**Abstract.** A directed graph is upward planar if it can be drawn in the plane such that every edge is a monotonically increasing curve in the vertical direction, and no two edges cross. An undirected graph is rectilinear planar if it can be drawn in the plane such that every edge is a horizontal or vertical segment, and no two edges cross. Testing upward planarity and rectilinear planarity are fundamental problems in the effective visualization of various graph and network structures. In this paper we show that upward planarity testing and rectilinear planarity testing are NP-complete problems. We also show that it is NP-hard to approximate the minimum number of bends in a planar orthogonal drawing of an $n$-vertex graph with an $O(n^{1-\epsilon})$ error, for any $\epsilon > 0$.

## 1 Introduction

Graph drawing addresses the problem of constructing geometric representations of abstract graphs and networks [5]. It is an emerging area of research that combines flavors of topological graph theory and computational geometry. The automatic generation of drawings of graphs has important applications in key computer technologies such as software engineering, database design, visual interfaces, and computer-aided-design.

Various graphic standards have been proposed for the representation of graphs in the plane. Usually, vertices are represented by points, and each edge $(u, v)$ is represented by a simple open Jordan curve joining the points associated with the vertices $u$ and $v$. A *straight-line* drawing maps each edge into a straight-line segment. An *orthogonal* drawing maps each edge into a chain of horizontal and vertical segments. A *rectilinear* drawing is an orthogonal straight-line drawing, i.e., a drawing where every edge is either a horizontal or a vertical segment. A drawing is *planar* if no two edges cross. A graph (or digraph) is planar if it admits a planar drawing. A graph is *rectilinear planar* if it admits a planar rectilinear drawing. A drawing of a digraph is *upward* if every edge is

monotonically nondecreasing in the $y$-direction. A digraph is *upward planar* if it admits a planar upward drawing.

Testing upward planarity and rectilinear planarity are fundamental problems in the effective visualization of various graph and network structures. For example, upward planarity is useful for the display of order diagrams and subroutine-call graphs, while rectilinear planarity is useful for the display of circuit schematics and entity-relationship diagrams. In this paper we show that the following two problems are NP-complete:

*Upward planarity testing:* testing whether a digraph is upward planar.

*Rectilinear planarity testing:* testing whether a graph is rectilinear planar.

These problems have challenged researchers in order theory, topological graph theory, computational geometry, and graph drawing for many years. Our intractability results motivate the following observations:

- Testing whether a graph admits a planar drawing or an upward drawing can be done in linear time. Combining the two properties makes the problem NP-hard.
- Every planar graph admits a planar straight-line drawing. Hence, we can say that planarity is equivalent to straight-line planarity, and both properties can be verified in linear time. We can view upward and rectilinear planarity as derived from straight-line planarity by adding further constraints, which make the problem become apparently much more difficult.

We also show that it is NP-hard to approximate the minimum number of bends in a planar orthogonal drawing of an $n$-vertex graph with an $O(n^{1-\epsilon})$ error, for any $\epsilon > 0$.

Previous results on upward and rectilinear planarity testing are summarized below. In the rest of this section, we denote with $n$ the number of vertices of the graph being considered.

Combinatorial results on upward planarity of covering digraphs of lattices were first given in [15, 22]. Further results on the interplay between upward planarity and ordered sets are surveyed by Rival [23]. Lempel, Even, and Cederbaum [16] relate the planarity of biconnected undirected graphs to the upward planarity of $st$-digraphs. A combinatorial characterization of upward planar digraphs is provided in [8, 14]: namely, a digraph is upward planar if and only if it is a spanning subgraph of a planar *st-digraph*. This characterization implies that upward planarity testing is in NP.

Di Battista, Liu, and Rival [7] show that every planar bipartite digraph is upward planar. Papakostas [21] gives a polynomial-time algorithm for upward planarity testing of outerplanar digraphs. Bertolazzi, Di Battista, Liotta, and Mannino [1, 2] give a polynomial-time algorithm for testing upward planarity of triconnected digraphs and of digraphs with a fixed embedding. Concerning single-source digraphs, Thomassen [28] characterizes upward planarity in terms of forbidden circuits. Hutton and Lubiw [12] combine Thomassen's characterization with a decomposition scheme to test upward planarity of a single-source digraph in $O(n^2)$ time. Bertolazzi, Di Battista, Mannino, and Tamassia [3] show

that upward planarity testing of a single-source digraph can be done optimally in $O(n)$ time. They also give a parallel algorithm that runs in $O(\log n)$ time on a CRCW PRAM with $n \log\log n / \log n$ processors.

