**Abstract.** The Atlantic meridional overturning circulation (AMOC) has been observed continuously at 26° N since April 2004. The AMOC and its component parts are monitored by combining a transatlantic array of moored instruments with submarine-cable-based measurements of the Gulf Stream and satellite derived Ekman transport. The time series has recently been extended to October 2012 and the results show a downward trend since 2004. From April 2008 to March 2012, the AMOC was an average of 2.7 Sv (1 Sv = 10<sup>6</sup> m<sup>3</sup> s<sup>-1</sup>) weaker than in the first four years of observation (95 % confidence that the reduction is 0.3 Sv or more). Ekman transport reduced by about 0.2 Sv and the Gulf Stream by 0.5 Sv but most of the change (2.0 Sv) is due to the mid-ocean geostrophic flow. The change of the mid-ocean geostrophic flow represents a strengthening of the southward flow above the thermocline. The increased southward flow of warm waters is balanced by a decrease in the southward flow of lower North Atlantic deep water below 3000 m. The transport of lower North Atlantic deep water slowed by 7 % per year (95 % confidence that the rate of slowing is greater than 2.5 % per year).

## 1 Introduction

The poleward transport of heat in the sub-tropical North Atlantic has been shown (Johns et al., 2011) to be highly correlated with the Atlantic meridional overturning circulation (AMOC). One petawatt (PW = 10<sup>15</sup> W) of heat carried by the AMOC is released to the atmosphere between 26° N and 50° N and has important impacts on the climate of the North Atlantic region (e.g. Srokosz et al., 2012). The AMOC varies on a range of timescales (e.g. Eden and Willebrand, 2001; Kanzow et al., 2010) and is thought to have played a key role in rapid climate change in the past (Ganopolski and Rahmstorf, 2001). Model simulations predict a decrease of the AMOC in the 21st century in response to increasing greenhouse gases (IPCC, 2007). Decadal-scale changes in the AMOC have been associated with the Atlantic multidecadal oscillation in climate simulations (Knight et al., 2005) and are thought to have impacts on surface temperature, precipitation and sea level in regions bordering the ocean (Delworth and Mann, 2000). The role of the AMOC in climate has motivated oceanographers to quantify its strength and variability.

The first observational estimates of the basin-wide AMOC were based on transatlantic hydrographic sections (Bryden and Hall, 1980; Roemmich and Wunsch, 1985). These observations provided important information about the structure and magnitude of the AMOC, but, with only a handful

of these snapshots, insight into the variability was limited. To quantify the variability it was proposed in the early 2000s to establish a dedicated observing system to make continuous measurements of the variability of the AMOC at 26° N (Cunningham et al., 2007). Early results highlighted the seasonal and shorter scale variability and enabled the quantification of the error bars for the hydrographic snapshot measurements (Kanzow et al., 2010).

Inter-annual AMOC variability was small compared to the seasonal variation during the first 4 yr of observations, but in 2009–2010 there was a large (30%) downturn in the strength of the AMOC (McCarthy et al., 2012). This caused a reduction in the heat content of the subtropical North Atlantic (Cunningham et al., 2013). Cunningham et al. (2013) suggested that this reduction was the major contributor to low wintertime sea-surface temperatures in the region between 26° N and 41° N. The downturn of 2009–2010 was followed by an anomalously cold winter in NW Europe with strong negative North Atlantic oscillation (NAO) in December 2010. Maidens et al. (2013) noted that the anomalous conditions were predicted by long-range forecasts several months in advance. Using an ensemble of hindcasts, Maidens et al. (2013) concluded that the factor that led to the predictability of this winter was the anomalous upper-ocean heat content and SST. This suggests that the monitoring AMOC at 26° N can provide valuable information for seasonal prediction.

The 26° N RAPID-MOCHA-WBTS program (hereafter referred to as the 26° N program) has thus provided important information about inter-annual, seasonal and shorter term variability of the AMOC but the limited length of the time series has precluded investigation of longer timescales. With the extension of the record to 8.5 yr we now present the first look at multi-year trends in the AMOC at 26° N.

