Abstract

Atmospheric observations of mini-Neptunes orbiting M dwarfs are beginning to provide constraints on their chemical and thermal properties, while also providing clues about their interiors and potential surfaces. With their relatively large scale heights and large planet–star contrasts, mini-Neptunes are currently ideal targets toward the goal of characterizing temperate low-mass exoplanets. Understanding the thermal structures and spectral appearances of mini-Neptunes is important to understand various aspects of their atmospheres, including radiative/ convective energy transport, boundary conditions for the interior, and their potential habitability. In the present study, we explore these aspects of mini-Neptunes using self-consistent models of their atmospheres. We begin by exploring the effects of irradiation, internal flux, metallicity, clouds, and hazes on the atmospheric temperature profiles and thermal emission spectra of temperate mini-Neptunes. In particular, we investigate the impact of these properties on the radiative–convective boundary and the thermodynamic conditions in the lower atmosphere, which serves as the interface with the interior and/or a potential surface. Building on recent suggestions of habitability of the mini-Neptune K2-18 b, we find a range of physically motivated atmospheric conditions that allow for liquid water under the H_2-rich atmospheres of such planets. We find that observations of thermal emission with JWST/MIRI spectrophotometry can place useful constraints on the habitability of temperate mini-Neptunes such as K2-18 b and provide more detailed constraints on the chemical and thermal properties of warmer planets such as GJ 3470 b. Our results underpin the potential of temperate mini-Neptunes such as K2-18 b as promising candidates in the search for habitable exoplanets.

1. Introduction

Of the thousands of exoplanets known to date, mini-Neptunes are the most common type (Fressin et al. 2013; Fulton et al. 2017). Yet no analog is known in the solar system. We refer to a mini-Neptune as a planet with a mass and radius smaller than Neptune whose density is too low to be explained by a purely rocky composition (e.g., Rogers 2015; Fulton et al. 2017). With properties between those of rocky planets and ice giants, these intermediate objects offer an intriguing window into a new realm of atmospheric, surface, and interior processes.

Mini-Neptunes arguably represent optimal targets for atmospheric studies of temperate planets with potentially "habitable" surfaces. By "habitable" we mean thermodynamic conditions at which liquid water is possible on a planetary surface (e.g., Kasting et al. 1993; Meadows & Barnes 2018) and at which life is known to survive on Earth, including extremophiles, i.e., at temperatures $\lesssim 400$ K and pressures $\lesssim 1250$ bar (e.g., Rothschild & Mancinelli 2001; Merino et al. 2019). On the one hand, temperate rocky planets in the habitable zone can host surfaces conducive to life (e.g., Yang et al. 2013; Koll & Abbot 2016; Wolf et al. 2017; Lincowski et al. 2018; Meadows & Barnes 2018), but their small radii and large atmospheric mean molecular weights make observations challenging (Barstow & Irwin 2016; de Wit et al. 2018; Lustig-Yaeger et al. 2019). On the other hand, larger Neptune-size ice giants with H_2-rich atmospheres are ideal for atmospheric characterization (e.g., Fraine et al. 2014; Wakeford et al. 2017), but the high pressures and temperatures in their deep atmospheres preclude habitable conditions. Temperate mini-Neptunes with the right mass and radius offer the potential for

habitable conditions below the atmosphere (Madhusudhan et al. 2020), while their hydrogen-dominated atmospheres make them conducive for spectroscopic observations, similarly to ice giants (e.g., Kreidberg et al. 2014; Chen et al. 2017; Benneke et al. 2019a, 2019b; Tsiaras et al. 2019).

Several studies have investigated the effects of various parameters on physical processes in H_2-rich atmospheres. For example, varying $T_{\rm int}$ changes the location of the radiative–convective boundary and the temperature structure in the lower atmosphere, with implications for chemical mixing and atmospheric circulation (Morley et al. 2017; Carone et al. 2020; Thorngren et al. 2019). While atmospheric mixing through eddy diffusion in the radiative zone can homogenize the observable atmosphere (e.g., $P \lesssim 1$ bar; Moses et al. 2011), convection makes it more efficient to mix material from the deep atmosphere. Similarly, clouds and hazes with strong optical scattering can cool the atmosphere, as they reflect incident stellar irradiation (e.g., Morley et al. 2015), which in turn can affect the surface and interior temperatures possible in such planets. The effects of other physical parameters on H_2-rich atmospheres of Neptunes/mini-Neptunes have also been explored in previous works, such as metallicity (Spiegel et al. 2010) and UV flux (Moses et al. 2013a; Miguel & Kaltenegger 2014). The effects of photospheric clouds and hazes on mini-Neptune atmospheric spectra have also been explored in detail (Howe & Burrows 2012; Morley et al. 2013). Furthermore, Malik et al. (2019) have recently used self-consistent atmospheric models to explore the occurrence of thermal inversions in both hydrogen-rich and higher-metallicity super-Earth atmospheres.

While habitability studies often focus on Earth-like terrestrial planets, this has also been explored for larger planets with

H_2-rich atmospheres. Since a nominal definition of habitability requires the presence of liquid surface water (e.g., Meadows & Barnes 2018), temperate conditions are required at the planetary surface to allow for habitability. For Earth-like rocky exoplanets, surface temperatures and pressures are regulated by their thin atmospheres dominated by gases such as N_2, H_2O, and CO_2, which define the traditional habitable zone (e.g., Kasting et al. 1993; Kopparapu et al. 2017; Meadows et al. 2018; Meadows & Barnes 2018). Recent studies have shown that H_2-dominated atmospheres on such planets could also cause a significant greenhouse effect (Stevenson 1999; Pierrehumbert & Gaidos 2011; Koll & Cronin 2019) and can extend the traditional habitable zone out to larger orbital separations. For example, Pierrehumbert & Gaidos (2011) argue for the habitability of such planets out to 1.5 au for a 3 $M_\oplus$ planet orbiting an early M dwarf, which could be accessible by microlensing. However, atmospheric characterization of such planets is challenging owing to their larger orbital distances. In this study, we focus on planets with H_2-rich atmospheres in close-in orbits that are accessible with transit observations and consider the conditions under which their surfaces could be habitable.

While past studies of habitability under H_2-rich atmospheres have been focused on rocky super-Earths (e.g., Pierrehumbert & Gaidos 2011; Seager et al. 2013), it is becoming evident that certain mini-Neptunes with H_2-rich atmospheres may also host habitable surfaces (Madhusudhan et al. 2020). Such mini-Neptunes must have masses and radii, i.e., bulk densities, that can allow a sufficiently low surface pressure for an H_2O layer under the H_2-rich atmosphere. Extremophiles on Earth are known to survive pressures as high as 1250 bar and temperatures up to 395 K (Merino et al. 2019). Therefore, a mini-Neptune with a surface pressure of $\lesssim$1000 bar could potentially be habitable if its surface temperature is cool enough. Madhusudhan et al. (2020) find that this is the case for the habitable-zone mini-Neptune K2-18 b. They find that the mass, radius, and atmospheric properties of K2-18 b are consistent with an interior structure comprising a silicate/Fe core, an H_2O layer, and an H_2-rich atmosphere. The pressure below the atmosphere can be as low as ~1 bar with temperatures $\lesssim$400 K, allowing habitable conditions in the H_2O layer underneath.

K2-18 b may therefore represent a Rosetta Stone for exoplanetary habitability, with the potential for both habitable conditions and detailed atmospheric characterization with current and future facilities. Of course, unlike K2-18 b, not all mini-Neptunes are expected to host habitable surfaces. Mini-Neptunes that are hotter and with lower bulk densities than K2-18 b would lead to significantly higher temperatures and pressures, respectively, below their H_2-rich atmospheres that would be too high to be habitable. For example, GJ 1214 b, with similar mass and radius to K2-18 b but with an equilibrium temperature of ~500 K, is expected to have supercritical H_2O beneath its atmosphere at temperatures inconducive to life (Rogers & Seager 2010). However, for planets such as K2-18 b, a wide range of atmospheric parameters may allow for habitable conditions. Indeed, conditions even slightly hotter than K2-18 b and a range of surface pressures may allow for habitability, as we explore in this study. K2-18 b may, therefore, be the archetype for this class of planets, many more of which may be discovered by current and upcoming surveys.

In this study, we focus on three primary aspects of mini-Neptune atmospheres. First, we explore the temperature structures and spectral appearance of mini-Neptunes as a function of key atmospheric parameters, such as incident irradiation, internal flux, metallicity, and cloud/haze properties. In particular, we investigate the interplay between radiative and convective energy transport mechanisms in mini-Neptune atmospheres as a function of these parameters, with important implications for atmospheric composition and dynamics. Second, we investigate the implications of atmospheric temperature structures of mini-Neptunes on their surface conditions underneath the atmosphere and assess their potential habitability. Finally, we evaluate the observability of mini-Neptune atmospheres in thermal emission with the James Webb Space Telescope (JWST) to characterize both potentially habitable and warmer mini-Neptunes. In particular, we propose a simple metric to identify temperate mini-Neptunes that could potentially host habitable conditions, with a view to guiding follow-up observations. We demonstrate our results on some case studies, including the habitable-zone mini-Neptune K2-18 b and the warmer mini-Neptune GJ 3470 b.

In what follows, we begin by outlining our atmospheric model in Section 2. In Section 3, we then present a suite of self-consistent P–T profiles and emergent spectra exploring the atmospheric parameter space of mini-Neptunes using K2-18 b as a prototype. We further conduct a detailed study of the mini-Neptune K2-18 b in Section 4 with the specific goal of assessing the thermodynamic conditions at the base of the atmosphere and the potential for habitable conditions therein. In Section 5 we investigate the observability of mini-Neptunes, both temperate and warmer planets, with JWST in the mid-infrared. We conclude and discuss our findings in Section 6.

2. Atmospheric Model

We model the atmospheres of mini-Neptunes using an adaptation of the self-consistent atmospheric modeling framework GENESIS (Gandhi & Madhusudhan 2017; also used in Piette et al. 2020). GENESIS self-consistently calculates the pressure–temperature (P–T) profile, the chemical profile, and the spectrum of a plane-parallel atmosphere under assumptions of radiative–convective, hydrostatic, local thermodynamic, and thermochemical equilibrium. In what follows, we discuss the model considerations and adaptations to GENESIS made in the present study, including radiative transfer, clouds/hazes, and comparisons with similar models in the literature.

2.1. Energy Budget and Radiative–Convective Equilibrium

Applying radiative–convective equilibrium to the model atmosphere involves balancing inward and outward energy transport in each layer of the atmosphere. The total energy budget of the atmosphere can be thought of as coming from two sources: incident irradiation from the host star and an intrinsic flux emanating from within the planet, which represents residual energy from formation/accretion and can also include other heating effects such as tidal heating. The level of incident irradiation can be characterized by the irradiation temperature,

$$T_{\mathrm{irr}} = \left(\frac{R_\star}{\sqrt{2}\, a} \right)^{\frac{1}{2}} T_\star, \qquad (1)$$

where $T_\star$ and $R_\star$ are the stellar temperature and radius, respectively, and a is the semimajor axis of the planet. $T_{\rm irr}$ is effectively the equilibrium temperature ($T_{\rm eq}$) of the dayside atmosphere of the planet assuming zero albedo and that the incident flux is redistributed and reradiated only on the day side, i.e., no day–night redistribution.

In our model we assume that the incident irradiation is uniformly redistributed over the dayside plane-parallel atmosphere. A significant amount of the incident irradiation is expected to be reflected back in the presence of strong optical scattering (e.g., due to clouds or hazes) as we consider in the present work. A fraction of the remnant irradiation that reaches the deeper atmosphere may be transported to the night side depending on the location of the atmosphere–interior boundary. For example, in cases where the boundary occurs at low pressures, the day–night redistribution may take place in the interior, e.g., the H_2O layer, rather than the atmosphere. We, therefore, do not include any day–night atmospheric redistribution explicitly; we discuss this in Section 6.

The internal flux can be characterized by internal temperature, $T_{\rm int}$. Values of $T_{\rm int}$ can depend on formation mechanisms, mass, composition, internal sources of heating, and age, since a planet loses its initial energy from formation over time at a rate determined by its internal and atmospheric properties. Estimates of $T_{\rm int}$ can therefore be made using planetary evolution models (e.g., Valencia et al. 2013; Lopez & Fortney 2014). In this work, we explore a wide range of plausible internal temperatures for mini-Neptunes. Valencia et al. (2013) find that for the mini-Neptune GJ 1214 b, $T_{\rm int}$ can be as high as 80 K/ 62 K if it has a water-rich/solar-like composition and a young age of 0.1 Gyr. Morley et al. (2017) consider higher values of $T_{\rm int}$ ($\gtrsim$300 K) for GJ 436 b, as this planet may be experiencing tidal heating. Conversely, the minimum possible value of $T_{\rm int}$ is 0 K. In this work, we explore the range $T_{\rm int} = 0$–200 K.

Once the energy budget of the atmosphere is set, energy transport can occur in two primary ways: radiative and convective transport. In GENESIS, convective fluxes are calculated using mixing-length theory (Kippenhahn et al. 2012) for regions of the atmosphere where the temperature gradient is steeper than the adiabatic gradient. In purely radiative regions of the atmosphere, the requirement of energy balance in a given atmospheric layer can be written as

$$\int_0^\infty \kappa_\nu (J_\nu - B_\nu) d\nu = 0,$$

where ν is frequency, J_ν is the mean intensity of radiation in that layer, B_ν is the Planck function corresponding to the temperature in the layer, and κ_ν is the absorption coefficient. This form of the equations assumes that the atmosphere is in local thermodynamic equilibrium, and the $\kappa_\nu J_\nu$ and $\kappa_\nu B_\nu$ terms represent the absorption and emission of radiation in the atmospheric layer, respectively. In convective regions of the atmosphere, the convective flux is also added to this equation (see Gandhi & Madhusudhan 2017, for more detail). In order to find a P–T profile that satisfies energy balance, GENESIS then uses Rybicki's method to iteratively solve the equations of radiative–convective equilibrium (Hubeny & Mihalas 2014; Gandhi & Madhusudhan 2017).