Regarding rectilinear planarity testing, Shiloach [24] and Valiant [29] show that any planar graph of degree at most 4 admits a planar orthogonal drawing. Vijayan and Wigderson [30] study structural properties of rectilinear planar drawings. From their results, the membership of rectilinear planarity testing in NP is easy to establish. Storer [25], Tamassia and Tollis [27], Liu, Marchioro, Morgana, Petreschi, and Simeone [18, 19, 20, 17], Even and Granot [9], and Biedl and Kant [13, 4] give various techniques for constructing planar orthogonal drawings with $O(n)$ bends. Tamassia [26] gives an $O(n^2 \log n)$-time algorithm that constructs a planar orthogonal drawing with the minimum number of bends for an embedded planar graph. Di Battista, Liotta, and Vargiu [6] give polynomial time algorithms for minimizing bends in planar orthogonal drawings of series-parallel and cubic graphs. The latter two results show that rectilinear planarity testing can be done in polynomial time for a fixed embedding or for special classes of graphs.

Our proof techniques are based on a two-phase reduction from the known NP-complete problem NOT-ALL-EQUAL-3-SAT. In the first phase, we reduce NOT-ALL-EQUAL-3-SAT to an auxiliary undirected flow problem. In the second phase, we reduce this undirected flow problem to the upward (or rectilinear) planarity testing of a special class of digraphs. The latter reduction is interesting in its own and provides new insights on the characterization by flow networks of the angles formed by the edges of upward planar drawings [1, 2] and orthogonal drawings [6, 26].

The rest of this paper is organized as follows. Preliminary definitions and results are provided in Section 2. The reduction from NOT-ALL-EQUAL-3-SAT to the auxiliary flow problem is given in Section 3. Sections 4 and 5 describe the reductions from the auxiliary flow problem to upward and rectilinear planarity testing, respectively. In this extended abstract, proofs and technical details are omitted. They can be found in the full paper [11].

## 2 Preliminaries

We assume standard concepts and definitions on NP-completeness [10]. Our results use reductions from the following well-known NP-complete problem:

NOT-ALL-EQUAL-3-SAT Given a set of clauses with three literals each, is there a truth assignment such that each clause has at least one true literal and one false literal?

An *embedding* of a planar graph is the collection of circular permutations of the edges incident upon each vertex in a planar drawing of the graph. An *embedded graph* is a planar graph equipped with an embedding. The *angles* of an embedded graph are the pairs of consecutive edges incident on the same vertex. Such angles are mapped to geometric angles in a straight-line drawing of the graph.

A *rectilinear embedding* of a graph $G$ is an embedding of $G$ where each angle is assigned a label in the set $\{1, 2, 3, 4\}$, such that there exists a rectilinear drawing of $G$ where each angle labeled $\ell$ in the embedding measures $\ell\pi/2$ in the drawing.

An *upward embedding* of a digraph $\vec{G}$ is an embedding of $\vec{G}$ where each angle formed by pairs of incoming or outgoing edges is assigned a label in the set $\{small, large\}$, such that there exists a planar straight-line upward drawing of $\vec{G}$ where each angle labeled *small* has measure $< \pi$ and each angle labeled *large* has measure $> \pi$.

In the rest of this section, we define several graphs that will be used as gadgets in our reductions.

We show in Fig. 1(a) *tendril* $T_k$ ($k \geq 1$), which is an acyclic digraph with $k+1$ sources and $k+1$ sinks. We also define tendril $T_0$ as a a digraph consisting of a single edge. Tendril $T_k$ ($k \geq 0$) has a designated source and a designated sink, called the *poles* of $T_k$. We shall consider transformations where a directed edge $(u, v)$ of a digraph is replaced with a tendril $T_k$, where the source is identified with $u$ and the sink with $t$.

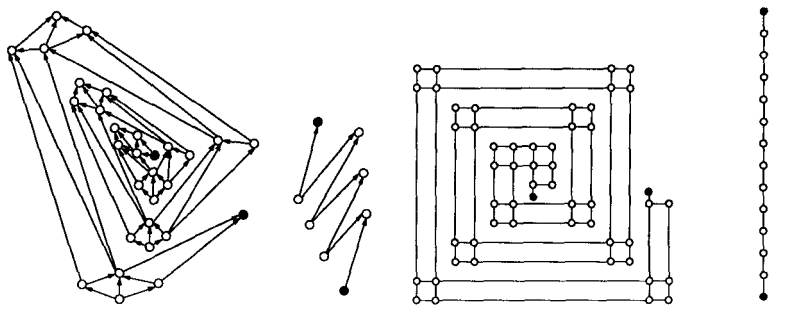

**Figure 1:** (a) Tendril $T_3$. (b) Wiggle $W_3$. (c) Rectilinear tendril $T_3$. (d) Rectilinear wiggle $W_3$. The poles are drawn as black-filled circles.

