## ABSTRACT

**Summary:** Recent advances in sequencing technologies have led to the rapid accumulation of molecular sequence data. Analyzing whole-genome data (as obtained from next-generation sequencers) from intra-species samples allows to detect signatures of positive selection along the genome and therefore identify potentially advantageous genes in the course of the evolution of a population.

We introduce OmegaPlus, an open-source tool for rapid detection of selective sweeps in whole-genome data based on linkage disequilibrium. The tool is up to two orders of magnitude faster than existing programs for this purpose and also exhibits up to two orders of magnitude smaller memory requirements.

**Availability:** OmegaPlus is available under GNU GPL at <http://www.exelixis-lab.org/software.html>.

**Contact:** [n.alachiotis@gmail.com](mailto:n.alachiotis@gmail.com), [pavlidisp@gmail.com](mailto:pavlidisp@gmail.com)

**Supplementary information:** Supplementary data are available at *Bioinformatics* online.

## 1 INTRODUCTION

Statistical tests that rely on selective sweep theory (Maynard Smith and Haigh, 1974) can localize targets of recent and strong positive selection by analyzing single-nucleotide polymorphism (SNP) patterns in intra-species multiple sequence alignments. Next-generation sequencing technologies allow for the rapid and cheap extraction of data to assess whole-genome variation in single-species populations. However, applying such statistical tests to whole-genome data is challenging because of increased execution times and memory requirements.

Several studies in the last decade have focused on detecting positive selection in genomes from natural populations of individuals. Kim and Stephan (2002) developed a composite maximum likelihood (ML) framework to detect selective sweeps using the empirical mutation frequencies of polymorphic sites (site frequency spectrum). This approach was later adapted by Nielsen *et al.* (2005) for populations that have experienced past demographic changes. Kim and Nielsen (2004) proposed the  $\omega$  statistic to accurately localize selective sweeps and developed a ML framework that uses linkage-disequilibrium (LD) information.

In this work, we introduce OmegaPlus, a high-performance implementation of the  $\omega$  statistic. To the best of our knowledge,

OmegaPlus represents the first scalable  $\omega$  statistic implementation that *can* be applied to whole-genome data. Previous implementations were not suitable for whole-genome analyses: the implementation by Jensen *et al.* (2007) is only suitable for analyses of sub-genomic regions, whereas the implementation by Pavlidis *et al.* (2010) has excessive memory requirements even for moderate datasets.

## 2 THE LD PATTERN OF SELECTIVE SWEEPS

The LD is used to capture the non-random association of alleles or states at different alignment positions. Selective sweep theory predicts a pattern of excessive LD in each of the two alignment regions that flank a recently fixed beneficial mutation. This genomic pattern can be detected by using the  $\omega$  statistic.

Assume a genomic region with  $S$  SNPs that is split into a left sub-region  $L$  and a right sub-region  $R$  with  $l$  and  $S-l$  SNPs, respectively. The  $\omega$  statistic is computed as follows:

$$\omega = \frac{\binom{l}{2} + \binom{S-l}{2}^{-1} (\sum_{i,j \in L} r_{ij}^2 + \sum_{i,j \in R} r_{ij}^2)}{(l(S-l))^{-1} \sum_{i \in L, j \in R} r_{ij}^2}, \quad (1)$$

where  $r_{ij}^2$  is one common measure of LD that represents the correlation coefficient between sites  $i$  and  $j$ . Candidate regions for positive selection are characterized by high  $\omega$  statistic values since the average LD is high within the  $L$  and  $R$  sub-regions but not across the beneficial mutation (see Section 1 in the Supplementary Material).

## 3 FEATURES

OmegaPlus is an open-source C code for Windows and Linux platforms. We provide a sequential version (OmegaPlus) for Windows and Linux, as well as two parallel versions for Linux that exploit fine-grain (OmegaPlus-F) and coarse-grain (OmegaPlus-C) parallelism (see Sections 2–6 in the Supplementary Material).

### 3.1 Computational workflow

OmegaPlus calculates the  $\omega$  statistic at  $N$  distinct positions in the alignment. For each position  $P$ ,  $1 \leq P \leq N$ , let  $k_L$  and  $k_R$  be the number of SNPs to the left and to the right of  $P$ , respectively, which are contained within a user-defined genomic region  $G$ . Thus, a number of  $k_L$  and  $k_R$  regions are located to the left and right side of  $P$ , each containing a different number of SNPs. The  $\omega$  statistic is computed for all  $k_L \times k_R$  pairs of sub-regions and the pair for which  $\omega$  statistic has the highest value is reported.

\*To whom correspondence should be addressed.