2.2. Radiative Transfer

Given a P–T profile and the opacity structure of an atmosphere, the radiation field of the atmosphere can be calculated using the radiative transfer equation. For a given frequency, ν, and atmospheric layer, this equation is

$$\mu \frac{dI_\nu}{d\tau_\nu} = I_\nu - S_\nu, \qquad (2)$$

where I_ν is specific intensity at angle θ to the normal, τ_ν is the optical depth of the layer, S_ν is the source function in the layer, and $\mu = \cos\theta$.

This procedure is necessary at two points in the calculation of the atmospheric model: (i) in the iterative solution of radiative–convective equilibrium, and (ii) in order to calculate the emergent spectrum of the planet once a converged, energy-balanced atmospheric model is found. For the solution of radiative–convective equilibrium, a fast radiative transfer solution is ideal, as the calculation needs to be performed in each iteration. Furthermore, values of mean intensity are not directly needed from this solution; instead, Eddington factors ($f_\nu = K_\nu/J_\nu$, where $K_\nu = 1/2\int_{-1}^{1}\mu^2 I_\nu(\mu)d\mu$) are sufficient for the calculation of radiative equilibrium. On the other hand, calculation of the emergent spectrum requires accurate solutions for the mean intensity and is only calculated once, so it need not be as fast. We therefore choose to use the Feautrier method (Feautrier 1964) in the iterative solution of radiative–convective equilibrium and the discontinuous finite element (DFE) method (Castor et al. 1992) combined with accelerated lambda iteration (ALI) for the calculation of the spectrum. Both methods are second-order accurate and provide direct solutions to the radiative transfer equation.

The Feautrier method solves radiative transfer under the assumption that the source function is isotropic. This is achieved by recasting Equation (2) in terms of the symmetric and antisymmetric averages of specific intensity, $j_\nu = (I_\nu(\mu) + I_\nu(-\mu))/2$ and $h_\nu = (I_\nu(\mu) - I_\nu(-\mu))/2$, respectively. This results in the Feautrier equation, $\mu^2 \frac{d^2 j_\nu}{d\tau_\nu^2} = j_\nu - S_\nu$. This equation is then solved using matrix methods as described in Hubeny & Mihalas (2014) and yields the desired Eddington factors that are used in the solution of radiative–convective equilibrium.

The DFE solution for radiative transfer divides the atmosphere into plane-parallel layers and solves for the specific intensity at the top and bottom of each layer, I_d^+ and I_d^-, respectively, for layer d. Crucially, a discontinuity between adjacent layers is allowed, i.e., $I_d^+ \neq I_{d+1}^-$, and it is this property that allows the method to be second-order accurate (Castor et al. 1992). The specific intensity for layer d, I_d, is then given by a weighted average of I_d^+ and I_d^-. This formalism leads to the following recurrence relations for I_d^+ and I_d^- (dropping the ν subscript for clarity):

$$a_d I_{d+1}^- = 2I_d^- + \Delta\tau_{d+1/2}S_d + b_d S_{d+1}$$
$$a_d I_d^+ = 2(\Delta\tau_{d+1/2} + 1)I_d^- + b_d S_d - \Delta\tau_{d+1/2}S_{d+1/2},$$

where $a_d = \Delta\tau_{d+1/2}^2 + 2\Delta\tau_{d+1/2} + 2$, $b_d = \Delta\tau_{d+1/2}(\Delta\tau_{d+1/2} + 1)$, and $\Delta\tau_{d+1/2} = (\tau_{d+1} - \tau_d)/|\mu|$. When scattering is present, this method must be used iteratively, which can be done using ALI. The general principle of ALI methods is to write a matrix equation such as $I = \Lambda[S]$ as an iterative process, i.e.,

$I^{\mathrm{new}} = \Lambda^*[S^{\mathrm{new}}] + (\Lambda - \Lambda^*)[S^{\mathrm{old}}]$, where Λ^* is an approximate operator chosen to minimize computation time and maximize convergence rate. Details of the implementation of ALI for the DFE method can be found in Hubeny (2017).

2.3. Chemistry, Opacities, and Clouds/Hazes

In this work, we consider opacity due to species in gas phase, hazes, and clouds. The gas-phase species we include here are the main volatiles expected in hydrogen-rich atmospheres: H_2O, CH_4, NH_3, CO, CO_2, HCN, and C_2H_2 (Madhusudhan 2012; Moses et al. 2013b). We calculate their equilibrium abundances self-consistently with the P–T profile using the analytic method of Heng & Tsai (2016) in each iteration of the radiative–convective equilibrium solver. We also include opacity due to H_2–H_2 and H_2–He collision-induced absorption (CIA). The cross sections we use for these species are calculated from the HITEMP, HITRAN, and ExoMol line list databases using the methods of Gandhi & Madhusudhan (2017) (H_2O, CO, and CO_2: Rothman et al. 2010; CH_4: Yurchenko et al. 2013; Yurchenko & Tennyson 2014; C_2H_2: Rothman et al. 2013; Gordon et al. 2017; NH_3: Yurchenko et al. 2011; HCN: Harris et al. 2006; Barber et al. 2014; CIA: Richard et al. 2012).

In our models we also consider the phase transition of gaseous H_2O in the atmosphere into both the liquid and ice phases. When H_2O condenses to the liquid phase, we remove it from the atmosphere as precipitation. This "rainout" happens if the H_2O mixing ratio is greater than the local saturation vapor pressure. In this case, we assume that any H_2O in excess of the saturation level rains out, and the remaining atmospheric H_2O vapor pressure is equal to the saturation vapor pressure in these regions. On the other hand, in regions of the atmosphere where the temperature is below the freezing point, the H_2O is removed entirely from the gas phase and instead included as an ice cloud as described below.

We also include a simple prescription for hazes in our models. We assume that the haze is homogeneously distributed in the atmosphere and its opacity is of the form of an enhanced H_2 Rayleigh scattering, i.e., H_2 Rayleigh scattering boosted by a multiplicative factor. This allows us to explore the general effects of haze on model P–T profiles with a simple parameterization. In order to compare the strength of our model hazes to more detailed studies, we look to the models of Howe & Burrows (2012) for GJ 1214 b. One of the best-fit models presented by Howe & Burrows (2012) includes a tholin haze of density 100 cm^{-3} and particle size 0.1 μm, whose extinction has a λ^{-4} dependence at wavelengths <1 μm. The scattering opacity of this haze is equivalent to $\sim$1000$\times$ the scattering opacity of H_2 Rayleigh scattering at 1 mbar and 300 K. In Section 3, we therefore explore haze opacities in the range 0–10,000 $\times$ H_2 Rayleigh scattering.

Our prescription for clouds involves cloud decks whose particle abundances decay exponentially with altitude above the cloud base given a cloud scale height, analogous to the condensate profiles of Ackerman & Marley (2001). Rather than parameterizing the cloud scale height according to parameters such as f_{rain} as in Ackerman & Marley (2001), we choose for simplicity a nominal cloud scale height of 1/3 of an atmospheric scale height, similar to Jovian ammonia clouds (e.g., Carlson et al. 1994; Brooke et al. 1998; see also Ackerman & Marley 2001). The base of the deck is fixed at a given pressure, which in Sections 4 and 5 we choose such that the temperature at the base of the cloud approximately

coincides with the condensation temperature of the cloud species (see, e.g., condensation curves of Morley et al. 2012). In Section 3, however, we independently explore the effect of cloud location on the P–T profile and therefore do not consider condensation temperature. We nominally assume a KCl composition to represent the effects of salt clouds, and we also explore the effects of water ice clouds. In Section 4, we include KCl, ZnS, and ice clouds wherever they are thermodynamically expected to occur.

We vary cloud opacity in our models by varying the abundance of the condensate species (i.e., varying metallicity). At the base of each cloud, we assume that all of the cloud species are in the condensed phase. For the salt clouds, the abundance of cloud particles is therefore determined by the abundance of the least abundant element in the condensate species (e.g., Cl for KCl) and the particle size. Cloud particle sizes are known to vary depending on a range of physical factors that have been explored in detail in several works (e.g., Ackerman & Marley 2001; Morley et al. 2014). For simplicity, throughout this work we assume a nominal modal particle size of 0.33 μm for the salt clouds and use the cloud extinction cross sections given by Pinhas & Madhusudhan (2017). For ice clouds, the particle abundance at the base of the cloud depends on the H_2O abundance and the particle size (which can vary between models; see Section 4). We use the extinction cross sections for water ice from Budaj et al. (2015).

Above an ice cloud deck, the abundance of gaseous H_2O can depend on the presence of vertical mixing. For our model parameter exploration in Section 3, we freeze out all H_2O above the base of the water ice cloud deck (i.e., assuming a cold trap and no vertical mixing) to provide a uniform comparison between models with different ice cloud abundance, which is a free parameter. In reality, however, if a thermal inversion occurs, it is possible that the temperature profile above the cloud deck is hotter than the freezing point. In such cases, it is conceivable that water vapor may be present above the cloud deck owing to vertical mixing in the atmosphere, e.g., analogous to condensable species being lofted to upper regions in irradiated atmospheres (e.g., Parmentier et al. 2013). For example, if the temperature at 0.1 bar is 250 K and the temperature at 10^{-3} bar is 300 K, H_2O will be frozen out at 0.1 bar but H_2O vapor could still be present at 10^{-3} bar given sufficient vertical mixing. Therefore, we allow for this possibility when modeling the specific case studies in Sections 4 and 5, i.e., H_2O is only frozen out when it is expected to be in the ice phase, allowing it to come back to vapor phase higher up in the atmosphere if the temperature there is above the freezing point.

2.4. System Parameters

In Section 3, we apply our model to a generic mini-Neptune to qualitatively assess the impacts of various atmospheric parameters on its P–T profile and spectrum. The planetary and host star parameters we choose to use for this test case are based on those of K2-18 b (Foreman-Mackey et al. 2015; Montet et al. 2015), and we use the values given by Cloutier et al. (2019) and Benneke et al. (2019b). For the planetary parameters, we assume a radius of 2.61$R_\oplus$ and log gravity of 3.094 (in cgs). For the stellar parameters, we assume a radius of 0.4445 $R_\odot$, log gravity of 4.836 (in cgs), temperature of 3457 K, and [Fe/H] metallicity of 0.12. We use a Kurucz
Figure 1. Comparisons with model pressure–temperature profiles of mini-Neptunes in the literature. Left panel: comparison to the model for K2-18 b from Figure 5 of Benneke et al. (2019b) (B19). Middle panel: comparison to the K2-18 b solar-metallicity model from Figure 11 of Scheucher et al. (2020) (S20, case 6 in their Table 6). Right panel: comparison to clear (solid lines) and cloudy (dashed lines) models for GJ 1214 b from Morley et al. (2013) (M13). See Section 2.5 for details.

stellar model for the stellar spectrum in our models (Kurucz 1979; Castelli & Kurucz 2003).

In Section 4, we calculate models specifically for K2-18 b using the same parameters as described above, and using its orbital separation to determine the irradiation temperature based on parameters from Benneke et al. (2019b). For K2-18 b, $T_{irr} = 332$ K. We further estimate the internal temperature of K2-18 b based on existing estimates for GJ 1214 b (Charbonneau et al. 2009), which has a similar mass and radius to K2-18 b (Benneke et al. 2019b; Cloutier et al. 2019). Valencia et al. (2013) find that for ages between ∼1 and 10 Gyr, considering both solar and water-rich atmospheric compositions, GJ 1214 b has an internal temperature in the range of ∼25–50 K. We therefore calculate models for these two end-member values of T_{int}.

We also calculate models for GJ 3470 b (Bonfils et al. 2012) in Section 4, a planet with radius comparable to Neptune but of lower mass. For this, we use planetary and stellar properties from Awiphan et al. (2016). The planetary radius and log gravity are $4.57 R_\oplus$ and 2.81 (in cgs), respectively, with a mass of $13.9 M_\oplus$ and semimajor axis of 0.0355 au. For the stellar parameters we use a radius of $0.547 R_\odot$, log gravity of 4.695 (in cgs), effective temperature of 3600 K, and [Fe/H] metallicity of 0.2. The irradiation temperature of GJ 3470 b given these system parameters is 812 K. For the internal temperature, we use an intermediate value of 30 K (Valencia et al. 2013).

In Section 2.5, we also model GJ 1214 b for comparison with previous models in the literature. For these models, we use the stellar and planetary parameters of GJ 1214/GJ 1214 b from Harpsœe al. (2013). The planetary radius and log gravity are $2.85 R_\oplus$ and 2.88 (in cgs), respectively, and the semimajor axis is 0.0141 au. For the star we use a radius of $0.216 R_\odot$, log gravity of 4.944 (in cgs), effective temperature of 3026 K, and [Fe/H] metallicity of 0.39.

The GENESIS models described above can be used to generate atmospheric models with arbitrary pressure and wavelength resolution. We choose to use 10,000 wavelength points uniformly distributed between 0.4 and 50 μm and 100

depth layers log-uniformly distributed between pressures of 10^3 and 10^{-6} bar.

2.5. Model Comparison

We compare our self-consistent forward model to three other examples of mini-Neptune models in the literature: Benneke et al. (2019b) and Scheucher et al. (2020) for K2-18 b, and Morley et al. (2013) for GJ 1214 b. We use the same input parameters and model setup as described in these works. The internal temperature is not specified for these models, so we choose to use $T_{int} = 100$ K, as this results in good agreement.