## 2 The calculation of the AMOC

The principles of the calculation of the AMOC volume transport have been described elsewhere (Cunningham et al., 2007; Kanzow et al., 2007). There are three main components to the measurements (Fig. 1). Firstly, the Gulf Stream transport ( $T_{GS}$ ) in the Florida Straits is measured by submarine cable measurements and quarterly hydrographic cruises (Baringer and Larsen, 2001; Meinen et al., 2010). Secondly, the Ekman transport ( $T_{EK}$ ) is determined from atmospheric reanalyses. In the analysis presented here the ERA interim product is used (Dee et al., 2011). Thirdly, an array of moored instruments measures the flow from the Bahamas to the continental shelf off Africa. The mooring array consists of two parts. From the Bahamas to 20 km offshore (76.75° W), current metre moorings make direct estimates of the flow (Johns et al., 2008). East of 76.75° W, an array of dynamic height moorings carrying vertical strings of temperature–salinity–pressure sensors defines the mid-ocean

**Fig. 1.** Schematic diagram illustrating the component parts of the AMOC and the 26° N observing system. Black arrows represent the Ekman transport (predominantly northward). Red arrows illustrate the circulation of warm waters in the upper 1100 m, and blue arrows indicate the main southward flow of colder deep waters. The array of moorings used to measure the interior geostrophic transport is illustrated too.

geostrophic flow to the eastern boundary. The combined transports from the moorings are referred to herein as the internal transport ( $T_{INT}$ ). Geostrophic calculations require a level of known motion, which, for the AMOC calculation, is determined by applying a constraint of zero net mass transport across the section. The additional transport necessary to satisfy this constraint is referred to as the external transport ( $T_{EXT}$ ). While the external transport is defined to satisfy an imposed constraint, this has been independently validated using in situ bottom pressure data (Kanzow et al., 2007; McCarthy et al., 2012). The internal and external transports are combined to give a zonally integrated mid-ocean transport profile as a function of depth. Transport profiles from the Gulf Stream in the Florida Straits and from the basin-wide Ekman layer are added to those from the internal and external transports to get a total transport profile.

$$T(z, t) = T_{GS}(z, t) + T_{EK}(z, t) + T_{INT}(z, t) + T_{EXT}(z, t) \quad (1)$$

Vertical integration of the transport profile results in the volume transport stream function, and the AMOC transport is defined to be the maximum of the stream function. This maximum predominantly occurs around 1100 m. Because the Ekman and Gulf Stream transport both occur shallower than 1100 m (Ekman transport is assumed to be within the upper 100 m and the maximum depth of the Florida Straits is 760 m) we can express the AMOC as the sum of three components

$$MOC(t) = GS(t) + EK(t) + UMO(t), \quad (2)$$

where we define upper mid-ocean (UMO) transport to be the mid-ocean transport above the depth of the maximum of the basin-wide AMOC stream function. This is in effect the volume transport of the southward flowing recirculation of the subtropical gyre less the northward flowing Antilles Current (Meinen et al., 2004).

**Table 1.** Annual averages of the AMOC and its components. Each annual average is for a 12 month period that starts on 1 April of the named year. Also shown are multi-year averages. All values are in Sv. Positive is northward.

Year(s)	AMOC	Ekman	Gulf Stream	Upper mid-ocean	UNADW	LNADW
2004	17.8	3.2	31.8	−17.1	−11.7	−6.9
2005	20.1	3.5	32.0	−15.4	−11.9	−8.5
2006	19.5	4.0	31.6	−16.1	−11.7	−8.1
2007	18.0	3.8	31.6	−17.3	−11.3	−7.0
2008	17.5	4.0	32.2	−18.6	−11.4	−6.7
2009	12.9	2.2	30.7	−20.0	−10.6	−3.5
2010	16.7	3.0	31.0	−17.2	−12.5	−5.2
2011	17.5	4.5	31.1	−18.0	−11.6	−6.5
2004–2007	18.9	3.6	31.8	−16.5	−11.6	−7.6
2008–2011	16.2	3.4	31.3	−18.5	−11.5	−5.5
2008, 2010, 2011	17.2	3.8	31.4	−18.0	−11.8	−6.1

### 3 Results

#### 3.1 Time series

In Fig. 2 we show the time series of the AMOC and its components parts: the Gulf Stream transport, the Ekman transport and the UMO transport as described in the previous section.

