 1.5 % ID/g of  $^{64}$ Cu (Fig. 6d). Since they were cleared in faeces, nanonaps themselves were not detected in any organs, except for a small trace amount remaining in the intestine.

PET was used to follow the movement of nanonaps through the GI tract. Radioactivity was present in the stomach and upper intestine after oral gavage, as can be seen from the PET images at 0.5 hours (Fig. 6e). A clear distribution pattern of <sup>64</sup>Cu-nanonaps in the intestine was observed 3 hours after administration. Since PET is tomographic with no tissue penetration limits, serial whole-body consecutive coronal slices of the mouse could be obtained (Fig. 6f). Tomographic analysis revealed background-free intestinal visualization in three dimensions (Supplementary Movie 2).

# Conclusion

Owing to high Nc hydrophobicity, kinetically-frozen nanonaps could be formed that are stable in the gut, avoid systemic absorption, and give rise to extreme and tunable optical absorption in the NIR. They are organic, assembled from an FDA-approved surfactant, and are completely excreted in faeces without observed toxicity. Real-time US/PA gut imaging using nanonaps provided for high resolution, low-background, real-time proof-of-principle mapping of intestinal anatomy, pathology and function. Additionally, direct use of nanonaps for PET enables quantitative, sensitive, clinically-established imaging approaches with full tissue penetration for whole body imaging. The spatial resolution limitations of PET (a few mm) can be compensated with localized PAT techniques using a single agent. Beyond GI imaging, based on their multimodal nature, stability and small size above the renal clearance threshold, nanonaps also hold potential for use as an intravenously administered contrast agent. Future directions of research may include modifying nanonap surface properties for targeted detection and examining multi-colour PA imaging for diagnosis of gut diseases.

# Methods

See Supporting Information for full methods. Materials were from Sigma unless otherwise noted.

#### Nanonap formation

LogP values were evaluated using the ALOGPS 2.1 algorithm. 2 mg of dyes were dissolved in organic solvent and added to 10 mL Pluronic F127 (10% w/v) and stirred until organic solvent evaporation. After centrifugation to remove aggregates, 100  $\mu$ L of the supernatant was diluted in 3 mL of 20 mM sodium cholate and dialyzed for 24 hours against 20 mM sodium cholate. Retention was based on absorbance. For nanonap formation, 2 mg of dye was dissolved in 1 mL dichloromethane and added to an F127 solution as above. To remove unincorporated F127 via CMC switching, the clarified solution was cooled on ice and subjected to centrifugal filtration (Fisher #UFC9-100-24) at 4 °C until 200  $\mu$ L of solution was retained. Water was added back to the concentrate and the washing procedure was repeated three times.

#### Nanonap physical and optical properties

Size and zeta potential measurement were carried out with dynamic light scattering using a Nano ZS90 Zetasizer (Malvern Instruments). Transmission electron microscopy was performed using a JEM-2010 electron microscope with 1 % uranyl acetate staining. Absorbance was measured with a Lambda 35 UV/VIS spectrophotometer (Perkin Elmer) using cuvettes with 1 cm path lengths, except for the high-concentration spectral shifting analysis which used 10 µm path length cuvettes. X-ray diffraction analysis was carried with freeze dried samples on a Rigaku Ultima IV. Scattering and fluorescence properties were assessed using a spectrofluorometer (Photon Technology International).

To assess the stability of nanonaps in SGF and SIF, concentrated nanonaps were diluted into the fluids so that the absorbance was close to 1, then dialyzed at 37 °C against SGF (Ricca, #7108-32) with added pepsin and pancreatin-containing SIF (Ricca #7109-32). 860 nm

CTAB stabilized gold nanorods and 850 nm thiol-PEG-stabilized gold nanorods (NanoRods LLC, #C122-CTAB and C120-PEG) were dialyzed in the same manner.

#### Nanonap clearance and toxicity

Animal experiments were performed in accordance with the University at Buffalo Institutional Animal Care and Use Committee. 6 weeks female BALB/c mice (Harlan) were held without food overnight with free access to water. After gavaging 100 ODs of ONc nanonaps or methylene blue, mice were transferred to metabolic cages and faeces and urine were collected separately. For determination of recovery, the absorbance of urine or serum samples was measured directly. Tissues or faeces were dissolved in 2 mL of organic solvent and were disrupted until the dyes were dissolved completely and absorbance was assessed. For acute toxicity, 6 week old male and female BALB/c mice were gavaged 1000 OD<sub>860</sub> of ONc nanonaps per 20 g or kept as controls (n=5 per group). Behaviour was monitored and mass was measured weekly. After 2 weeks, mice were sacrificed and organs were harvested. Organs were immersed in formalin (VWR #16004-114) prior to sectioning and haematoxylin and eosin staining.