**Lemma 1.** *Tendril $T_k$ is upward planar and admits a unique upward planar embedding.*

In the upward planar embedding of $T_k$, the external face consists of two paths between $s$ and $t$. One such path, called *outer path*, has $2k$ large angles and no small angles, and the other path, called *inner path*, has $2k$ small angles and no large angles. When a tendril replaces an edge of an embedded planar digraph, the outer path becomes a subpath of a face, and we say that the *contribution* of the outer path to the face is $+2k$. Similarly, we say that the contribution of the inner path to its face is $-2k$.

Figure 1(b) shows a *wiggle* $W_k$, which is an acyclic digraph consisting of a chain of $2k+1$ edges whose orientation alternates along the chain. The extreme vertices of $W_k$, a source and a sink, are called the *poles* of $W_k$. We shall consider transformations where a directed edge $(u, v)$ of an embedded digraph is replaced with wiggle $W_k$, where $s$ is identified with $u$ and $v$ with $t$. Given an upward embedding of $W_k$, we say that the *contribution* of $W_k$ to a face $f$ containing

$W_k$ is the number of large angles minus the number of small angles of $W_k$ in $f$. Clearly, $W_k$ can be upward embedded to give to $f$ any contribution $2i$ with $0 \leq i \leq k$. Note that if $G_k$ gives contribution $c$ to a face, it gives contribution $-c$ to the other face it belongs to.

We show in Fig. 1(*c*) an undirected graph called *rectilinear tendril* $T_k$, which also has two designated poles denoted by $s$ and $t$. We also define rectilinear tendril $T_0$ as a a graph consisting of a single edge. We show in Fig. 1(*d*) *rectilinear wiggle* $W_k$, which is a chain of $4k+1$ edges.

The *contribution* of a rectilinear tendril (or wiggle) to a face containing it is the number of angles of the tendril (or wiggle) labeled 3 minus the number of angles labeled 1 that lie in the face. Rectilinear tendril $T_k$ contributes $4k$, $4k+1$, or $4k+2$ to one face, and the opposite value to the other face. Rectilinear wiggle $W_k$ contributes to one face any value between 0 and $4k$, and the opposite value to the other face.

## 3 An Auxiliary Undirected Flow Problem

In this section we define two auxiliary flow problems and show that they are equivalent to NOT-ALL-EQUAL-3-SAT under polynomial-time reductions.

A *switch-flow network* is an undirected flow network $\mathcal{N}$ where each edge is labeled with a range $[c' \cdots c'']$ of nonnegative integer values, called the *capacity range* of the edge. For simplicity, we denote the capacity range $[c \cdots c]$ with $[c]$. A *flow* for a switch-flow network is an orientation of and an assignment of integer "flow" values to the edges of the network. A *feasible flow* is a flow that satisfies the following two properties:

*Range property:* the flow assigned to an edge is an integer within the capacity range of the edge.

*Conservation property:* the total flow entering a vertex from the incoming edges is equal to the total flow exiting the vertex from the outgoing edges.

Starting from an instance $\mathcal{S}$ of NOT-ALL-EQUAL-3-SAT, we construct a switch-flow network $\mathcal{N}$ as follows (see Fig. 2). Let the literals of $\mathcal{S}$ be denoted with $x_1, y_1, \cdots, x_n, y_n$, where $y_i = \overline{x_i}$, and the clauses of $\mathcal{S}$ be denoted with $c_1, \cdots, c_m$. Let $\theta$ be a positive integer parameter. We denote with $\alpha_i$ and $\beta_i$ $(i = 1, \cdots, n)$ the number of occurrences of literals $x_i$ and $y_i$ in the clauses of $\mathcal{S}$, respectively. Note that $\sum_{i=1}^{n}(\alpha_i + \beta_i) = 3m$. Also, we define $\gamma_i = (2i-1)\theta$ and $\delta_i = 2i\theta$ $(i = 1, \cdots, n)$. Network $\mathcal{N}$ has a *literal vertex* for each literal of $\mathcal{S}$ and a *clause vertex* for each clause of $\mathcal{S}$, plus a special dummy vertex $z$. There are three types of edges in $\mathcal{N}$:

*Literal edges* joining pairs of literals associated with the same boolean variable. The capacity range of literal edge $(x_i, y_i)$ is $[\alpha_i\gamma_i + \beta_i\delta_i]$.