Kanzow et al. (2010) showed that there is a clear annual cycle in the AMOC, and therefore to identify long-term trends it is instructive to consider annual average values; these are shown in Table 1. We choose to start annual averages on 1 April. In this way we do not split the winter season; furthermore, the mid-ocean measurements began in April 2004. As highlighted by McCarthy et al. (2012), the year starting April 2009 stands out with a remarkable low in the average value of the AMOC. It is also apparent that the average value of the AMOC in each of the last 4 yr is lower than each of the first 4 yr. If we compare the averages for the periods from April 2004 to March 2008 and from April 2008 to March 2012 then the AMOC is 2.7 Sv lower in the latter period. The 90 % confidence interval<sup>1</sup> (c.i.) for the distribution of possible values (Lindgren, 1993) of the reduction is 0.3 to 5.1 Sv. Thus there is 95 % confidence that the reduction in overturning is 0.3 Sv or more. Reduction in Ekman transport contributes 0.2 Sv to this decrease, and a further 0.5 Sv results from a small slowing of the Gulf Stream, but the major contributor is the strengthening southward flow of the UMO (2.0 Sv).

The year of 2009 alone contributes about 1.0 Sv to the difference between the two halves of the series. It could be argued that this is an extreme inter-annual event rather than a part of decade long trend so we also consider the significance of the changes without this anomalous year. Calculation of

<sup>1</sup>Note that we refer to the 90 % confidence interval as the range between the 5th and 95th percentile of the distribution of possible values. There is 95 % chance that the true value is greater than the 5th percentile of the distribution.

**Fig. 2.** Ten-day (colours) and three month low-pass (black) time series of Gulf Stream transport (blue), Ekman transport (green), upper mid-ocean transport (magenta), and overturning transport (red) for the period 1 April 2004 to 1 October 2012. A dashed black line shows the mean annual cycle for the AMOC. Positive transports correspond to northward flow.

the distribution of possible values indicates that even excluding 2009 the mean of 2008, 2010 and 2011 is lower than mean of 2004, 2005, 2006 and 2007 with 95 % confidence for 5 degrees of freedom. The change in UMO has a similar level of significance but the corresponding changes in Gulf Stream and Ekman transports are not significantly different from zero. Estimated changes and confidence ranges for each of the components are summarised in Table 2.

#### 3.2 Anomalies relative to seasonal cycle

An alternative approach to quantify the trend in the time series is to first remove the mean annual cycle from the data and then fit a trend by linear regression. The mean annual cycle for each component was calculated by fitting a sinusoidal

**Fig. 3.** Anomalies (positive is northward) relative to mean annual cycle. From top to bottom: MOC, Ekman, Gulf Stream, and UMO. A 45-day low-pass filter was applied to each time series. For each time series horizontal dashed lines show  $\pm 2$  standard deviations and the solid black lines show the average trend  $\pm 1.64$  standard errors (i.e. 90 % confidence limits).

function of annual period and two harmonics to the ten-day filtered data. The annual cycle for the AMOC is shown in Fig. 2. The annual cycles were then subtracted from the original data to create de-seasonalized time series; filtered versions of these data are shown in Fig. 3.

Calculation of the standard error of the estimated trend requires an estimation of the number of degrees of freedom in the time series. Several approaches can be used to determine the integral timescale and degrees of freedom. Here we followed Leith (1973) and set

$$\text{Degrees of freedom} = \frac{\text{Length of timeseries}}{2 \times \text{e-folding time of autocorrelation}}.$$

The e-folding timescales were determined by fitting an exponential function to the 10-day filtered data after removal

**Table 2.** Estimated changes for the AMOC at  $26^\circ$  N and its component parts between the period from April 2004 to March 2008 and the period from April 2008 to March 2012. Two values are shown for each variable. The first (upper) value includes the year starting in April 2009 and the second excludes 2009. Also shown are the 5 and 95 percentile values of the estimate. All values are Sv. Positive implies increased northward transport (or reduced southward transport).