#### Photoacoustic experiments

A custom-built, reflection-mode single-element transducer PAT system was used for high resolution scanning imaging. A Vevo LAZR US/PA system was used for real-time imaging. The movement of nanonaps in the digestive system was monitored after gavage of 100 ODs of the indicated nanonaps in female BALB/c mice. Region of interest analysis was performed with the system software. Rate of peristaltis was determined by derivative analysis of region-of-interest intensity. For intestinal obstruction, 12–14 g female CD-1 mice (Harlan) were used with n=3 per group. The abdomen was opened with a 1 cm transverse incision near the stomach and the duodenum was ligated with nylon sutures (VWR #89219-096). Sham-treated mice had no duodenum ligation performed, but otherwise it was an identical procedure. The abdomen skin was sutured closed again and within a few hours, mice were administered a 100 OD<sub>860</sub> dose of ONc nanonaps by gavage. 1 hour later, the mice were anesthetized and imaged with the Vevo LAZR system.

#### **Radiolabelling experiments**

For labelling, 37 MBq of <sup>64</sup>CuCl<sub>2</sub> was diluted in 300  $\mu$ L of 0.1 M sodium acetate (pH 5.5) and added to 400 OD<sub>860</sub> ONc nanonaps for 30 minutes at 37 °C. The <sup>64</sup>Cu-nanonaps were purified by centrifugal filtration and re-suspended in 500  $\mu$ L of PBS for further use. For in vitro stability, one OD<sub>860</sub> of <sup>64</sup>Cu-nanonaps was re-suspended in 1 mL of SGF or SIF and incubated at 37 °C with stirring. Portions of the mixture (50  $\mu$ L) were sampled at different time points and washed by centrifugal filtration for analysis. Radioactivity was measured by a Wizard2 gamma counter (Perkin Elmer).

PET scans were performed using an Inveon microPET/microCT rodent model scanner (Siemens). After overnight fasting, each BALB/c mouse was gavaged ~7.4 MBq of <sup>64</sup>Cu-nanonaps (100 OD<sub>860</sub>). 5–10 minute static PET scans were performed at various time points post-injection. Images were reconstructed using a maximum a posteriori algorithm without

scatter correction. After 24 hours mice were euthanized and biodistribution was measured with gamma-counting.

Figure 1. Spontaneous formation of non-exchangeable F127-naphthalocyanine frozen micelles a) Retention of dyes of varying hydrophobicity added to an aqueous solution of 10% (w/v) F127 and then dialyzed against 20 mM cholate for 24 hours. MB=Methylene blue, QR=Quinaldine Red, 6G=Rhodamine 6G, IR780=IR780 iodide. b) Chemical structure of napthalocyanines used. BNc:  $X_1=2H$ ;  $X_2=t$ -Bu;  $X_3, X_4=H$ . VBNc:  $X_1=V=O$ ;  $X_2=t$ -Bu;  $X_3, X_4=H$ . ZnBNc:  $X_1=Zn$ ;  $X_2=t$ -Bu;  $X_3, X_4=H$ ; ONc:  $X_1=2H$ ;  $X_2=t$ ;  $X_3, X_4=O$ -(CH<sub>2</sub>)<sub>3</sub>CH<sub>3</sub>. Phthalocyanines lack outer benzenes: BPc:  $X_1=2H$ ;  $X_2=t$ -Bu;  $X_3, X_4=H$ . VBPc:  $X_1=V=O$ ;  $X_2=t$ -Bu;  $X_3 = N(CH_3)_2$ ,  $X_4=H$ .

Zhang et al.

#### Figure 2. Temperature-mediated CMC switching to generate surfactant-free nanonaps

a) Generation of purified nanonaps. F127 PEO blocks are shown in blue, PPO blocks in black and Nc dyes in red.
b) F127 retention as a function of centrifugal filtration washes at 4 °C (black) and 25 °C (red). Mean +/- std. dev. for n=3.
c) F127-solubilized dye retention as a function of centrifugal filtration washes at 4 °C for Nc (black) and methylene blue (red). Mean +/- std. dev. for n=3.
d) Nanonap size distribution by dynamic light scattering in water.
e) Negative-stained transmission electron micrograph of dried nanonaps. Scale bar, 50 nm.
f) Equivalent absorbance from concentrated, reconstituted nanonaps (black) or liposomes (red, 1:19 molar ratio Nc:lipid) following freeze drying of nanoparticles formed with 2 mg of ONc. Inset shows magnified liposomal absorbance.