*Clause edges* joining each literal to each clause. The capacity range of clause edge $(x_i, c_j)$ is $[\gamma_i]$ if $x_i \in c_j$, and $[0]$ otherwise. The capacity range of clause edge $(y_i, c_j)$ is $[\delta_i]$ if $y_i \in c_j$, and $[0]$ otherwise.

*Dummy edges* joining each literal and each clause to the dummy vertex. The capacity ranges of dummy edges $(z, x_i)$ and $(z, y_i)$ are $[\beta_i\delta_i]$ and $[\alpha_i\gamma_i]$, re-

spectively. The capacity range of dummy edge $(z, c_j)$ is $[0 \cdots \eta_j - 2\theta]$, where $\eta_j$ is the sum of the capacities of the clause edges incident on $c_j$.

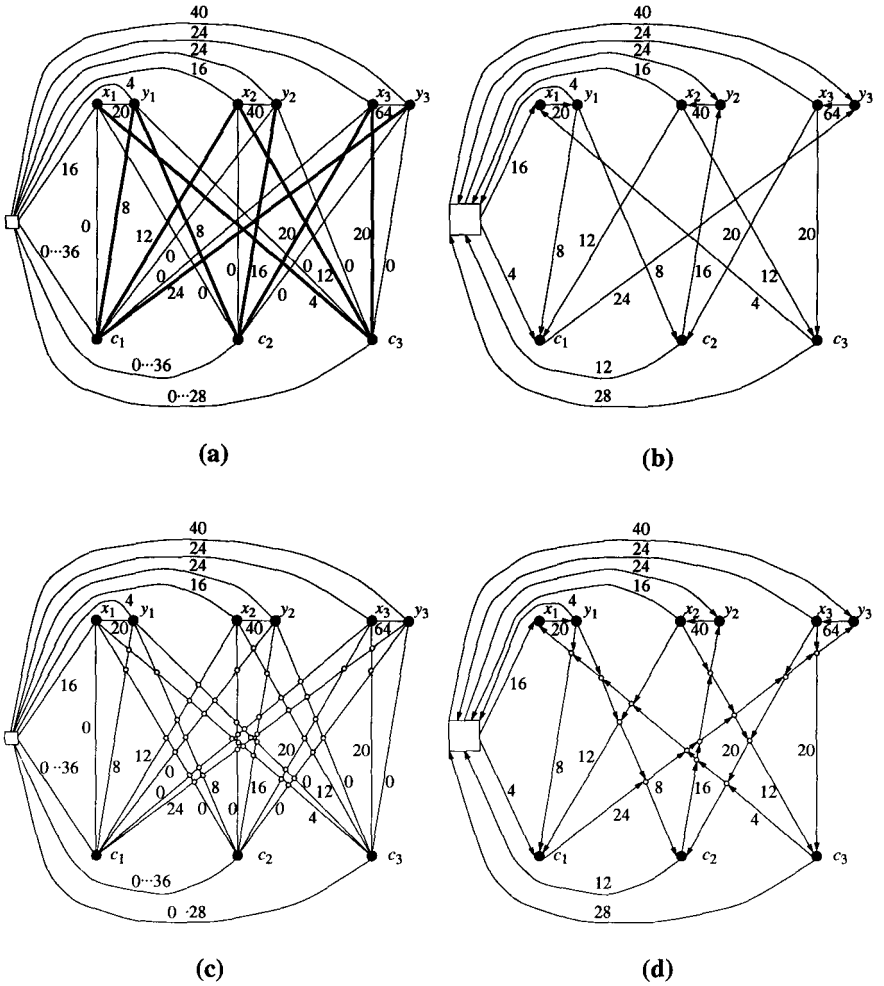

**Figure 2:** (a) Switch-flow network $\mathcal{N}$ with parameter $\theta = 4$ associated with the the NOT-ALL-EQUAL-3-SAT instance $\mathcal{S}$ with clauses $c_1 = y_1x_2y_3$, $c_2 = y_1y_2x_3$, and $c_3 = x_1x_2x_3$. The clause edges with nonzero capacity range are shown with thick lines. (b) Feasible flow for $\mathcal{N}$ corresponding to the satisfying truth assignment $(y_1, x_2, x_3)$ for $\mathcal{S}$. Only the edges with nonzero flow are shown. (c) Planar switch-flow network $\mathcal{P}$ associated with $\mathcal{S}$. (d) Feasible flow for $\mathcal{P}$ corresponding to the satisfying truth assignment $(y_1, x_2, x_3)$ for $\mathcal{S}$. Only the edges with nonzero flow are shown.