We first reproduce the model P–T profile of K2-18 b from Figure 5 of Benneke et al. (2019b). We include opacity due to H_2O vapor, H_2–H_2 and H_2–He CIA, and Rayleigh scattering due to H_2. Following Benneke et al. (2019b), we assume an albedo of 0.3. We further assume that uniform day–night redistribution of the incident flux, i.e., 50% of the incident irradiation, minus the reflected component, remains on the day side. We use an H_2O abundance of 40× the expected abundance for a solar composition in thermochemical equilibrium, i.e., approximately the best-fitting value found by Benneke et al. (2019b, their Figure 4), which they use to calculate their model P–T profile. We also use the planetary and stellar parameters for K2-18 b/K2-18 given by Benneke et al. (2019b), which are also listed in Section 2.4. The left panel of Figure 1 shows the model from Benneke et al. (2019b), as well as our reproduction, which agrees very closely.

Note that the P–T profile of Benneke et al. (2019b) does not appear to explicitly include the effects of water ice clouds, despite having temperatures below the freezing point of H_2O. Instead, an albedo of 0.3 was assumed to remove the corresponding amount of incident flux at the top of the atmosphere. Our reproduction is, therefore, also cloud-free and assumes the same albedo treatment. We explore cloudy and hazy models of K2-18 b in Section 4.

We further reproduce the solar-metallicity P–T profile for K2-18 b from Figure 11 of Scheucher et al. (2020) (case 6 in

their Table 6). Their model assumes equilibrium chemical abundances for an isotherm at 320 K, and this chemistry is kept fixed for the calculation of the P–T profile. We therefore include opacity due to H_2O, CH_4, and NH_3 in our reproduction (the dominant carriers of O, C, and N, respectively, at this temperature) assuming fixed, constant-with-depth abundances corresponding to the equilibrium abundances expected at 320 K (i.e., mixing ratios of 10^{-3}, $10^{-3.3}$, and $10^{-3.9}$ for H_2O, CH_4, and NH_3, respectively; see, e.g., Woitke et al. 2018). We also include opacity due to H_2–H_2 and H_2–He CIA, as well as H_2 Rayleigh scattering. Following Scheucher et al. (2020), we do not include any clouds or hazes in this model. We also assume uniform day–night energy redistribution. We also use the planetary and stellar parameters for K2-18 b/K2-18 given in Section 2.4. Both the model from Scheucher et al. (2020) and our reproduction of this are shown in the middle panel of Figure 1.

Our model and that of Scheucher et al. (2020) agree closely. Any differences between them may be due to differences in the treatment of radiative transfer and radiative–convective equilibrium, e.g., Scheucher et al. (2020) do not self-consistently consider convective flux. We further note that this P–T profile enters the ice phase of H_2O and should therefore include the presence of water ice clouds. We find in Section 4 that assessing the habitability of K2-18 b requires consideration of optical opacity in the atmosphere, e.g., clouds and/or hazes. As such, the cloud- and haze-free models of Scheucher et al. (2020) are limited in assessing the habitability of this planet.

We also use our model to reproduce a clear and a cloudy P–T profile for GJ 1214 b from Figure 1 of Morley et al. (2013). We model a $1\times$ solar clear atmosphere and a $50\times$ solar cloudy atmosphere, both assuming that incident irradiation is redistributed on the day side only (i.e., corresponding to the hotter P–T profiles in Figure 1 of Morley et al. 2013). In both cases, we include opacity due to all of the volatile species discussed in Section 2.3. In the cloudy model, we also include KCl and ZnS clouds with base pressures of 0.025 and 0.158 bar, respectively. This is where the Morley et al. (2013) model crosses the condensation curves for each of these species and where the cloud bases are positioned in their model. We use a modal particle size of 38.6 μm for these clouds. Since the effective temperature of GJ 1214 is cooler than 3500 K, we are not able to use a spectral model from the Kurucz library as described above (which includes models with $T_{\rm eff} \geqslant 3500$ K) and instead use a model from the PHOENIX library (Husser et al. 2013) with the closest stellar parameters to GJ 1214, i.e., $T_{\rm eff} = 3000$ K, $\log(g/{\rm cgs}) = 5.0$, and [Fe/H] = 0.5. Our models and those of Morley et al. (2013) are shown in the right panel of Figure 1. The models show good agreement and differ by $\lesssim 100$ K, which may be due to differences in the stellar spectrum used.

3. Effects of Atmospheric Parameters

The temperature profiles of mini-Neptune atmospheres are determined by a range of atmospheric properties, including the internal flux, irradiation, and the opacity structure of the atmosphere, which are, therefore, key to understanding the various processes discussed above. In this section, we investigate the effects of these properties on the temperature structures and thermal emission spectra of mini-Neptune atmospheres. In particular, we explore the effects of internal temperature, irradiation, infrared opacity, and cloud/haze

properties, discussing how they impact the observability and physical processes of these atmospheres, as well as consequences for modeling the interiors of mini-Neptunes.

We consider a fiducial model with $T_{\rm irr} = 350$ K, $T_{\rm int} = 40$ K, and $1\times$ solar metallicity and explore models in the range $T_{\rm irr} = 350$–1000 K, $T_{\rm int} = 0$–200 K, and metallicities of 0.1–100× solar. We present both clear and hazy/cloudy models, exploring haze opacities up to 1000× Rayleigh scattering (according to the parameterization discussed in Section 2.3) and salt/water ice clouds with up to 100× solar metallicity. We discuss the P–T profiles and thermal emission spectra of these models in Sections 3.1 and 3.2, respectively.

3.1. Temperature Profiles and Energy Transport

We begin by exploring how $T_{\rm int}$, $T_{\rm irr}$, metallicity, cloud/haze opacity, and cloud type affect the thermal profiles of mini-Neptunes. Energy transport in a planetary atmosphere is governed by the boundary conditions at the top and bottom of the atmosphere, characterized by $T_{\rm irr}$ and $T_{\rm int}$, respectively, and by the opacity profile that lies between them. In the upper, low-opacity regions of the atmosphere, energy transport is primarily radiative, an effect that is enhanced by strong incident irradiation. In the deeper, high-opacity layers, convective transport begins to dominate. Where the transition between the two regimes—the radiative–convective boundary—occurs depends on several factors, including incident and intrinsic flux, as well as optical and infrared opacity. Depending on the location of the radiative–convective boundary, the presence of convection can in turn impact atmospheric mixing and, therefore, the chemical homogeneity of the atmosphere.

Here, we investigate how the parameters listed above impact the thermal profile and energy transport mechanisms of an atmosphere by generating self-consistent P–T profiles, as described in Section 2, and independently varying each parameter in turn. Figure 2 shows model P–T profiles for which we vary the haze opacity (left panel) or cloud opacity (middle and right panels). In the middle and right panels, we place a KCl cloud at 10 bar and an H_2O ice cloud at 0.1 bar, respectively, to test the effects of different types of clouds. We test the effects of $T_{\rm int}$, $T_{\rm irr}$, and metallicity in Figure 3, for both a clear atmosphere (top panels) and a hazy one (bottom panels). For each P–T profile, we also show the 1–30 μm photosphere, smoothed by a Gaussian of width 0.1 μm, to represent the pressures and temperatures probed by low-resolution infrared thermal emission observations. In what follows, we describe the effects of each of these parameters in turn on the atmospheric temperature profile.

3.1.1. Effect of Clouds/Hazes

Figure 2 shows the effects of hazes, high-altitude ice clouds, and deeper salt clouds on the thermal profile of a mini-Neptune. Here the cloud/haze properties are varied according to the prescriptions described in Section 2. For example, in the middle and right panels the abundance of cloud species is varied according to the metallicity specified, keeping the cloud scale heights and locations fixed. While in reality the cloud base location is driven by its condensation temperature, in this section we choose to only vary cloud opacity in order to independently demonstrate the structural effects that this has on the P–T profile. Note that, for the purpose of demonstration here, the abundance of water ice particles is varied
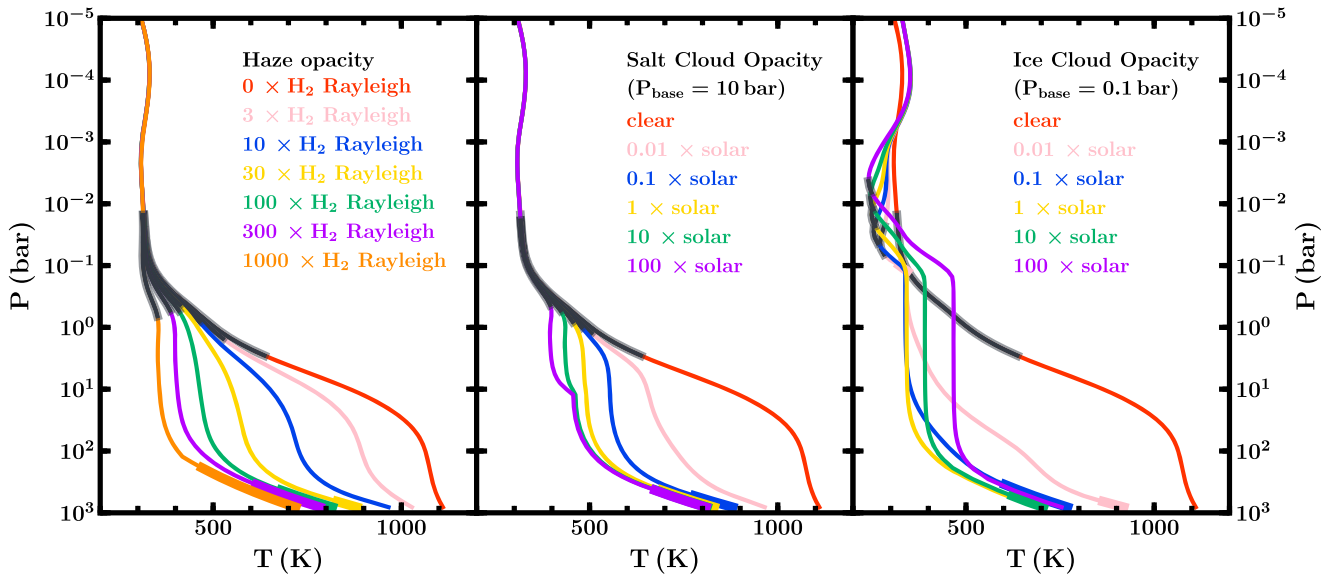

Figure 2. *P–T* profiles for model atmospheres with varying haze and cloud opacities. The left panel shows effects of varying haze, which is included homogeneously throughout the atmosphere and implemented using an enhanced Rayleigh scattering prescription (see Section 2.3). The middle and right panels show the effects of a KCl/water ice cloud deck, with the abundance of the cloud condensate parameterized by the metallicity, as described in Section 2.3. For the salt/water ice clouds, the base of the cloud deck is at a pressure of 10 bar/0.1 bar and the modal particle size is 0.33 μm/4 μm, respectively. We use a nominal cloud scale height of 1/3 of an atmospheric scale height. For each model, $T_{int} = 40$ K, $T_{irr} = 350$ K, and the metallicity of the gaseous species in the atmosphere is 1× solar. In each panel, the red profile denotes a clear atmosphere. Convective regions are shown by thick lines, and photospheres are shown by thick dark-gray lines (see Section 3.1).

independently of the gaseous H$_2$O abundance. The models in Figure 2 all assume $T_{int} = 40$ K, $T_{irr} = 350$ K, and solar abundances of the gaseous species listed in Section 2.

Clouds and hazes both provide optical opacity that scatters incident irradiation and can therefore cool the atmosphere. This is shown clearly in the left and middle columns of Figure 2, as increasing the haze/KCl cloud abundance results in a cooler temperature profile. Ice clouds can also cool the atmosphere (right column of Figure 2), though very high opacity clouds can also warm the atmosphere by intercepting outgoing flux (Morley et al. 2014). Both the photospheric temperature and the temperature at deeper pressures are affected by these effects, meaning that clouds and hazes are important components in understanding both the spectra and interiors of mini-Neptunes. Figure 2 also shows that stronger cloud/haze opacity typically results in a more isothermal temperature profile below the photosphere. This can impact the habitability of the planet, as cooler, more habitable temperatures are maintained to higher pressures where a surface may occur. We discuss this further in Section 4.

The location of the radiative–convective boundary is also affected by the presence of clouds/hazes. As we discuss in Section 3.1.2, the boundary between the radiative and convective regions of the atmosphere is dependent on the incident irradiation, with weaker irradiation resulting in a shallower radiative–convective boundary. By scattering incident irradiation, clouds/hazes also raise this boundary to lower pressures. For example, in Figure 2, only the models with the strongest haze/cloud opacities have a radiative–convective boundary shallower than 1000 bar (i.e., the edge of the computational domain), and the boundary occurs at lower pressures for models with higher cloud/haze opacity.

3.1.2. Irradiation versus Internal Flux

As the boundary conditions at the top and bottom of the atmosphere, irradiation and internal flux compete in

determining the location of the radiative–convective boundary. A high T_{irr} results in a larger region of the atmosphere being dominated by radiative transport, pushing the radiative–convective boundary deeper. Conversely, a hotter T_{int} pushes this boundary higher up. These effects can be seen in Figure 3 and are strongest for the hazy models in the bottom left and bottom middle panels. As T_{irr} decreases, the temperature gradient at 1000 bar gradually becomes steeper, transitioning from almost isothermal at $T_{irr} = 1000$ K to an adiabatic gradient at $T_{irr} \leqslant 650$ K, when the radiative–convective boundary occurs within the computational domain.