Variable	Mean value 2004–2012	Estimated change (2008–2012) – (2004–2008)		
		5 %	50 %	95 %
Confidence value				
AMOC	17.5	–5.1 –3.0	–2.7 –1.6	–0.3 –0.2
Gulf Stream	31.5	–1.2 –1.0	–0.5 –0.3	0.2 0.4
Ekman	3.5	–1.3 –0.7	–0.2 0.2	0.9 1.0
Upper mid-ocean (UMO)	–17.5	–3.4 –2.7	–2.0 –1.5	–0.6 –0.2
UNADW	–11.6	–0.7 –0.8	0.1 –0.2	0.9 0.4
LNADW	–6.5	0.5 0.2	2.1 1.5	3.8 2.7

of the seasonal cycle. The values obtained were 40 days for the MOC, 24 days for the Ekman transport, 14 days for the Gulf Stream and 21 days for the UMO. Based on an 8.5 yr record length, these e-folding scales correspond to estimates of the number of degrees of freedom between 39 and 111; to be conservative here a value of 35 degrees of freedom was used for each time series.

Superimposed on the data in Fig. 3 are the trends calculated by linear regression of the 10-day filtered data. Lines illustrating the trend  $\pm 1.64$  standard errors (for 35 degrees of freedom) are also shown. These represent the 90 % confidence interval for the trend. The estimated trend in the AMOC is  $-0.54 \text{ Sv yr}^{-1}$  (90 % c.i.  $-0.08$  to  $-0.99 \text{ Sv yr}^{-1}$ ). This is consistent with the values obtained in the previous section by looking at the four-year mean. The results in Table 2 suggest a reduction of  $2.7 \text{ Sv}$  over a four-year equivalent to a trend of about  $-0.68 \text{ Sv yr}^{-1}$ . Trends and confidence intervals for the components of the AMOC are summarized in Table 3. The UMO is the only component that has a trend significantly different from zero ( $-0.41 \text{ Sv yr}^{-1}$ , 90 % c.i.  $-0.07$  to  $-0.74 \text{ Sv yr}^{-1}$ ). The trend in the de-seasonalized time series of the AMOC accounts for 10 % of the total variance of the AMOC 10-day low-pass filtered time series. After removal of the trend the standard deviation of the AMOC residuals is  $4.0 \text{ Sv}$ .

The analysis was also applied to the time series with data from April 2009 to March 2010 removed. In this case the trend was a little weaker being  $-0.42 \text{ Sv yr}^{-1}$  (90 % c.i.  $0.01$  to  $-0.84 \text{ Sv yr}^{-1}$  based on 31 degrees of freedom).

**Table 3.** Estimated trends for the AMOC at 26° N and its component parts. Two values are shown for each variable. The first (upper) value includes the year starting in April 2009 and the second excludes 2009. Also shown are the 5 and 95 percentile values of the estimated trends. All values are  $\text{Sv yr}^{-1}$ . Positive implies increasing northward transport (or reducing southward transport). The number of degrees of freedom was set to 35 for the full time series and 31 when excluding data from 2009–2010.

Variable	Estimated trend		
Confidence value	5 %	50 %	95 %
AMOC	−0.99	−0.54	−0.08
	−0.84	−0.42	0.01
Gulf Stream	−0.43	−0.11	0.21
	−0.42	−0.09	0.24
Ekman	−0.33	0.00	0.32
	−0.27	0.04	0.36
Upper mid-ocean (UMO)	−0.74	−0.41	−0.07
Upper mid-ocean (UMO)	−0.68	−0.36	−0.03
UNADW	−0.29	−0.03	0.22
	−0.26	−0.00	0.26
LNADW	0.16	0.46	0.77
	0.11	0.39	0.68

A further assumption in the estimation of the regression coefficients is that the deviations about the trend are approximately normal. In fact the distribution of residuals shows a slight skewness towards negative values, and so a second calculation was made using maximum likelihood estimation to fit a linear regression model with skew-normal errors (Azzalini and Capitanio, 1999). There was however no significant change to the results.

### 3.3 Transport profiles

Comparison of the annual means in Sect. 3.1 indicated that the slowing of the AMOC was primarily due to the strengthening of the southward flowing waters above the thermocline in the basin interior. To examine this further we show in Fig. 4 the stream function profile averaged over the first four years of the time series and over the last four years. Also shown is the difference between the two and the corresponding change in the transport per depth profile. It can be seen that during the later period there was a stronger southward flow above 1000 m depth that intensified towards the surface. The vertical integral of the transport per depth profile must be zero and so there is a corresponding weakening of the southward flow in the deeper layers. Figure 4 indicates that this occurred below 2000 m and mostly below 3000 m. There is a broad maximum in the change around 4000 m.