The construction of network $\mathcal{N}$ from $\mathcal{S}$ is straightforward, and we have:

**Lemma 2.** *Given an instance $\mathcal{S}$ of* NOT-ALL-EQUAL-3-SAT *with $n$ variables and $m$ clauses, the associated switch-flow network $\mathcal{N}$ has $O(n + m)$ vertices and*

*$O(nm)$ edges, and can be constructed in $O(nm)$ time.*

A feasible flow in network $\mathcal{N}$ corresponds to a satisfying truth assignment for $\mathcal{S}$. Namely, we have that a literal is true whenever its incident literal edge is incoming in the feasible flow (see Fig. 2(b)) and its incident clause edges with nonzero capacity range are outgoing. Also, the three clause edges with nonzero capacity range incident on a clause vertex $c_j$ cannot be all incoming or all outgoing because of the conservation property at vertex $c_j$ and the choice of capacity range for the dummy edge incident on $c_j$. We obtain:

**Lemma 3.** *An instance $\mathcal{S}$ of* NOT-ALL-EQUAL-3-SAT *is satisfiable if and only if the associated switch-flow network $\mathcal{N}$ admits a feasible flow. Also, given a feasible flow for $\mathcal{N}$, a satisfying truth assignment for $\mathcal{S}$ can be computed in time $O(nm)$, where $n$ and $m$ are the number of variables and clauses of $\mathcal{S}$, respectively.*

Now, starting from $\mathcal{N}$, we construct a planar switch-flow network $\mathcal{P}$ as follows (see Fig. 2). First, we construct a drawing of $\mathcal{N}$ such that the literal vertices and the clause vertices are arranged on two parallel lines, and crossings occur only between clause edges. Next, we replace the crossings formed by the clause edges with new vertices, called *crossing* vertices. We call *fragment edges* the edges originated by the splitting of the clause edges. Each fragment edge inherits the capacity range of the originating clause edge.

**Lemma 4.** *Given network $\mathcal{N}$ representing an instance $\mathcal{S}$ of* NOT-ALL-EQUAL-3-SAT *with $n$ variables and $m$ clauses, the associated planar switch-flow network $\mathcal{P}$ has $O(n^2m^2)$ vertices and edges, and can be constructed in $O(n^2m^2)$ time. Also, network $\mathcal{N}$ admits a feasible flow if and only if network $\mathcal{P}$ admits a feasible flow, and a feasible flow for $\mathcal{N}$ can be computed from a feasible flow for $\mathcal{P}$ in $O(n^2m^2)$ time.*

By combining Lemmas 3 and 4, we obtain the main result of this section.

**Theorem 5.** *Given an instance $\mathcal{S}$ of* NOT-ALL-EQUAL-3-SAT *with $n$ variables and $m$ clauses, the associated planar switch-flow network $\mathcal{P}$ has $O(n^2m^2)$ vertices and edges, and can be constructed in $O(n^2m^2)$ time. Instance $\mathcal{S}$ is satisfiable if and only if network $\mathcal{P}$ admits a feasible flow. Also, given a feasible flow for $\mathcal{P}$, a satisfying truth assignment for $\mathcal{S}$ can be computed in time $O(n^2m^2)$.*

## 4 Upward Planarity Testing

In this section we show how to reduce the problem of computing a feasible flow in the planar switch-flow network $\mathcal{P}$ associated with a NOT-ALL-EQUAL-3-SAT instance $\mathcal{S}$ to the problem of testing the upward planarity of a suitable digraph. We set parameter $\theta$ equal to 4.

**Lemma 6.** *Let $\mathcal{S}$ be a* NOT-ALL-EQUAL-3-SAT *instance with at least three variables and three clauses. The planar switch-flow network $\mathcal{P}$ associated with $\mathcal{S}$ is triconnected.*

Now, we construct on orientation $\vec{\mathcal{P}}$ of $\mathcal{P}$ as follows (see Fig. 3):

- Every literal edge $(x_i, y_i)$ is oriented from $x_i$ to $y_i$.
- Every fragment edge is oriented away from the clause vertex and towards the literal vertex.

- Every dummy edge incident on a literal vertex is oriented towards the dummy vertex, and every dummy edge incident on a clause vertex is oriented towards the clause vertex.