As expected, T_{int} has the opposite effect. Models with higher T_{int} show significantly shallower radiative–convective boundaries, with the shallowest within this parameter space at ∼1 bar for the model with $T_{int} = 200$ K. However, such a high value of T_{int} may be unlikely for a mini-Neptune (e.g., Valencia et al. 2013), though high T_{int} values have been considered for planets that may be affected by tidal heating (e.g., GJ 436 b; Morley et al. 2017). For models with $T_{int} \leqslant 100$ K the radiative–convective boundary is deeper than 10 bar. This suggests that intrinsic heat in mini-Neptunes may be insufficient to mix their atmospheres up to shallow pressures through convection unless they have significant haze/cloud opacities. Instead, eddy diffusion in the radiative regime may be a more likely mechanism for vertical mixing.

While T_{irr} and T_{int} have strong effects on the radiative–convective boundary when haze is present, in the haze-free models their influence is reduced at the pressures investigated here. The top left and middle panels in Figure 3 show that none of the T_{irr} or T_{int} values explored result in a radiative–convective boundary shallower than 1000 bar for a clear model. Though the larger values of T_{int} explored do result in a higher temperature gradient at high pressures, this suggests that for the clear models in the parameter space explored here (i.e., $T_{irr} \gtrsim 350$ K), incident irradiation and radiative transport dominate the atmosphere up to pressures of at least 1000 bar.
Figure 3. Self-consistent atmospheric *P–T* profiles across a range of internal temperatures, irradiation temperatures, and infrared opacities (parameterized by metallicity relative to solar abundances). The top panels show *P–T* profiles for a clear atmosphere, while the bottom panels include haze equivalent to $1000 \times H_2$ Rayleigh scattering. The fiducial values used for T_{int}, T_{irr}, and infrared opacity are 40 K, 350 K, and 1× solar metallicity, respectively. Thick line segments indicate convective regions, and photospheres are shown by thick dark-gray lines (see Section 3.1).

Aside from the radiative–convective boundary, irradiation and internal flux also have significant effects on the temperature profile in general. As expected, a hotter T_{irr} translates the temperature profile to higher temperatures, and consequently the photospheric temperature is extremely sensitive to this parameter. In contrast, T_{int} only affects the deepest regions of the atmosphere and does not affect the photosphere unless it is extremely high (e.g., Morley et al. 2017). The left and middle columns of Figure 3 also show that the temperatures at high pressures are strongly dependent on both T_{irr} and T_{int}, meaning that these properties are important to consider when using such models as boundary conditions for internal structure models.

3.1.3. Effect of Infrared Opacity

Infrared opacity is an important factor in determining energy transport, as it intercepts outgoing planetary flux. For planets with a cool stellar host whose spectrum peaks in the near-infrared, such as K2-18, the infrared opacity can also absorb incident irradiation. As a result, higher abundances of these infrared absorbers result in a hotter temperature profile. This can be seen in the right column of Figure 3, which shows *P–T* profiles for different infrared opacities, characterized by metallicity relative to solar elemental abundances. These *P–T* profiles also show that metallicity predominantly affects deeper regions of the atmosphere; the profiles are similar at low pressures and begin to diverge at $P \gtrsim 0.1$ bar. At these higher pressures, models with higher metallicity also exhibit convective zones as the increase in opacity reduces the efficiency of radiative transport. We also note that for models with very

high IR opacity (e.g., $\gtrsim 100\times$ solar), the H_2O mixing ratio in the lower atmosphere can be close to saturated. We consider the rainout that can result from supersaturation in Sections 4 and 5.

Since high infrared opacities result in hotter temperatures deep in the atmosphere, this property is an important factor both for boundary conditions in internal structure models and for considerations of habitability. However, the photosphere is not strongly affected by changes in infrared opacity. This is because an increase in infrared opacity effectively translates the *P–T* profile to lower pressures, while the photosphere of a higher-opacity model also occurs at lower pressures (Spiegel et al. 2010). As a result, the photospheres of the models in the right column of Figure 3 probe similar temperatures despite the differences in their infrared opacities.

3.2. Thermal Emission Spectra

In this section, we investigate the effects of internal temperature, irradiation, metallicity, and clouds/hazes on the thermal emission spectra of mini-Neptunes. These emergent spectra are strongly sensitive to the atmospheric temperature profile and are therefore impacted by the parameters listed above through their effects on the temperature profile. Figures 4 and 5 show thermal emission spectra corresponding to the *P–T* profiles in Figures 2 and 3, respectively. In each of these, a flux ratio of 10 ppm is shown by a dashed line to indicate an optimistic minimum uncertainty expected with JWST.
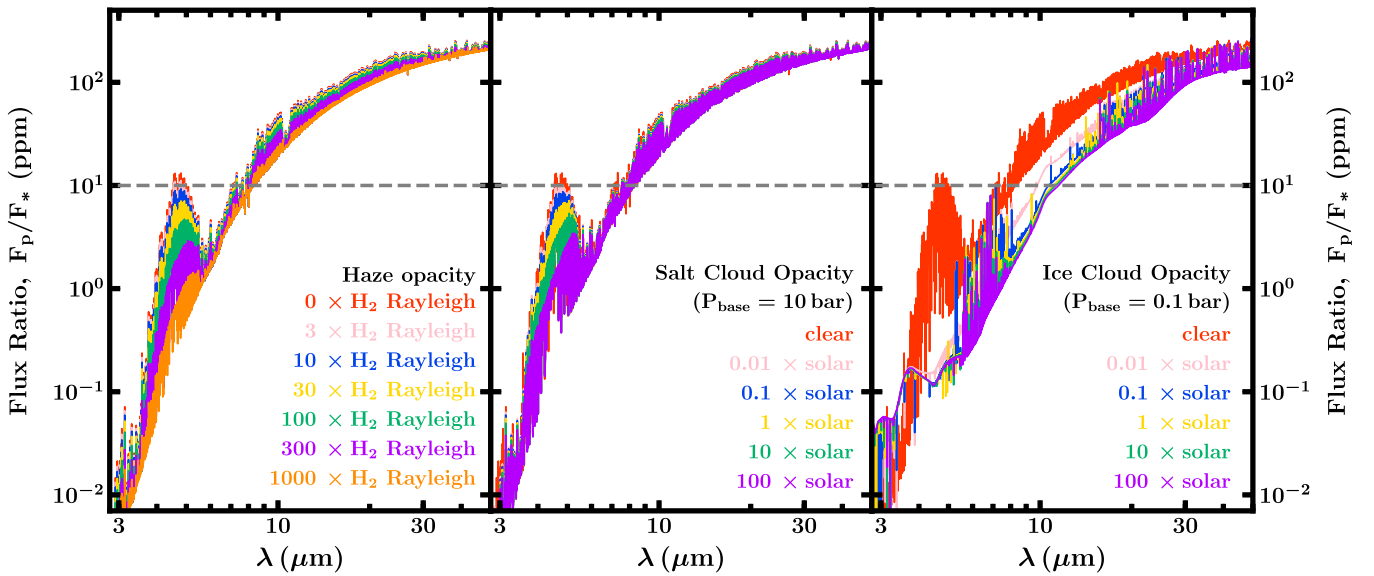

Figure 4. Model thermal emission spectra corresponding to the P–T profiles in Figure 2. For each model, $T_{int} = 40$ K, $T_{irr} = 350$ K, and the metallicity of the gaseous species in the atmosphere is $1\times$ solar. We vary haze, salt cloud, and water ice cloud opacities in the left, middle, and right panels, respectively. The horizontal dashed gray lines show the 10 ppm level, which may be considered an optimistic precision achievable with JWST.

Clouds and hazes predominantly affect the spectrum at shorter wavelengths, as they reflect incident stellar irradiation that peaks in the optical. However, this reflected light is well below an optimistic 10 ppm uncertainty for JWST and is, therefore, unlikely to be detectable for the temperate mini-Neptunes modeled here. Nevertheless, clouds and hazes can also affect the spectrum through their effects on the P–T profile. For example, high-altitude ice clouds significantly cool the photospheric temperature, which results in less emitted flux. In the case of hazes and deeper KCl clouds, stronger haze/cloud opacity results in a more isothermal P–T profile in the photosphere and weaker absorption features. This can be seen in the continuum peak at ~ 5 μm, which is smaller for models with stronger haze/KCl cloud opacity.

Although T_{irr} and T_{int} both play major roles in determining the P–T profile and radiative–convective boundary (Section 3.1.2), only T_{irr} has a significant effect on the observable spectrum. As T_{irr} translates the P–T profile to hotter/cooler temperatures, the emergent flux increases/decreases accordingly. However, T_{int} largely affects the P–T profile below the photosphere and does not impact the spectrum unless its value is sufficiently high. For the models shown here with $T_{irr} = 350$ K, $T_{int} = 200$ K is enough to affect the photosphere and result in a slightly higher continuum peak at ~ 5 μm. This is a stronger effect for hazy models compared to clear ones (left column of Figure 5), though the haze also mutes the continuum feature. Estimates of T_{int} for mini-Neptunes will therefore rely on theoretical cooling models, as this parameter will not be derivable from observed dayside spectra unless it is very high.

The right column of Figure 3 shows that metallicity does not have a strong effect on the observable spectrum, especially at longer wavelengths. As discussed by Spiegel et al. (2010), this is because the increase in temperature due to increased metallicity is balanced by the photosphere shifting to lower pressures. Furthermore, this shallower photosphere is also more isothermal, which weakens the strength of spectral features.

While each atmospheric parameter affects the observable spectrum to different extents, we note that all of the spectra in

Figures 4 and 5 are well above 10 ppm at longer wavelengths and should be observable with JWST. In Section 5, we discuss how JWST observations could help to constrain the conditions in atmospheres of mini-Neptunes.

4. Considerations for Habitability

In the search for extrasolar habitability, planets in the habitable zones of M dwarfs provide excellent targets thanks to their small host star radii and semimajor axes. Furthermore, mini-Neptunes have large atmospheric scale heights and planet/star size ratios, making them especially conducive to atmospheric characterization. K2-18 b is a prime example of such a planet, and its atmosphere has been characterized through transmission spectroscopy, leading to a strong detection of water vapor (Benneke et al. 2019b; Tsiaras et al. 2019). Using the observed spectrum and bulk properties (mass and radius), Madhusudhan et al. (2020) placed joint constraints on the atmosphere and interior of K2-18 b and found several solutions allowing for liquid water at habitable temperatures and pressures at its surface. The Transiting Exoplanet Survey Satellite (TESS) is expected to find more planets of this type, with several existing candidates and some already confirmed (e.g., Günther et al. 2019).

Traditional definitions of the habitable zone are typically designed for terrestrial planets with thin atmospheres (Kasting et al. 1993; Kopparapu et al. 2017; Meadows & Barnes 2018), for which the equilibrium temperature can be comparable to the surface temperature. This is not the case for mini-Neptunes, which host H_2-rich envelopes and whose surfaces can occur at much deeper/higher pressures. Due to the greenhouse effect of H_2, the temperatures at these higher pressures can be significantly hotter than the equilibrium temperature of the planet (Pierrehumbert & Gaidos 2011; Koll & Cronin 2019). Habitability on mini-Neptunes therefore relies on physical processes that can counter this heating effect, such as clouds and hazes.

In this section, we explore atmospheric conditions under which K2-18 b could host liquid water on its surface at
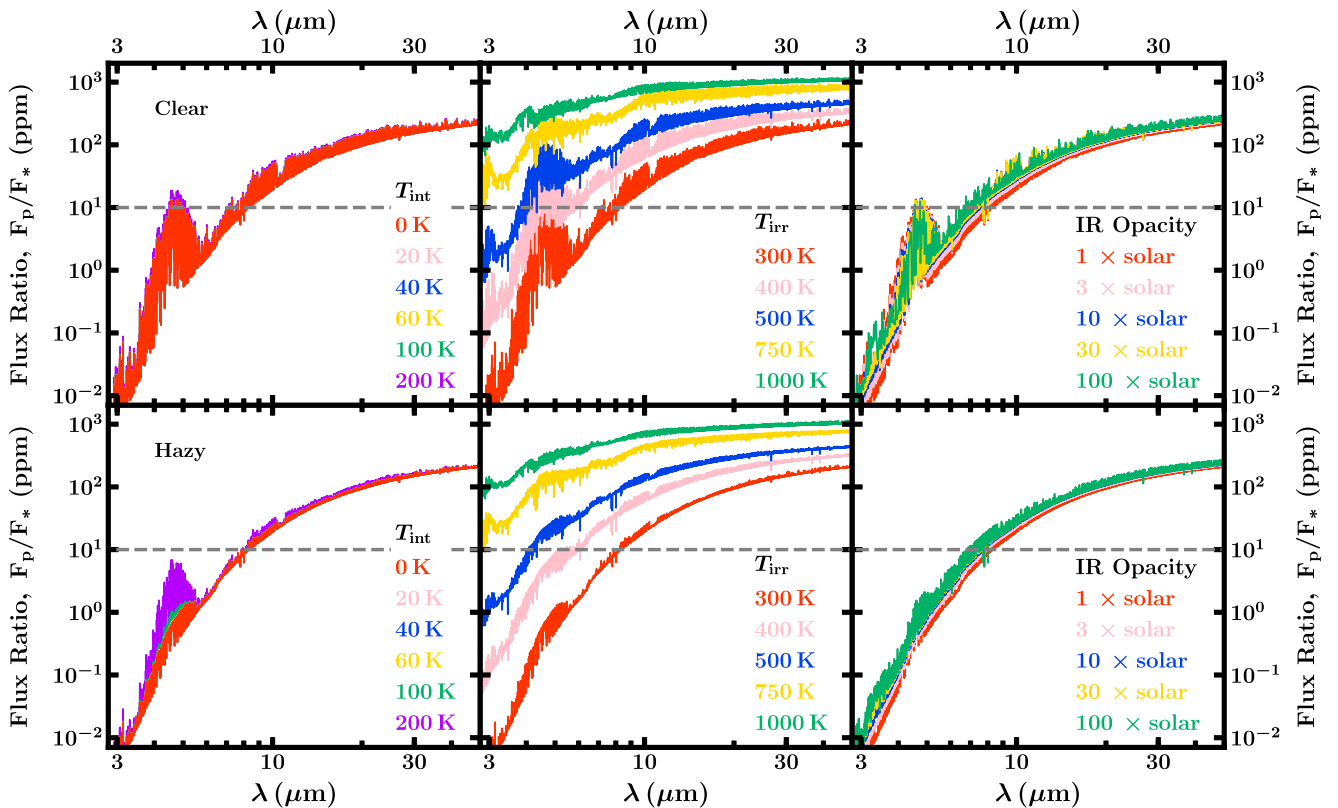