Southward flow of water between 1100 m and 3000 m is usually regarded as upper North Atlantic deep water

**Fig. 4.** Left: mean stream function profile (Sv) for the two four-year periods April 2004 to March 2008 and April 2008 to March 2012. Centre: difference between the two profiles in the left hand plot. Right: change of the transport per depth profiles ( $\text{Sv m}^{-1}$ ) between the two four-year periods, positive values correspond to northward flow. Black shows total change in transport per depth, blue shows that part due to changes on the eastern boundary and red shows that part of the change due to changes on the western boundary. Note that the black curve includes changes of Ekman and Gulf Stream transports and a small contribution from changes of density adjacent to the mid-Atlantic ridge.

(UNADW), while the flow between 3000 m and 5000 m is regarded as lower North Atlantic deep water (LNADW) (see for example Atkinson et al., 2012). In Fig. 5 we show deseasonalized transport time series for each of these depth ranges. There is a significant trend of decreasing transport in LNADW but no apparent change in the transport of UNADW (Table 3). The mean value of the transport of LNADW over the eight years of the time series is 6.5 Sv southward. Thus as a percentage of the mean the absolute change in transport of LNADW is greater than that of the UMO and amounts to 7 % per year (95 % confidence that the reduction is more than 2.5 % per year). For the UMO the rate is 3 % per year (95 % confidence that the increase is more than 0.5 % per year).

The change to the interior geostrophic flow may be separated into two parts corresponding to the changes on the eastern and western boundaries and these are shown by the blue and red curves in the right hand panel of Fig. 4. It can be seen that the transport change is due in large part to the changes on the western boundary. The RAPID array combines data from several moorings on the sloping boundaries to create one merged profile of temperature and salinity on the west and one on the east. Further details are given in the supplementary material of Cunningham et al. (2007). The changes in density on the eastern and western merged profiles are shown in Fig. 6. The left hand panel of Fig. 6 shows

**Fig. 5.** Time series of the upper NADW (top) and lower NADW (bottom). Values are anomalies relative to mean annual cycle (positive is northward). A 45-day low-pass filter was applied to each time series. For each time series horizontal dashed lines show  $\pm$  two standard deviations and the solid black lines show the average trend  $\pm 1.64$  standard errors (i.e. 90 % confidence limits).

the difference between the profiles averaged over the period from 2008 to 2012 and those averaged the period from 2004 to 2008. Except in the upper 500 m the changes on the west are greater than those on the east and so we focus our attention on the western profile. Temperature and salinity both increase towards the surface (Fig. 6, right hand panel) and so vertical displacement of isopycnals results in temperature and salinity having opposing effects on density at fixed depth levels with temperature having the greatest effect. Figure 6 shows that the main changes are a reduction in density at depths of 500 m to 1200 m. There is also an increase in density above 500 m due to a cooling of the upper layers (also evident on the east). However, this had less impact on the change in transport. On deeper layers there was a reduction of density between 2000 m and 4000 m. Comparing the changes due to temperature and salinity indicates that isopycnals have deepened in this depth range too, but there has also been a freshening and cooling on isopycnal surfaces.

## 4 Discussion

### 4.1 Relationship of AMOC changes to the climate of the North Atlantic

Excluding the anomalous year of 2009, the mean AMOC for the second half of the  $26^\circ$  N measurements (2008–2012) is about 1.6 Sv (90 % c.i. 0.2 to 3.0 Sv) lower than the first four years. Including 2009 increases the reduction to 2.7 Sv (90 % c.i. 0.3 to 5.1 Sv). Model simulations predict a decrease of the AMOC in the 21st century in response to increasing

**Fig. 6.** Left: mean density difference (black) between the two four-year periods: April 2004 to March 2008 and April 2008 to March 2012. Continuous line shows the change on the western boundary and dashed shows the change on the eastern boundary. Also shown is that part of the density change on the western boundary due to temperature (blue) and that due to salinity (red). Left: mean temperature (blue) and salinity (red) profiles on the western boundary of the  $26^\circ$  N array.