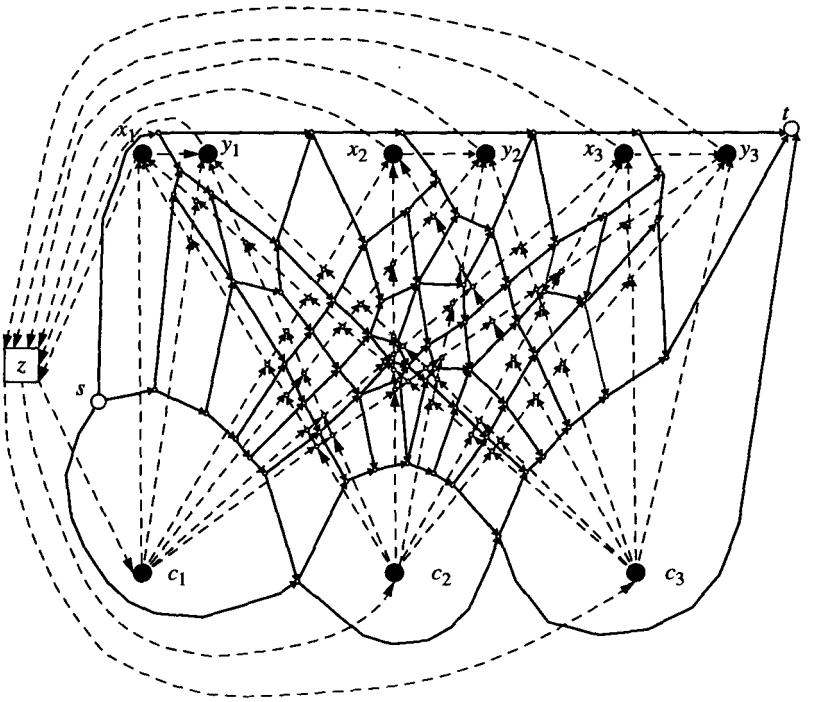

**Figure 3:** Orientation $\vec{\mathcal{P}}$ (drawn with dashed lines) of the network $\mathcal{P}$ shown in Fig. 2(c) and dual digraph $\vec{\mathcal{D}}$ (drawn with solid lines) of $\vec{\mathcal{P}}$.

**Lemma 7.** *In digraph $\vec{\mathcal{P}}$, every vertex has at least one incoming and one outgoing edge, every directed cycle contains the dummy vertex, and there are exactly two faces that are directed cycles.*

By Lemma 6, the planar embedding of $\mathcal{P}$ and the dual graph $\mathcal{D}$ of $\mathcal{P}$ are unique. We construct the dual digraph $\vec{\mathcal{D}}$ of $\vec{\mathcal{P}}$ by orienting every dual edge of $\mathcal{D}$ from the face on the left to the face on the right of the primal edge (see Fig. 3).

**Lemma 8.** *The dual digraph $\vec{\mathcal{D}}$ of $\vec{\mathcal{P}}$ is upward planar, triconnected, acyclic and has exactly one source and one sink, denoted with $s$ and $t$.*

Starting from digraph $\vec{\mathcal{D}}$ we construct a new digraph $\vec{\mathcal{G}}$ by replacing the edges of $\vec{\mathcal{D}}$ with subgraphs (tendrils or wiggles), as follows (see Fig. 4):

- Every edge of $\vec{\mathcal{D}}$ that is the dual of a literal edge, fragment edge, or dummy edge incident on a literal vertex is replaced with tendril $T_c$, where $[c]$ is the capacity range of the dual edge. Note that $c$ is a multiple of parameter $\theta$.
- Every edge of $\vec{\mathcal{D}}$ that is the dual of a dummy edge incident on a clause vertex is replaced with wiggle $W_c$, where $[0 \cdots c]$ is the capacity range of the dual edge.

The vertices of $\vec{\mathcal{G}}$ that are also in $\vec{\mathcal{D}}$ are called *primary vertices*. The remaining vertices of $\vec{\mathcal{G}}$ are called *secondary vertices*.

**Lemma 9.** *Digraph $\vec{\mathcal{G}}$ is planar and acyclic. Also, the only primary source vertex is $s$ and the only primary sink vertex is $t$.*

By Lemma 8 and the construction of digraph $\vec{\mathcal{G}}$, all the embeddings of $\vec{\mathcal{G}}$ are obtained by choosing one of the two possible flips for each tendril.

**Lemma 10.** *Digraph $\vec{\mathcal{G}}$ is upward planar if and only if the tendrils can be flipped and the wiggles can be arranged such that for every face the total contribution of the tendrils and wiggles is zero.*

The proof of Lemma 10 uses the characterization of upward embeddings by Bertolazzi, Di Battista, Liotta, and Mannino [1, 2].