Figure 5. Model thermal emission spectra corresponding to the P–T profiles in Figure 3, for varying T_{int}, T_{irr}, and infrared opacity (left, middle, and right columns, respectively). The fiducial values used for T_{int}, T_{irr}, and infrared opacity are 40 K, 350 K, and 1× solar metallicity, respectively. The top panels show spectra for a clear atmosphere, while the bottom panels include haze equivalent to 1000 × H_2 Rayleigh scattering. The horizontal dashed gray lines show the 10 ppm level, which may be considered an optimistic precision achievable with JWST.

habitable temperatures and pressures. Liquid water on the surface is typically considered to be a nominal requirement for habitability (e.g., Meadows & Barnes 2018). Furthermore, it is known that extremophiles on Earth are able to survive at temperatures up to 395 K and pressures up to 1250 bar (Merino et al. 2019). In what follows, we therefore refer to temperatures ≲395 K at pressures ≲1250 bar as habitable conditions. We begin by discussing the requirements for a liquid ocean in Section 4.1. Since the atmospheric H_2O abundance above an ocean can be a complex function of altitude (as seen on Earth; e.g., Pierrehumbert et al. 2006), we then explore atmospheric P–T profiles for two end-member scenarios: fixed metallicity in Section 4.2 and 100% relative humidity in Section 4.3.

4.1. Conditions for an Ocean

An essential condition for the presence of a water ocean in a planet is the availability of a water reservoir beneath the atmosphere at the right thermodynamic conditions. Several works have explored the possibility of water oceans in super-Earths and water worlds with a large H_2O layer in the interior (e.g., Léger et al. 2004; Rogers & Seager 2010; Rogers et al. 2011; Zeng & Sasselov 2013; Thomas & Madhusudhan 2016), as well as ice giants with mixed-composition interiors that require sufficiently large H_2O mixing ratios at low photospheric temperatures (e.g., Wiktorowicz & Ingersoll 2007). In the present work, we assume the presence of a water layer below the H_2-rich atmosphere, following the recent constraints on the mini-Neptune K2-18 b from Madhusudhan et al. (2020). Whether or not a liquid water ocean is possible below the

atmosphere thus depends on the pressure–temperature conditions at the bottom of the atmosphere as we model here.

For K2-18 b, Madhusudhan et al. (2020) find that the atmospheric mass fraction is between ≲10^{-6} and ~6×10^{-2}, allowing surface pressures as low as ~1 bar for some atmospheric P–T profiles. In their interior model, a 100% H_2O layer exists below the atmosphere, similar to other models in the literature for super-Earths and mini-Neptunes (e.g., Nettelmann et al. 2011; Rogers et al. 2011; Valencia et al. 2013). As discussed in Section 1, not all mini-Neptunes would have masses and radii consistent with habitable pressures (≲1000 bar) below their H_2-rich atmospheres. However, mini-Neptunes with bulk densities similar to or higher than K2-18 b could allow for habitable surface pressures.

In what follows, we use the term HHB, as in Madhusudhan et al. (2020), to denote the boundary between the H_2O surface and the H_2-rich atmosphere, i.e., the pressure level where the atmosphere terminates and the 100% H_2O layer begins. Just above the HHB, the H_2O abundance is that of the atmosphere, i.e., lower than 100%. At the HHB and below, the H_2O abundance is 100%, i.e., in the water layer. Therefore, the phase of water can change across the HHB depending on the pressure and temperature conditions at the HHB, for example, from vapor in the atmosphere to liquid in the 100% H_2O layer below. To assess the phase of the 100% H_2O layer just below the HHB, we compare model atmospheric P–T profiles to the phase diagram of 100% H_2O (Fei et al. 1993; Wagner & Pruß, 2002; Seager et al. 2007; French et al. 2009; Sugimura et al. 2010; Thomas & Madhusudhan 2016), as shown in the right panel of Figure 6. Note that this phase diagram does not
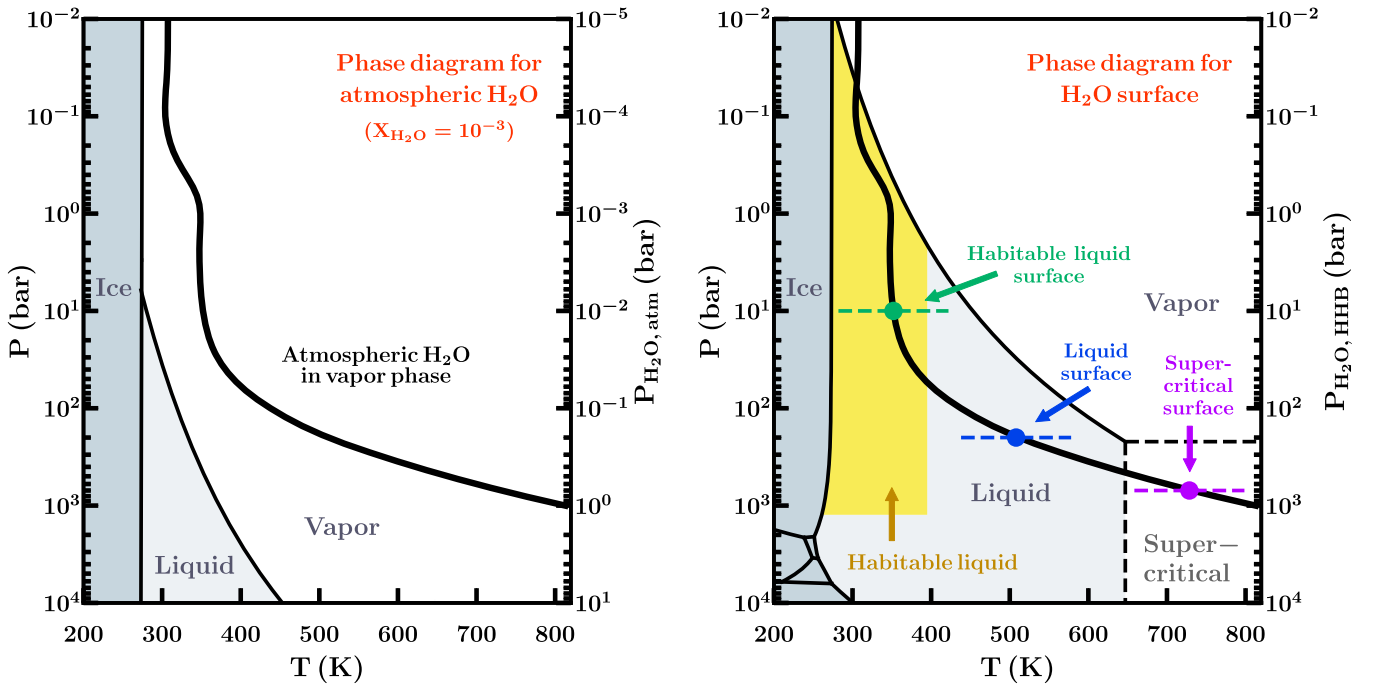

Figure 6. Schematic of an atmospheric P–T profile (bold black lines) and the corresponding phases of the atmospheric H_2O (left panel) and of the 100% H_2O layer beneath the atmosphere (right panel). Left panel: background shows the phase diagram for the atmospheric H_2O assuming a fixed mixing ratio of 10^{-3}. For the P–T profile shown here, the atmospheric H_2O is in the vapor phase throughout. Right panel: background shows the phase diagram for 100% H_2O, corresponding to the phase at the surface of the 100% H_2O layer beneath the atmosphere. The region of the liquid phase satisfying $P < 1000$ bar, $T < 395$ K is highlighted in yellow and corresponds to conditions known to be habitable for extremophiles on Earth (e.g., Merino et al. 2019). Depending on the location of the H_2O layer/H_2-rich atmosphere boundary (HHB), the surface of the H_2O layer in this example can be in the liquid phase (at habitable or inhabitable temperatures) or the supercritical phase. These scenarios are marked by the green, blue, and purple dashed lines and circles, respectively. In both panels, the left y-axis (P) corresponds to the total atmospheric pressure, while the right y-axes ($P_{H_2O,atm}$ and $P_{H_2O,HHB}$) show the partial pressure of H_2O in the atmosphere (left panel) and the total pressure of H_2O at the HHB (right panel), respectively. In the following figures, the H_2O phase diagram is always shown for the HHB, as shown in the right panel here.

correspond to the atmospheric H_2O, as the partial pressure of H_2O in the atmosphere is less than the total pressure (see left panel of Figure 6). Instead, at each pressure and temperature it corresponds to the phase of H_2O at the surface of the 100% H_2O layer below assuming that the bottom of the atmosphere is at that pressure and temperature.

4.2. Effects of Cloud/Hazes, Metallicity, and T_{int}

In this section, we explore the effects of clouds, hazes, metallicity, and internal temperature on the potential habitability of K2-18 b. For these models, we assume a fixed atmospheric metallicity informed by the transmission spectrum of K2-18 b, as described below. The assumed H_2O abundance is largely subsaturated in these models, representing one extreme in relative humidity, which is known to be a complex function of many parameters on Earth (e.g., Pierrehumbert et al. 2006). We then explore models with a saturated H_2O abundance in Section 4.3.

Our model P–T profiles are shown in Figures 7 and 8 and discussed further below. At any given pressure, P, in the P–T profile, the comparison to the H_2O phase diagram indicates the phase at the surface of the H_2O layer if the HHB occurred at that pressure (i.e., $P_{HHB} = P$), as shown in the right panel of Figure 6. Note that we do not assume a particular location for the HHB in our models. Instead, we calculate the atmospheric P–T profile up to 1000 bar and see where the HBB would cross the H_2O phase diagram for different values of P_{HHB}. For example, if a model P–T profile crosses the liquid phase for 100% H_2O at 10 bar, this suggests that if the HHB were to

occur at 10 bar, the surface of the 100% H_2O layer would be liquid.

Madhusudhan et al. (2020) show that $P_{HHB} \gtrsim 1$ bar for K2-18 b. That is, the surface between the atmosphere and the 100% H_2O layer can exist at pressures $\gtrsim 1$ bar. Therefore, atmospheric P–T profiles that intersect with the liquid H_2O phase at pressures $\gtrsim 1$ bar could allow for surface liquid water below the atmosphere at that pressure. Furthermore, if the P–T profile intersects the liquid phase at <395 K, this liquid surface water would be at habitable temperatures. We reiterate that the phase diagram of H_2O shown here does not correspond to the phase of H_2O in the atmosphere. Instead, it corresponds to the phase of the 100% H_2O layer at the HHB, just below the atmosphere.

In order to generate atmospheric P–T profiles for K2-18 b, we use spectroscopic constraints on the atmospheric chemistry from Madhusudhan et al. (2020). Madhusudhan et al. (2020) find an atmospheric H_2O abundance of ∼1–100× solar, with no detection of any other species. We therefore include only H_2O in our models, varying its metallicity from 1 to 100× solar. In all our models, we also include salt (KCl/ZnS) clouds and water ice clouds wherever they are thermochemically expected to occur (Section 2). Water ice cloud particle sizes can have a wide range of modal particle sizes (e.g., Morley et al. 2014); we tried a range of sizes and in the models presented here use particle sizes in the range of 1–3 μm. The base of each ice cloud is located approximately where the atmospheric H_2O enters the ice phase (as described in Section 2.3). In the models shown in Figure 7, the cloud bases lie in the range of 0.01–0.2 bar. As described in
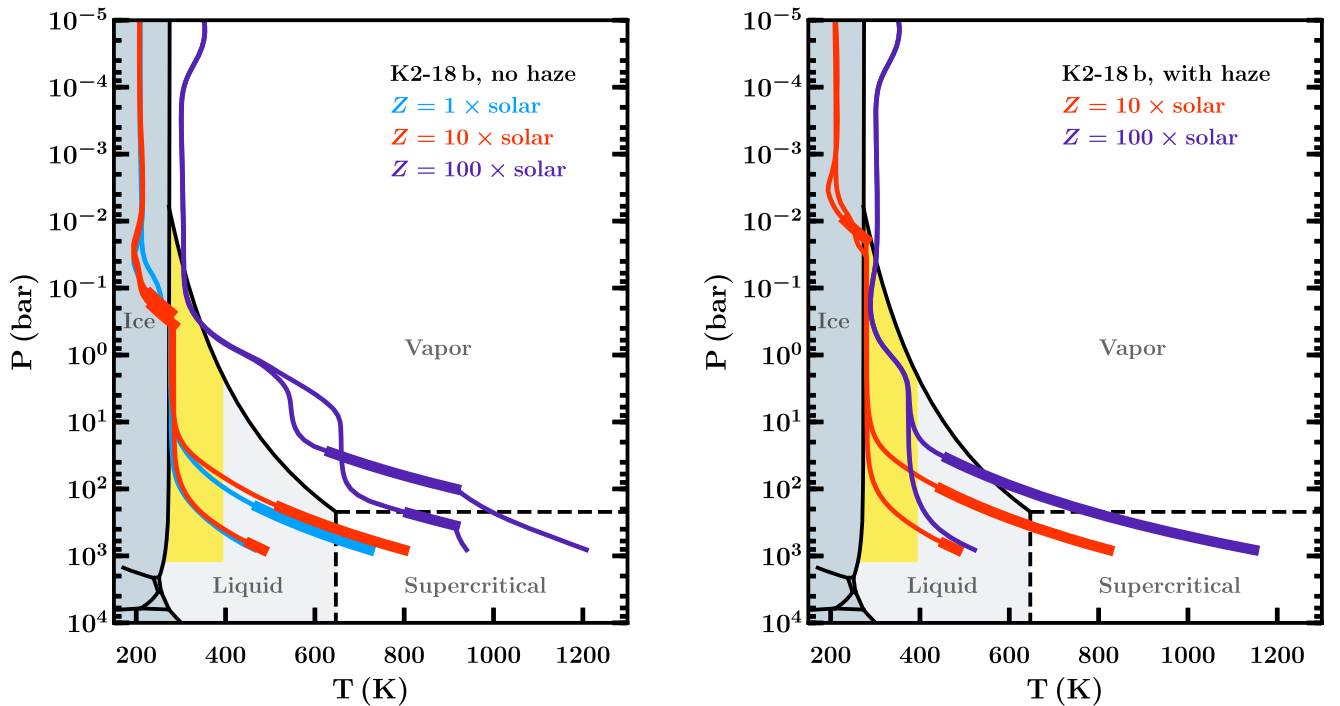