**Figure 3. Multispectral nanonaps without peak wavelength shifting at ultrahigh optical densities a)** Normalized absorbance of nanonaps formed from BPc (blue), ZnBNc (dark green), BNc (light green) or ONc (bronze). **b**) Photograph of nanonaps in water. From left to right: BPc, ZnBNC, BNc and ONc. **c**) Absorption peak wavelength shift at high optical densities. Concentrated solutions were measured in a 10 µm path length cuvette and compared to a 1000 fold dilution in water. Indicated nanonaps are compared to indocyanine green (ICG) and methylene blue (MB). Mean +/– std. dev. for n=3.

Zhang et al.

**Figure 4.** Nanonaps pass safely through the intestine following oral administration **a)** Retention of ONc nanonaps dialyzed in simulated gastric fluid (red) or simulated intestinal fluid (black) at 37 °C. Mean +/– std. dev. for n=3. **b**) Excretion of 100 ODs of ONc nanonaps in faeces (black) and urine (red). Mean +/– std. dev. for n=3 mice. **c**) Excretion of 100 ODs of methylene blue (MB) in faeces (black) and urine (red). Mean +/– std. dev. for n=3 mice. **d**) Haematoxylin and eosin-stained intestine section of a control mouse (left) or a mouse 24 hours after gavage of 100 ODs of ONc nanonaps (right). Villi and crypts were intact without influx of inflammatory cells. Scale bar, 100 μm.

Zhang et al.

**Figure 5.** Non-invasive anatomical and functional PA imaging of the intestine using nanonaps **a**) PA maximum intensity projection (MIP) of nanonaps following gavage of 100 ODs of ZnBNc nanonaps using a single transducer PA system. Red arrows show nanonap transit. **b**) Depth-encoded PA MIP of the intestine visualizing ZnBNc nanonaps. **c**) Real-time multimodal mouse intestinal transverse plane with PA signal (colour) and simultaneous US (grey) acquisition following gavage of 100 ODs of ONc nanonaps. **d**) Nanonap movement in the intestine. Black arrow shows inflow and white arrow shows outflow. **e**) Intestinal region of interest analysis. First derivative zero-crossings provide the time of maximal

nanonap inflow (black triangles) and outflow points (grey triangles). **f**) Rate of contractile motion from the region, plotted over time. **g**) Co-registered US for anatomical mapping of nanonaps. The bladder (B) and kidneys (K) are located with US (grey), while nanonap PA signal is shown in colour. **h**) US (grey)/PA(colour) MIPs of transverse slices show ONc nanonap intestinal transit over time. The MIP was used to orient the PA signal within a single slice of interest (lower left). Outflow quantification over time of nanonaps in area "A" (red) is shown in reference to two others that maintained steady nanonap content in "B" (blue) and "C" (grey). The fluctuations in "A" are due to contractile inflow and outflow of nanonaps. **i**) US/PA detection of intestinal obstruction. Mice were subjected to duodenal ligations or sham surgery. 100 ODs of ONc nanonaps were administered and mice were imaged 1 hour later. The top shows a transverse slice 2.4 cm above the bladder, showing the swollen stomach in the obstructed mice. The bottom shows US/PA MIPs. Unobstructed flow of nanonaps is clear in the sham group. The dashed line indicates approximate surgical incision site and the image width corresponds to 2.4 cm. Representative images for n=3 per group. Solid scale bars, 5 mm where indicated.

Zhang et al.

Figure 6. Seamless nanonap labelling with <sup>64</sup>Cu for whole body PET imaging of the GI tract a) Nanonap labelling using <sup>64</sup>Cu. F127 PEO blocks are shown in blue, PPO blocks in black, Nc dyes in red and <sup>64</sup>Cu is shown as the radioactive yellow circle. b) Retention stability of <sup>64</sup>Cu chelation in radiolabelled nanonaps in simulated gastric fluid (red), simulated intestinal fluid (blue) and water (black) incubated at 37 °C. Mean +/– std. dev. for n=3. c) Faecal clearance of ONc nanonaps and chelated <sup>64</sup>Cu in mice 24 hours after gavage of 100 ODs of ONc nanonaps. <sup>64</sup>Cu was assessed using gamma counting and nanonaps using absorption. Mean +/– std. dev. for n=3–4 mice d) Biodistribution of <sup>64</sup>Cu and nanonaps 24 hours after gavage. No data ("N.D.") was obtained for some organs since they were not measured. Mean +/– std. dev. for n=3–4 mice. e) Representative PET imaging of nanonaps. 100 ODs of <sup>64</sup>Cu-labelled ONc nanonaps were gavaged and mice were imaged at the

indicated time points. Scale bar, 1 cm. **f**) Representative 0.8 mm thick coronal slices through the mouse, 3 hours after gavage.