We establish the following correspondence between digraph $\vec{\mathcal{G}}$ and network $\mathcal{P}$ (see Fig. 4): the faces of $\vec{\mathcal{G}}$ correspond to the vertices of $\mathcal{P}$; the tendrils and

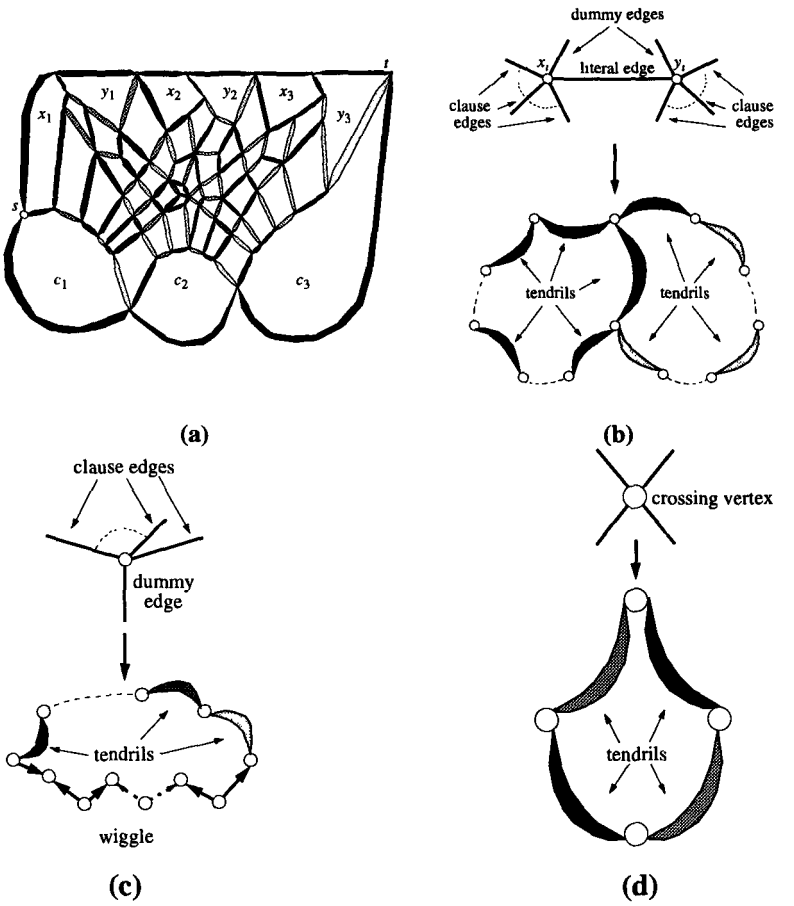

**Figure 4:** Schematic illustration of: (a) digraph $\vec{\mathcal{G}}$ obtained from $\vec{\mathcal{D}}$ by replacing edges with tendrils and wiggles; (b) the two faces of $\vec{\mathcal{G}}$ associated with literal vertices $x_i$ and $y_i$ of $\mathcal{P}$; (c) the face of $\vec{\mathcal{G}}$ associated with a clause vertex of $\mathcal{P}$; and (d) the face of $\vec{\mathcal{G}}$ associated with a crossing vertex of $\mathcal{P}$.

wiggles of $\vec{\mathcal{G}}$ correspond to the the edges of $\mathcal{P}$; flipping a tendril of $\vec{\mathcal{G}}$ corresponds to orienting an edge of $\mathcal{P}$; the contribution of a tendril or wiggle of $\vec{\mathcal{G}}$ corresponds to the flow in an edge of $\mathcal{P}$; the balance of the contributions of the tendrils and wiggles in the faces of $\vec{\mathcal{G}}$ corresponds to the conservation of flow at the vertices of $\mathcal{P}$.

**Theorem 11.** *Given an instance $\mathcal{S}$ of* NOT-ALL-EQUAL-3-SAT *with $n$ variables and $m$ clauses and the associated planar switch-flow network $\mathcal{P}$, digraph $\vec{\mathcal{G}}$ associated with $\mathcal{S}$ and $\mathcal{P}$ has $O(n^3m^2)$ vertices and edges, and can be constructed in $O(n^3m^2)$ time. Instance $\mathcal{S}$ is satisfiable and network $\mathcal{P}$ admits a feasible flow if and only if digraph $\vec{\mathcal{G}}$ is upward planar. Also, given an upward planar embedding for $\vec{\mathcal{G}}$, a feasible flow for $\mathcal{P}$ and a satisfying truth assignment for $\mathcal{S}$ can be computed in time $O(n^3m^2)$.*

From Theorems 5 and 11 we conclude:

**Corollary 12.** *Upward planarity testing is NP-complete.*

## 5 Rectilinear Planarity Testing

In this section we show how to reduce the problem of computing a feasible flow in the planar switch-flow network $\mathcal{P}$ associated with a NOT-ALL-EQUAL-3-SAT instance $\mathcal{S}$ to the problem of testing the rectilinear planarity of a suitable graph $\mathcal{G}$. The construction of graph $\mathcal{G}$ is carried out in several stages, where at each stage an intermediate graph is produced.