Figure 7. Model dayside P–T profiles for K2-18 b, for a range of metallicities and internal temperatures, that could allow habitable conditions below the atmosphere. For each metallicity, the cooler/hotter profile at 1000 bar corresponds to T_{int} = 25 K/50 K. Left panel: models with no haze. Models with 1× and 10× solar metallicity enter the water ice phase, so we include ice clouds where they are thermodynamically required (cloud bases in the range of 0.2–0.3 bar). The 100× solar-metallicity model has KCl and ZnS clouds in the deep atmosphere (cloud bases between 100 and 1000 bar). Right panel: models with hazes. The 10× solar-metallicity model with T_{int} = 25 K has haze equivalent to 500 × H_2 Rayleigh scattering, while the other models have 1000 × H_2 Rayleigh scattering. Models with 10× solar metallicity have water ice clouds (cloud bases in the range of 0.01–0.03 bar). The phase diagram of H_2O is shown in the background, corresponding to the surface conditions of a 100% H_2O layer beneath the H_2-rich atmosphere, i.e., at the HHB (see Section 4 and right panel of Figure 6). The shaded yellow regions show habitable conditions in Earth's oceans, with T < 395 K and P < 1250 bar (Merino et al. 2019). Models passing through the yellow region could therefore potentially host habitable liquid water at the HHB.

Section 2, we calculate models for two end-member values of T_{int}: 25 and 50 K.

We find that a range of atmospheric conditions allow for habitability in K2-18 b. Madhusudhan et al. (2020) find habitable solutions for two atmospheric P–T profiles. Here, we explore a wider range of parameters and their impact on potential habitability. Figure 7 shows model P–T profiles for K2-18 b both with and without hazes (right and left panels, respectively). As expected, higher-metallicity models are hotter and host salt clouds in the lower atmosphere, while the low-metallicity models are cooler. The haze-free models with 1 and 10× solar metallicity are sufficiently cool that ice clouds are present in the upper atmosphere, which further cools the deeper regions of the atmosphere (light-blue and red lines in left panel of Figure 7, respectively). Higher-metallicity models with hazes also remain cool at high pressures (right panel of Figure 7). For both the hazy models and the haze-free 1 and 10× solar models, an H_2O surface beneath the atmosphere could potentially host habitable liquid surface water if this surface occurs at the right pressure (see shaded yellow regions in Figure 7).

We find that a planet resembling K2-18 b but with a higher irradiation temperature can also be potentially habitable. Figure 8 shows model P–T profiles for a planet like K2-18 b but with T_{irr} = 420 K rather than 332 K (i.e., receiving ∼2.5× more incident flux, achieved by decreasing the semimajor axis). With no hazes or ice clouds (left panel), these profiles reach high temperatures deep in the atmosphere. In this case, the models do not cross the "potentially habitable"

shaded yellow region. However, models with strong haze opacity (right panel) are significantly cooled such that habitable liquid water could exist at the surface of an H_2O layer beneath the atmosphere. Therefore, mini-Neptunes similar to but somewhat warmer than K2-18 b could also have the potential for habitability, although stronger optical opacity is needed to cool such planets sufficiently. We also note that throughout this work we have assumed no day–night redistribution of the incident radiation. Therefore, our habitability estimates are conservative. Allowing for efficient day–night redistribution could allow such planets at even higher T_{irr} to be potentially habitable. We discuss this further in Section 6.

4.3. Effects of H_2O Saturation

In this section, we explore models for K2-18 b for which the atmosphere is saturated with H_2O vapor, representing the upper extreme in relative humidity. We consider two surface pressures corresponding to the base of the atmosphere: P_{HHB} = 100 bar (left panel of Figure 9) and P_{HHB} = 1 bar (right panel of Figure 9). For each surface pressure, we consider a range of haze opacities and T_{int} = 25–50 K to explore how these parameters affect the habitability of the ocean.

We assume the atmosphere to be 100% saturated between the ocean surface and the cold trap at higher altitudes. The mixing ratio of water vapor follows the saturation curve up to the cold trap where it reaches the minimum value in saturation for the corresponding temperature profile. The pressure level at this minimum is ∼0.1–0.3 bar for most cases, but it can be as
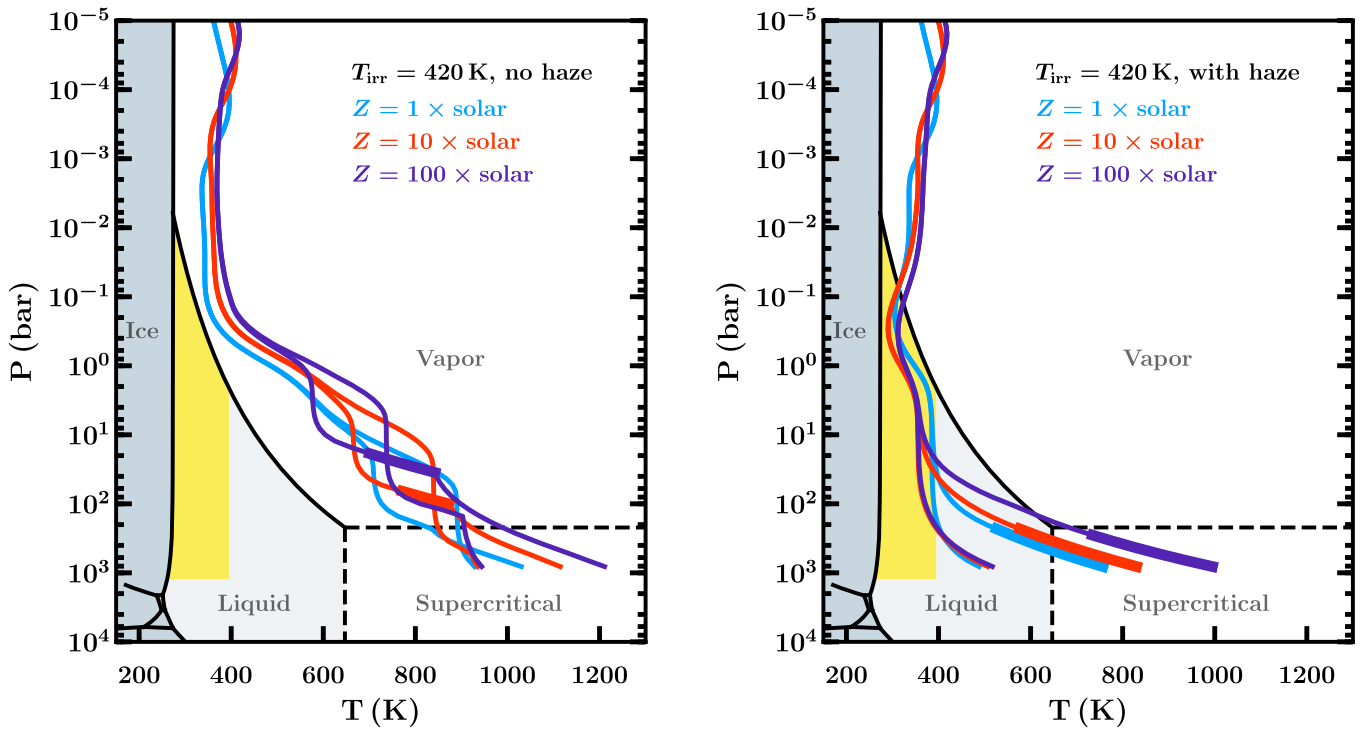

Figure 8. Same as Figure 7, but for a planet resembling K2-18 b with an irradiation temperature of 420 K (i.e., receiving ~2.5× more incident flux). Left panel: models with no hazes. Each model includes KCl and ZnS clouds with cloud base pressures between 30 and 1000 bar. Right panel: models including hazes. 1× solar models include haze equivalent to 3000 × H_2 Rayleigh scattering, while the other models have 10,000 × H_2 Rayleigh scattering. Strong haze opacity is required for the P–T profiles to enter the shaded yellow region, where an H_2O surface beneath the atmosphere could host habitable liquid water.

deep as 20 bar for cases with $P_{HHB} = 100$ bar and $T_{int} = 50$ K. Beyond the cold trap the H_2O saturation vapor pressure begins to increase with altitude and the actual H_2O mixing ratio there depends on various factors, including the efficiency of atmospheric mixing (e.g., Pierrehumbert et al. 2006). At altitudes beyond the cold trap (i.e., at lower pressures) we assume the H_2O mixing ratio to be constant at either the minimum value at the cold trap or 100× solar, whichever is smaller. The maximum abundance of 100× solar is set by the upper limit on the H_2O abundance at the photosphere (~1–100 mbar level) derived from the observed transmission spectrum of K2-18 b (Madhusudhan et al. 2020).

We note that in some cases, especially when the temperature structure is nearly isothermal in the lower atmosphere, a second cold trap can occur close to the ocean surface. Here, the saturation vapor pressure increases with altitude starting right at the surface of the ocean, before decreasing again higher up in the atmosphere and leading to the more conventional cold trap there as discussed above. For such "surface cold traps" we assume that atmospheric mixing easily overcomes the cold trap and causes the H_2O abundance to remain saturated in the lower atmosphere.

In Figure 9, we show models for which the surface of the 100% H_2O layer is in the liquid phase. For a surface pressure of 100 bar (left panel of Figure 9), we find several cases that allow for habitable temperatures at the ocean surface (i.e., ≲400 K). In particular, models with $T_{int} = 25$ K and haze abundances above ~1250 × H_2 Rayleigh scattering satisfy this condition. Models with higher T_{int} and/or less haze have warmer surface temperatures but still allow for a liquid ocean. We note that since the definition of habitability used here is based solely on Earth-like life, these warmer temperatures do not preclude

unknown life forms that may have adapted to more extreme conditions.

For a surface pressure of 1 bar (right panel of Figure 9), we find that even more solutions allow for habitable conditions at the ocean surface. First, at these low pressures, a T_{int} in the range of 25–50 K does not affect the P–T profile, allowing for more habitable cases. Second, much less haze is needed to achieve a habitable surface temperature (≳400 × H_2 Rayleigh scattering), as the atmosphere is thinner and has less greenhouse warming. We therefore find that despite the high relative humidity (i.e., 100% saturation) above the ocean, a range of surface pressures, haze opacities, and T_{int} allow for potentially habitable conditions in planets like K2-18 b.