greenhouse gases of the order of one half a Sverdrup per decade (IPCC, 2007). Our observations indicate that the actual change over the last decade is much greater. The magnitude of the observed changes suggests that they are a part of a cyclical change rather than being directly linked to the projected anthropogenic AMOC decrease. A much longer time series would be needed to identify a trend of the magnitude associated with greenhouse warming in model simulations. Thomas et al. (2012) looked at how the components of the AMOC changed during a warming scenario in a model simulation and found that the reduction of the AMOC was primarily a reduction in southward flow of deep water balanced by a reduced Gulf Stream with little change in the strength of the gyre circulation, which appeared to be determined by Sverdrup balance. This contrasts with our observations that show no significant change in the Gulf Stream transport over the 2004–2012 period when the AMOC is decreasing.

The majority of the change in the AMOC is associated with the UMO transport, which was about 1.5 Sv (90 % c.i.  $-0.1$  to 3.0 Sv) lower in the latter four years than in the first four years. Including 2009 increases the reduction to 2.0 Sv (90 % c.i. 0.2 to 3.7 Sv). Model simulations completed by Matei et al. (2012) exhibited some skill in hindcasting the AMOC at  $26^\circ$  N, and they concluded that this skill was associated primarily with the interior mid-ocean transport and the long timescales associated with internal ocean dynamics.

**Fig. 7.** Annual average estimates of the AMOC from the  $26^{\circ}$  N array (red, Sv right axis, error bar = 1.5 Sv), estimates of the AMOC from 6 hydrographic sections (black, Sv right axis, error bar = 5 Sv), the time series of annual average values of the AMO (blue,  $^{\circ}$ C left axis) and accumulated NAO index (green, arbitrary units).

During the time of the  $26^{\circ}$  N array observations there has been a predominantly negative NAO (Fig. 7). Associated with the negative NAO is a tripole SST pattern with cooler mid-latitudes and warm subtropics. Cunningham et al. (2013) suggested that the AMOC has a role in setting sub-surface temperature anomalies, which have been linked to re-emerging SST patterns and subsequent anomalies in the NAO (Taws et al., 2011). The results presented here are consistent with AMOC driven changes to the SST tripole pattern but they are not sufficient to conclude a causal relationship. Li et al. (2012) found an anti-correlation between sea-surface height (SSH) between  $30^{\circ}$  and  $50^{\circ}$  N in the Atlantic and accumulated (i.e. time integrated) NAO. If SSH changes primarily reflect variations in heat content then this also supports the association of reducing AMOC and negative NAO.

In Fig. 7 we show the data from the  $26^{\circ}$  N observations superimposed on the accumulated NAO and the index for the Atlantic multidecadal oscillation (AMO). To date the length of the  $26^{\circ}$  N time series is short compared with timescale of the low frequency variability of the AMO (of the order of 60 yr). However, snapshots of the AMOC were made in hydrographic cruises going back to 1957 and these are also shown on Fig. 7. The values are taken from Table 5 in (Atkinson et al., 2012), which compared all six section from 1957, 1981, 1992, 1998, 2004 and 2010 and adjusted the figures to remove the effect of the seasonal variability as determined from the  $26^{\circ}$  N observations. However, we used annual average values for the Ekman and Gulf Stream components. The error bars on the hydrographic estimates are too large to draw any conclusions about the association of the AMOC with the NAO or AMO. Bryden et al. (2005) suggested that the errors could be as large as 6 Sv. In fact the AMOC measured by the hydrographic cruise in 2010 was stronger than that in

2004. This underlines the fact that continuous observations are required to determine the variability of the AMOC.

## 4.2 Deep water changes

The results presented here indicate that the reduction of the AMOC between April 2004 and October 2012 was manifested as a strengthening of the southward flow of the waters above the thermocline and a weakening of the southward flow of lower North Atlantic deep water (LNADW). Surprisingly the upper North Atlantic deep water (UNADW) has shown little change.