Given an instance $\mathcal{S}$ of NOT-ALL-EQUAL-3-SAT with $n$ variables and $m$ clauses, let $\mathcal{P}$ be the associated planar switch-flow network with parameter $\theta = 32nm$.

Let $\mathcal{D}$ be the dual graph of $\mathcal{P}$. The edges of $\mathcal{D}$ are classified as literal, clause, and dummy edges according to the type of their dual edge in $\mathcal{P}$. Starting from $\mathcal{D}$, we construct a degree-3 planar graph $\mathcal{F}$ by first replacing every vertex of degree $d$ with a binary tree with $d$ leaves, and then replacing every edge of the resulting graph with a chain of 5 edges. Graph $\mathcal{F}$ has $O(n^2m^2)$ vertices and edges.

**Lemma 13.** *Graph $\mathcal{F}$ has a unique planar embedding and admits a rectilinear embedding.*

We classify the edges of $\mathcal{F}$ as expansion, literal, clause, and dummy edges, where the edges forming the binary trees replacing the former vertices of $\mathcal{D}$ are expansion edges, and the remaining edges of $\mathcal{F}$ are classified according to the type of the edge of $\mathcal{D}$ that originated them. Note that each edge $e$ of $\mathcal{P}$ is thus associated with exactly 5 edges of $\mathcal{F}$ forming a path, and we call the middle edge the *representative* of $e$ in $\mathcal{F}$.

Finally, we construct graph $\mathcal{G}$ as follows. Let $e$ be an edge of $\mathcal{P}$. If $e$ is a dummy clause edge with capacity range $[0 \cdots c]$, we replace the representative of $e$ in $\mathcal{F}$ with rectilinear wiggle $W_c$. Else, $e$ is a literal, fragment, or dummy literal edge with capacity range $[c]$, and we replace the representative of $e$ in $\mathcal{F}$ with rectilinear tendril $T_c$.

By Lemma 13 and the construction of digraph $\mathcal{G}$, all the embeddings of $\vec{\mathcal{G}}$ are obtained by choosing one of the two possible flips for each rectilinear tendril.

**Lemma 14.** *Graph $\mathcal{G}$ admits a rectilinear planar drawing if and only if the rectilinear tendrils can be flipped and the rectilinear wiggles can be arranged such that for every face the total contribution of the tendrils and wiggles is zero.*

We establish the following correspondence between graph $\mathcal{G}$ and network $\mathcal{P}$: the faces of $\mathcal{G}$ correspond to the vertices of $\mathcal{P}$; the rectilinear tendrils and wiggles of $\mathcal{G}$ correspond to the the edges of $\mathcal{P}$; flipping a rectilinear tendril of $\mathcal{G}$ corresponds to orienting an edge of $\mathcal{P}$; the contribution of a rectilinear tendril or wiggle of $\mathcal{G}$ corresponds to the flow in an edge of $\mathcal{P}$; the balance of the contributions of the rectilinear tendrils and wiggles in the faces of $\mathcal{G}$ corresponds to the conservation of flow at the vertices of $\mathcal{P}$.

**Theorem 15.** *Given an instance $\mathcal{S}$ of* NOT-ALL-EQUAL-3-SAT *with $n$ variables and $m$ clauses, graph $\mathcal{G}$ associated with $\mathcal{S}$ has $O(n^4m^3)$ vertices and edges, and can be constructed in $O(n^4m^3)$ time. Instance $\mathcal{S}$ is satisfiable if and only if graph $\mathcal{G}$ is rectilinear planar. Also, given a rectilinear planar embedding for $\mathcal{G}$, a satisfying truth assignment for $\mathcal{S}$ can be computed in time $O(n^4m^3)$.*

From Theorem 15 we conclude:

**Corollary 16.** *Rectilinear planarity testing is NP-complete.*

**Corollary 17.** *Let $G$ be an $n$-vertex planar graph whose minimum number of bends in any planar orthogonal drawing is $b^*$. Computing a planar orthogonal drawing of $G$ with $O(b^* + n^{1-\epsilon})$ bends is NP-hard for $\epsilon > 0$.*