5. Observability

As we have shown above, mini-Neptunes such as K2-18 b could provide potential targets in the search for habitability in exoplanets. In particular, their observability with current and future facilities arguably makes them optimal targets for such studies. Recent observations of K2-18 b (Benneke et al. 2019b; Tsiaras et al. 2019) have already shown that current facilities are able to observe temperate mini-Neptunes with transmission spectroscopy. Furthermore, Madhusudhan et al. (2020) showed that for K2-18 b an H_2O layer beneath the atmosphere could have a surface as shallow as ~1 bar and surface temperatures low enough for habitable liquid water. In this section, we investigate how thermal emission spectra of such planets can be used to learn about their atmospheres and to place limits on their surface conditions. In particular, we explore how observations using JWST/MIRI (Rieke et al. 2015; Kalirai 2018) can constrain both potentially habitable and warmer mini-Neptunes.
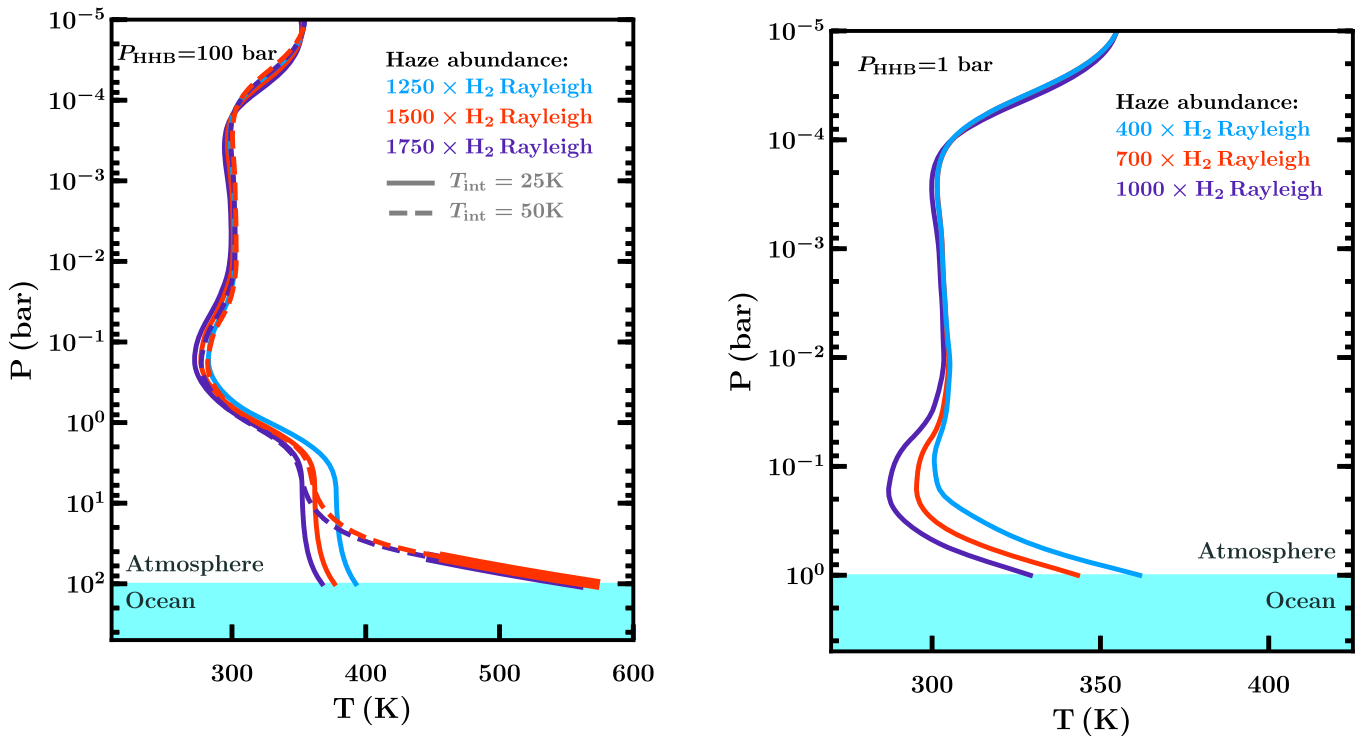

Figure 9. Model dayside P–T profiles for K2-18 b with 100% relative humidity that allow for a liquid ocean at the surface. Surface temperatures below $\sim$400 K could allow for habitable conditions for Earth-like aquatic life (e.g., Merino et al. 2019). Left panel: models with an ocean-atmosphere boundary (HHB) at 100 bar and varying haze abundances and internal temperatures (see legend). Right panel: models with the HHB at 1 bar and varying haze abundances; these P–T profiles are not sensitive to $T_{\rm int}$ between 25 and 50 K. The atmospheric H_2O abundance is fully saturated between the ocean surface and the cold trap (see Section 4.3).

5.1. Constraints on Habitability

In this section, we consider how atmospheric thermal emission observations can help to constrain the potential habitability of surface conditions in temperate mini-Neptunes similar to or smaller than K2-18 b (see Section 1). In particular, thermal emission spectra can provide information about the temperature in the photosphere. The P–T profiles in Figures 2 and 3 show that the photospheres of these atmospheres can extend as deep as $\sim$0.1–1 bar, while high-altitude clouds can raise the photosphere to shallower pressures. Below the photosphere, different P–T profiles can have a variety of gradients, from more isothermal profiles (e.g., due to ice clouds or haze) to relatively steep ones (e.g., due to high metallicity and/or low optical opacity), as demonstrated in Figure 7. Therefore, the photospheric temperature provides a lower limit to the temperature of a potential surface beneath the atmosphere. For example, if the brightness temperature of the atmosphere in an observed band is >400 K, the temperature at deeper pressures will be even higher, and habitable conditions are less likely. However, a photospheric temperature of $\sim$300 K could allow habitable conditions if the P–T profile is isothermal below the photosphere, though a steeper temperature gradient could result in surface temperatures too high for habitability. For models with ice clouds, a high cloud opacity can result in the photosphere occurring at very low temperatures, e.g., $\lesssim$250 K, while making the P–T profile isothermal below the cloud base and resulting in potentially habitable conditions at higher pressures. Observing such a low photospheric temperature, i.e., below the freezing point of H_2O, could therefore suggest the presence of such clouds and the possibility of a habitable surface.

For temperate mini-Neptunes with the potential for habitability, the emergent flux peaks in the mid-infrared ($\gtrsim$10 μm) and is therefore more easily observable at these wavelengths. Figures 4 and 5 show that the spectrum of a planet with irradiation temperature $\sim$350 K typically exceeds 10 ppm for wavelengths $\gtrsim$10 μm. Assuming optimistic uncertainties of $\sim$10 ppm, JWST observations in the mid-infrared (i.e., using MIRI) will be able to characterize these cool atmospheres and place limits on their habitability. Another advantage of this wavelength range is that the spectrum in the mid-infrared is predominantly sensitive to irradiation temperature and is less sensitive to composition (see Section 3.2). This can be seen in Figures 4 and 5, where model spectra with different metallicities converge at longer wavelengths. The mid-infrared spectrum is therefore optimal for determining the temperature in the photosphere, regardless of its chemistry.

For a planet with mass and radius low enough for habitable surface pressures (e.g., K2-18 b), the photospheric temperature measured in the mid-infrared can therefore provide a quick metric for assessing whether a mini-Neptune could potentially host habitable conditions and can rule out atmospheres that are likely too hot for habitability. Promising candidates can then be investigated further, e.g., using transmission spectroscopy to infer chemical compositions. Photometry provides an ideal way to measure this metric. In what follows, we explore how JWST/MIRI photometry can be used to measure photospheric temperature and distinguish potentially habitable planets from those that are too hot.

5.2. JWST for Mini-Neptune Habitability

JWST/MIRI will allow both photometric and spectroscopic observations beyond 10 μm, where potentially habitable mini-
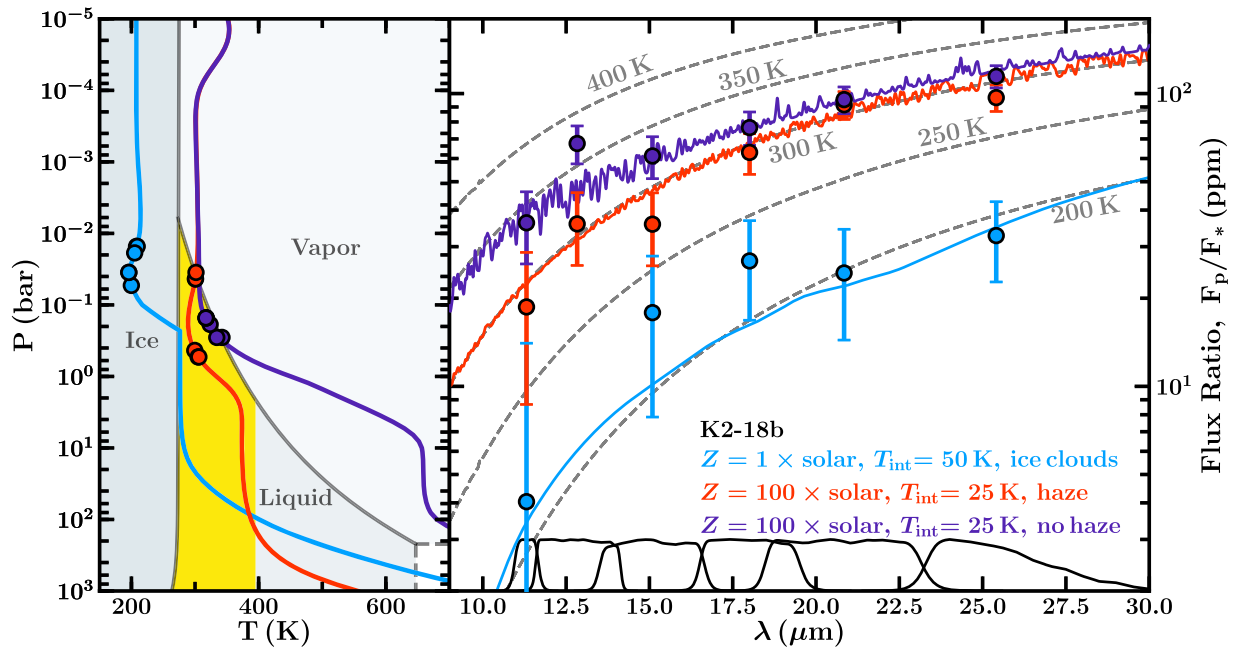

Figure 10. Observability of temperate and potentially habitable mini-Neptunes with JWST/MIRI. Left: model *P–T* profiles for K2-18 b with varying metallicities (1 and 100× solar) and internal temperatures (T_{int} = 25 and 50 K). Clouds are included wherever they are thermodynamically expected (see Figure 7 for details). The phase diagram for 100% H_2O shows the phase that a water layer would have at the boundary between the H_2-rich atmosphere and H_2O interior (HHB). The yellow region highlights pressures and temperatures where this water would be liquid and habitable. The colored circles denote brightness temperatures in different JWST/MIRI photometric bands described in the right panel. Right: model spectra corresponding to the *P–T* profiles in the left panel. Simulated photometric data from the JWST/MIRI filters at wavelengths >10 μm are shown for each spectrum (colored circles; see Section 5), with best-case error bars of 10 ppm. The brightness temperatures for the central unperturbed value of each photometric point are plotted on the corresponding *P–T* profile in the left panel, showing the depths probed by each measurement. Sensitivity curves for each filter are shown in black. Gray dashed lines show blackbody curves corresponding to planetary temperatures of 200, 250, 300, 350, and 400 K.

Neptunes can most easily be observed. Here, we assess how MIRI photometry can be used to constrain the photospheric temperatures of such planets. To do this, we simulate photometric data with the six MIRI photometric bands that probe wavelengths above 10 μm (F1130W–F2550W; Bouchet et al. 2015; Rieke et al. 2015) for a range of model atmospheres. The simulated photometric data are calculated by binning each model spectrum according to the instrument spectral response (Glasse et al. 2015). We assume best-case error bars of 10 ppm, which is a reasonable estimate for JWST photometry considering that the Hubble Space Telescope (HST) WFC3 spectrum of K2-18 b is known to a precision of ∼25 ppm at R ∼ 40 (Benneke et al. 2019b; Tsiaras et al. 2019). Figure 10 shows these data alongside the *P–T* profiles for each model. For each photometric point, we also calculate the brightness temperature probed and indicate this on the corresponding *P–T* profile; this gives an indication of the pressure being probed by each data point. For a spectral bin in the wavelength range λ_{min}–λ_{max} and a normalized instrument sensitivity function ζ, we calculate brightness temperature, T_b, such that

$$\int_{\lambda_{min}}^{\lambda_{max}} \pi \zeta B_\lambda(T_b) d\lambda = \frac{F_p}{F_s} \frac{R_s^2}{R_p^2} \times \int_{\lambda_{min}}^{\lambda_{max}} \pi \zeta I_s d\lambda,$$

where $\frac{F_p}{F_s}$ is the observed planet–star flux ratio in the photometric band, πI_s is the stellar surface flux (we use Kurucz model spectra; Kurucz 1979; Castelli & Kurucz 2003), R_p is the planetary radius, R_s is the stellar radius, and B_λ is the Planck function.

Figure 10 shows the brightness temperatures corresponding to the six photometric bands and the pressures that they probe for each *P–T* profile. In particular, for the model with ice clouds, the pressures probed are limited by the high optical depth of the cloud and are shallower than 0.1 bar. Conversely, for the warmest models with no ice clouds, the photometric points probe deeper than 0.1 bar. In all three cases, the brightness temperatures of the photometric points are cooler than the temperatures at higher pressures, where a surface could be expected to exist (e.g., ≳1 bar; Madhusudhan et al. 2020). As such, the photometric data can provide a lower limit on the temperature of such a surface.

Figure 10 also shows that profiles whose photospheric temperatures differ by ∼100 K can easily be distinguished using MIRI photometry beyond 10 μm. Brightness temperatures ≳300 K (e.g., for the warmer models in Figure 10) correspond to several tens to ∼100 ppm, which can be measured precisely if the error bars are ∼10 ppm. Brightness temperatures of ∼200–250 K (e.g., for the coolest model in Figure 10) can also be measured precisely using the longer-wavelength MIRI filters (≳17.5 μm) and can easily be distinguished from the warmer models. Indeed, the brightness temperature of this cooler model (∼200 K) can be constrained to within <50 K using the F2550W filter (25.5 μm) and assuming 10 ppm uncertainties. As such, MIRI photometry provides a way to place lower limits on surface temperature and to rule out atmospheres that are likely too hot to host habitable surfaces. Furthermore, a nondetection with the longest-wavelength MIRI photometric band (F2550W) could suggest a very cool photospheric temperature and motivate further

observations, as habitable temperatures could be present deeper in the atmosphere.

While we have used K2-18 b as a case study, these results also apply to similar planets around other M dwarfs. Given the photospheric temperature of a planet, the observed flux ratio depends on the effective temperature of the star and is higher for cooler stars. Since K2-18 is an M2.5 V star, this case study provides a conservative estimate of the observability of mini-Neptunes orbiting M dwarfs; later types can result in stronger signals.

5.3. JWST for Warmer Mini-Neptunes

Mid-infrared atmospheric observations can also be used to constrain the chemical and thermal properties of warmer mini-Neptunes. While these planets may not host habitable surfaces, their higher temperatures allow more detailed observations and constraints on their properties. In turn, such constraints can provide boundary conditions for internal structure models or give clues about their formation. Furthermore, since cooler mini-Neptunes are less suited to chemical characterization with thermal emission, their warmer counterparts may help to constrain the dayside compositions of mini-Neptunes as a population. In this section, we investigate the observability of warm mini-Neptunes with JWST/MIRI using GJ 3470 b as a case study.