To accelerate  $\omega$  statistic calculations, a 2D matrix  $M$ ,  $M_{l,m} = \sum_{l \leq i < j \leq m} r_{ij}^2$ , is calculated for each region  $G$ . Thereafter, all sums in Equation (1) are retrieved from  $M$ . This avoids redundant calculations and keeps the memory requirements proportional to  $k^2$ , where  $k$  is the total number of SNPs in  $G$ .

### 3.2 Input/output

OmegaPlus is a command line tool that only requires five input arguments for a typical run: an alignment file (`-input`), the number  $P$  of positions at which the  $\omega$  statistic will be calculated (`-grid`), a minimum (`-minwin`) and maximum (`-maxwin`) size for the  $L$  and  $R$  sub-regions, and a name for the specific run (`-name`). Additional command line flags, such as the number of threads (`-threads`) for the parallel versions, are described in the manual. Binary data (derived/ancestral states) in ms (Hudson, 2002) or MaCS (Chen *et al.*, 2009) format and DNA data in FASTA format can be analyzed. For ms and MaCS files, the length of the alignment (`-length`) also needs to be provided by the user.

The program generates three text files: an information file, a warning file and a report file. The information file contains details about program execution, such as the command line and the run time. The warning file reports conflicting SNP positions (SNPs which refer to the same alignment positions) when binary data are analyzed. Finally, the report file provides the highest  $\omega$  statistic value for each position  $P$ . A detailed description of the input and output options is provided in the manual.

## 4 USAGE EXAMPLE

To demonstrate the ability to efficiently process genome datasets, we used an off-the-shelf laptop with an Intel Core i5 CPU @ 2.53 GHz with 4 GBs main memory running Ubuntu 10.04.3. The X chromosome of 37 *Drosophila melanogaster* genomes sampled in Raleigh, North Carolina was analyzed. The sequences (available from the Drosophila Population Genomics Project at [www.dpgp.org](http://www.dpgp.org)) were converted from fastq to fasta using a provided script (available at [www.dpgp.org](http://www.dpgp.org)) and Solexa quality score threshold of 30. OmegaPlus was called as follows:

```
./OmegaPlus-F -maxwin 100000
-minwin 1000
-name DPGP -input DPGP.fa -grid 10000 -threads 4.
```

We calculated the  $\omega$  statistic at 10 000 equidistant positions, assuming that the maximum length of the  $L$  and  $R$  sub-regions to the left and right of a beneficial mutation is 100 000 bp. Thus, a selective sweep may affect at most 200 000 bp in total. The minimum length of  $L$  and  $R$  is set to 1000 bp. A few entries of the report file are shown below. Each row denotes an alignment position  $P$  and the OmegaPlus score. In this example, there is a peak at position 1 079 493.

```
1077252 1.640796
1079493 48.282642
1081734 2.086421
```

The alignment comprised 37 sequences and 22 422 827 sites (339 710 SNPs). To analyze such an alignment, OmegaPlus used less than 2% of the available 4 GBs of main memory. Note that a peak memory requirement of 20.8% was recorded for some seconds to temporarily store the alignment in memory,

discard non-polymorphic sites, and compress the remaining SNPs. Using both physical cores on the laptop and hyper-threading (two more virtual cores), the fine-grain version of OmegaPlus required 15 min. Assuming that a selective sweep only affects at most 60 000 bp (`-maxwin 30 000`) instead of 100 000, the analysis only takes 5 min.

## 5 PERFORMANCE

An accuracy evaluation of the  $\omega$  statistic and comparison to SweepFinder (Nielsen *et al.*, 2005) has been presented in Pavlidis *et al.* (2010). To provide a performance comparison, we generated a simulated dataset with 500 sequences and 70 000 SNPs using Hudson's ms (see Section 5 in the Supplementary Material), and employed a 12-core AMD Opteron CPU running at 2.2 GHz. OmegaPlus analyzed this dataset in 71.8 s occupying 75.8 MBs of main memory, whereas SweepFinder required 783.2 s and 2.7 MBs of main memory. Note, however, that SweepFinder employs the site frequency spectrum and not the  $\omega$  statistic. The  $\omega$  statistic implementation by Pavlidis *et al.* (2010), which attempts to process the entire alignment at once, required more than 2 days and allocated ~30 GBs of main memory.

To evaluate the parallel implementations, we generated a dataset with 1000 sequences and 500 000 alignment sites. For this dataset size, fine-grain parallelism scales better on DNA data. Coarse-grain parallelism exhibits similar behavior on both data types and scales better on binary data (see Section 6 in the Supplementary Material).

## 6 CONCLUSION

We presented OmegaPlus to accurately identify selective sweeps in whole-genome data using the  $\omega$  statistic. We intend to further improve the memory requirements as well as to support additional file formats and methods to calculate LD. We also plan to set up a web-server. User support is provided via the OmegaPlus Google group <http://groups.google.com/group/omegaplus>.