Send et al. (2011) reported observations from the MOVE array at  $16^{\circ}$  N. The MOVE array (Kanzow et al., 2006) measures the deep flow on the western side of the Atlantic only but Send et al. (2011) argued that this captures all of the southward deep water flow. Send et al. (2011) concluded that there was a reduction of about 3 Sv in the southward flow of NADW between 2000 and 2009. In contrast to our observations Send et al. (2011) attributed most of the changes to the variability of UNADW and found that LNADW transport remained roughly constant. Whilst there is an overlap of about 5 yr (2004–2009) between the period considered by Send et al. (2011) and our record, it is not sufficient to make a direct comparison with the data reported in this paper, where the major change was observed after 2008. Furthermore, the advection time from the  $26^{\circ}$  N array to the MOVE array is expected to be about 2–3 yr, assuming the speed of advection between  $26^{\circ}$  N and  $15^{\circ}$  N is similar to that between the Labrador Sea and  $26^{\circ}$  N which was found to be about 9 yr by van Sebille et al. (2011) though faster wave mediated responses are also expected (Johnson and Marshall, 2002).

Mercier et al. (2013) have used repeat hydrographic sections, Argo data and altimetry to diagnose the AMOC in the sub-polar gyre. They found a reduction in overturning between 1993 and 2010 of about 2.4 Sv. However, a significantly longer period of overlap between the time series at  $26^{\circ}$  N and the Greenland–Portugal section would be needed to assess the meridional coherence of variability in the AMOC.

A primary driver of the thermohaline circulation is the formation of deep waters at high latitudes. Observations of the deep water formation regions and the overflows suggest that the rate of formation in the Nordic Seas has remained remarkably constant (Jochumsen et al., 2012; Olsen et al., 2008), whereas variability of deep-water formation in the Labrador and Irminger seas has been documented (e.g. Yashayaev and Loder, 2009). Climate models also generally indicate that changes in convection in the AMOC strength are linked to changes in convection in the Labrador and Irminger seas (Danabasoglu et al., 2012). This would lead us to expect greater variability in the UNADW than in the LNADW. Changes in temperature and salinity on the western boundary of the  $26^{\circ}$  N array (Fig. 4) do indicate freshening and warming of UNADW and this is consistent with the changes

described by Peña-Molino et al. (2011) and van Sebille et al. (2011), but no significant change in the transport of UNADW is apparent. It is also interesting to note that in the modelling study of the period from 1985 to 2002 by Marsh et al. (2005), variability in the formation of UNADW in the Labrador Sea was not seen to affect the MOC at 26° N.

Our observations alone cannot explain the changes in the deep water circulation, but reconciling our observations at 26° N with a constant production of LNADW requires a time-varying meridional divergence and convergence associated with a decadal change in the circulation. On average there was 2 Sv less southward transport of LNADW at 26° N from 2008 to 2012 than there was from 2004 to 2008. If the volume transport of the overflows has remained constant this would imply an average change in the rate of convergence equivalent to an uplift of about 5 m yr<sup>-1</sup> over the 1.34 × 10<sup>7</sup> km<sup>2</sup> of the North Atlantic between 26° N and 60° N that is deeper than 3000 m. Without further information we can only infer the change but not the absolute value of the uplift. Cunningham and Alderson (2007), based on an analysis of deep isopycnal displacements near the western boundary at 26.5° N, conclude that there was about 50 m of uplift of the upper interface of LNADW between 1957 and 2004.

## 5 Conclusions

On the timescale of decadal changes in the North Atlantic the 8.5 yr length of the 26° N array observations is still short, but the results demonstrate the capability of the array to detect changes in the magnitude and structure of the overturning circulation. We have shown that there was a slowdown in the AMOC transport between 2004 and 2012 amounting to an average of -0.54 Sv yr<sup>-1</sup> (95 % c.i. -0.08 to -0.99 Sv yr<sup>-1</sup>) at 26° N, and that this was primarily due to a strengthening of the southward flow in the upper 1100 m and a reduction of the southward transport of NADW below 3000 m. This trend is an order of magnitude larger than that predicted by climate models associated with global climate change scenarios, suggesting that this decrease represents decadal variability in the AMOC system rather than a response to climate change. Further observations from the 26° N array will in time allow a better understanding of decadal variability of the AMOC and its relationship to the climate of the North Atlantic region.

*Acknowledgements.* The 26° N array is a collaborative effort supported through the UK Natural Environment Research Council (NERC) RAPID-WATCH program, the US National Science Foundation (NSF) Meridional Overturning Circulation Heat-flux Array project, and the US National Oceanographic and Atmospheric Administration (NOAA) Western Boundary Time Series project.