To model GJ 3470 b, we use the bulk properties given in Section 2.4 and spectroscopic atmospheric constraints from Benneke et al. (2019a). Benneke et al. (2019a) find a significant detection of H_2O and constrain its abundance to be that expected from a solar-metallicity atmosphere with an uncertainty of roughly ± 1 dex. They also infer the presence of CO and/or CO_2 from the emission spectrum of the planet observed with Spitzer IRAC 1 and IRAC 2. However, since both of these species result in absorption features in the IRAC 2 4.5 μm bandpass, their abundances are degenerate with each other and form a knee-like degeneracy. We therefore do not vary the abundances of CO and CO_2 in our models and use the median mixing ratios inferred by Benneke et al. (2019a), i.e., $10^{-3.04}$ and $10^{-2.71}$, respectively, as the enhancement of one would merely lead to the depletion of the other. Benneke et al. (2019a) further infer a depletion of CH_4 and NH_3 in GJ 3470 b, so we omit these species from our models. Since the abundances of CO and CO_2 relative to H_2O are significantly higher than expected from equilibrium chemistry, we choose to use constant-with-depth abundances for these three species. We also include KCl and ZnS clouds as described in Section 2, with cloud bases at 0.3 bar. The P–T profiles and spectra for these models are shown in Figure 11. As in Figure 10, we also show simulated MIRI photometry assuming uncertainties of 10 ppm, which allows high signal-to-noise ratio measurements of the emergent flux and photospheric temperature.

Figure 5 shows that a model spectrum with $T_{irr} = 800$ K exceeds an optimistic uncertainty of 10 ppm at wavelengths greater than ~ 3 μm. In this wavelength range, the MIRI Low Resolution Spectroscopy (LRS) and Medium Resolution Spectroscopy (MRS) can be used to observe the thermal emission from these planets. In Figure 11, we show simulated MIRI LRS data for the model spectra of GJ 3470 b. We simulate these data using PandExo (Batalha et al. 2017) for the MIRI LRS slitless mode. For the error bars we assume a single eclipse, and the data are binned by a factor of 10. Absorption features due to H_2O, CH_4, CO_2, and HCN are present in this spectral range, and, using retrieval analyses, abundances of these species could be inferred from such spectra. For example, a strong absorption feature is visible at ~ 9–10 μm. In addition to chemical information, the emission spectrum can also be used to constrain the P–T profile of the planet. In the examples shown in Figure 11, the spectra probe pressures within the range of ~ 0.01–0.1 bar, meaning that the temperature profile in this range could be inferred using retrieval techniques.

6. Discussion and Conclusions

Mini-Neptunes in the habitable zones of M dwarfs can provide an excellent opportunity to study temperate exoplanets and their potential habitability. In particular, Madhusudhan et al. (2020) showed that the mass, radius, and atmospheric properties of the habitable-zone mini-Neptune K2-18 b allow it to have an H_2O surface beneath the atmosphere with a surface pressure as low as ~ 1 bar, potentially with habitable conditions. In this study, we explore the effects of a range of atmospheric parameters on the thermal profiles and spectra of such planets. We investigate three primary aspects of mini-Neptune atmospheres: (i) the diversity of atmospheric temperature structures, with implications for energy transport, chemistry, and their emergent spectra; (ii) thermodynamic conditions deep in the atmosphere, which impact the potential for habitability, as well as boundary conditions for internal structure models; and (iii) their observability with thermal emission spectra, including constraints on potential habitability.

We begin by exploring the diversity of temperature structures and emission spectra of mini-Neptunes as a function of several atmospheric parameters. The parameters we consider are irradiation temperature, internal temperature, metallicity, and cloud/haze properties. We find that for typical internal temperatures of mini-Neptunes, the radiative–convective boundary occurs well below the photosphere. As a result, vertical mixing in the photosphere is more likely to be caused by eddy mixing rather than convection. We also find that strong optical opacity due to clouds/hazes can result in an isothermal temperature structure beneath the photosphere, which can maintain cool temperatures to high pressures, with implications for habitability on deep surfaces. For all of the models we consider, which have irradiation temperatures $\geqslant 350$ K, we further find that the emergent spectra are above the 10 ppm level at wavelengths > 10 μm. This means that the emission spectra of such mini-Neptunes could be observable with JWST/MIRI, which we discuss below.

We also apply our atmospheric model to the habitable-zone mini-Neptune K2-18 b to assess its atmospheric conditions and potential habitability. We consider a range of physically motivated thermal profiles by varying metallicity, internal temperature, and haze abundance. We compare our P–T profiles to the phase diagram of water in order to assess the phase that an H_2O surface would have given a particular surface pressure. We find that many of our models intersect the liquid or supercritical phases at pressures $\gtrsim 1$ bar, suggesting that liquid or supercritical surface water could be possible on this planet for a range of atmospheric conditions. This has implications for internal structure models of mini-Neptunes, as the equation of state of H_2O is strongly temperature dependent for phases other than ice (Thomas & Madhusudhan 2016; Madhusudhan et al. 2020).
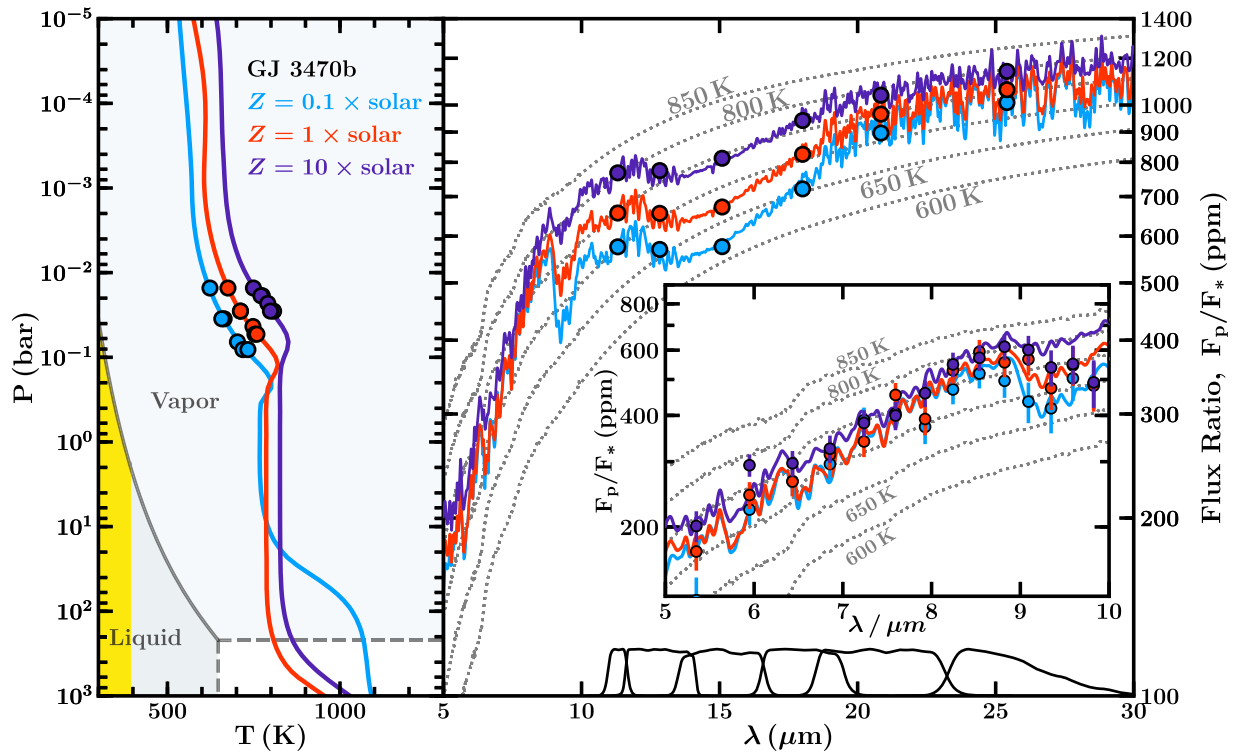

Figure 11. Observability of thermal emission from warm mini-Neptunes with JWST/MIRI. Left panel: model P–T profiles for GJ 3470 b with varying metallicities (0.1, 1, and 10× solar) and $T_{int} = 30$ K (see Section 5.3). The phase diagram shows the phase of a 100% H_2O layer at the HHB, as in Figure 10. The colored circles denote brightness temperatures in different JWST/MIRI photometric bands described in the right panel. Right panel: spectra corresponding to these P–T profiles, with simulated MIRI photometry data (colored circles; see Section 5). Brightness temperatures for the central value of each photometric point are plotted on the corresponding P–T profile in the left panel. We assume error bars of 10 ppm, which are smaller than the data symbols. Sensitivity curves for each MIRI filter used are shown in black, as in Figure 10. Inset: enlarged view of spectra in the range of 5–10 μm. Simulated MIRI LRS data, generated using PandExo (Batalha et al. 2017), are shown as colored circles and error bars. Dashed gray lines show blackbody curves for planetary temperatures of 600, 650, 700, 750, 800, and 850 K.

We also explore atmospheric models for K2-18 b that allow liquid surface water at habitable temperatures and pressures, i.e., $T \lesssim 395$ K and $P \lesssim 1250$ bar, corresponding to the most extreme temperature and pressure conditions habitable for extremophiles on Earth (Merino et al. 2019). Madhusudhan et al. (2020) model the atmosphere and interior of K2-18 b and find that, for two atmospheric P–T profiles, solutions with habitable liquid water at the surface are possible. Here, we explore a variety of atmospheric models for K2-18 b spanning a range of metallicities, internal temperatures, and haze opacities and find several solutions that allow habitable liquid water at the surface. We also consider a hypothetical planet resembling K2-18 b but with $T_{irr} = 420$ K rather than 332 K (i.e., receiving $\sim 2.5\times$ more incident flux). We find that, despite its hotter irradiation temperature, several model solutions for this planet also allow liquid surface water at habitable temperatures and pressures. In these scenarios, stronger optical scattering is needed to sufficiently cool a planetary surface. These results suggest that mini-Neptunes throughout the traditionally defined habitable zone could potentially host habitable conditions, depending on their atmospheric properties and surface pressures.

In our current models, optical scattering due to clouds/hazes is necessary to cool the lower atmosphere to habitable temperatures. In principle, some of the dayside energy may also be redistributed to the night side, thereby cooling the dayside atmosphere. Here, we have conservatively assumed that any redistribution of the stellar irradiation from the day side to the night side occurs in the interior, below the

atmosphere. In principle, where the interior–atmosphere boundary is deep enough, the day–night energy redistribution can occur in the atmosphere, as is known to occur in irradiated gas giants (Showman et al. 2009). In the context of 1D models, such an effect can be modeled by an artificial energy sink in the dayside atmosphere (e.g., Burrows et al. 2008). If energy is removed from the day side at pressures $\lesssim 1000$ bar, this could contribute to cooling the atmosphere at habitable pressures, thereby increasing the chances of habitable conditions in our models. As such, our estimates for habitable conditions in the present work may be conservative. Including such an effect may also mean that less optical opacity is required for habitable conditions to be possible. This can be explored in future work, alongside more complex prescriptions for clouds and hazes, in order to understand the potential habitability of mini-Neptunes in greater detail.

We further note that our current models do not include the effects of water condensation on convection and the temperature profile. Latent heat released by the condensation of water is known to make convection easier in some circumstances (e.g., Pierrehumbert 2010), resulting in a more isothermal "moist" adiabat. Conversely, in atmospheres where the background gas is lighter than the condensing species (e.g., H_2O condensation in an H_2-rich atmosphere), condensation can inhibit both moist and double-diffusive convection and result in a superadiabatic temperature gradient (e.g., Guillot 1995; Friedson & Gonzales 2017; Leconte et al. 2017). The ways in which these effects can shape the energy transport and P–T profiles in H_2-rich atmospheres are not yet fully understood,

17

though future missions to Uranus or Neptune may help to elucidate this (Guillot 2019).

Finally, we consider the observability of mini-Neptune thermal emission with JWST, including observable signatures of potentially habitable conditions. We find that photometry with JWST/MIRI could be used to measure the photospheric temperatures of mini-Neptunes such as K2-18 b down to $\sim$200 K assuming 10 ppm error bars. Based on our models, we find that photospheric temperatures below the freezing point of H_2O suggest the presence of ice clouds and could be a sign of temperate conditions below the atmosphere. Photospheric temperatures of $\sim$300–400 K can also be a sign of habitable conditions below the atmosphere, though this depends on the temperature gradient at higher pressures. This gradient is driven by several factors, including infrared opacity and the presence of hazes/clouds. However, photospheric temperatures $\gtrsim$400 K typically imply even hotter, and therefore nonhabitable, conditions at higher pressures.

Our models therefore show that MIRI photometry can provide a simple way to establish whether a mini-Neptune such as K2-18 b could potentially host habitable conditions, guiding follow-up observations. For example, transmission spectroscopy could provide more detailed chemical constraints, which in turn could be used to provide further insight into the habitability of the planet (e.g., Seager et al. 2013; Bains et al. 2014; Meadows & Barnes 2018). In addition to temperate, potentially habitable mini-Neptunes, we also explore the observability of warmer mini-Neptunes with JWST and find that MIRI low-resolution spectroscopy could be used to constrain their chemical compositions and thermal profiles.

Our results show that mini-Neptunes similar to or smaller than K2-18 b, whose masses and radii allow for habitable surface pressures, could potentially host habitable conditions beneath their H_2-rich envelopes for a wide range of atmospheric parameters. Since these planets are more easily observable than temperate terrestrial planets, they arguably represent optimal targets for the study of habitability in exoplanets. Furthermore, JWST/MIRI could provide initial constraints on the habitability of such mini-Neptunes.
