ABSTRACT (246 words)

Recent studies have shown that cancer risk related to overweight and obesity is mediated by time and might be better approximated by using life years lived with excess weight. In this study we aimed to assess the impact of overweight duration and intensity in older adults on the risk of developing different forms of cancer. Study participants from seven European and one US cohort study with two or more weight assessments during follow-up were included (n=329,576). Trajectories of body mass index (BMI) across ages were estimated using a quadratic growth model; overweight duration (BMI \geq 25) and cumulative weighted overweight years were calculated. In multivariate Cox models and random effects analyses, a longer duration of overweight was significantly associated with the incidence of obesity-related cancer (overall Hazard Ratio (HR) per 10-yr increment: 1.36; 95%CI: 1.12-1.60), but also increased the risk of postmenopausal breast and colorectal cancer. Additionally accounting for the degree of overweight further increased the risk of obesity-related cancer. Risks associated with a longer overweight duration were higher in men than in women and were attenuated by smoking. For postmenopausal breast cancer, increased risks were confined to women who never used hormone therapy. Overall, 8.4% of all obesity-related cancers could be attributed to overweight at any age. These findings provide further insights into the role of overweight duration in the etiology of cancer and indicate that weight control is relevant at all ages. This knowledge is vital for the development of effective and targeted cancer prevention strategies.

Keywords: CHANCES; Ageing; Cohort; Obesity; Cancer; Prevention

INTRODUCTION

Obesity has emerged as one of the most prevalent risk factors for non-communicable diseases and is still on the rise in many populations.(1, 2) Currently about 69% of all US adults are considered overweight or obese (body mass index, BMI ≥ 25 kg/m²) and 35% obese (BMI ≥ 30 kg/m²), making it one of the countries with the highest prevalence of obesity in the world.(2, 3) Even though the level of obesity has been catching up in Western Europe over the past two decades, obesity prevalence is still presently lower than in North America, 20% in 2008.(4) In addition, overweight has become a growing problem specifically in the elderly, the fastest growing population segment in most high-income countries. For example, both in Europe and in the US, women aged 60 and above are more likely to be overweight or obese than any other age group. (3, 5)

These developments have come at the cost of parallel rises in obesity-related morbidities, health care expenditures and mortality, most notably from cardio-vascular diseases and cancer.(6) In 2012, nearly half a million cancer cases globally were attributable to high BMI; more than half of this burden occurred in higher-income regions, most notably in Europe and Northern America.(7) These disparities across countries and regions not only reflect varying levels of obesity, but also differences in the strength of the cancer-obesity association between populations and in the prevalence and distribution of other risk factors modifying the association, such as smoking, diabetes and the use of hormone therapy (HT).(8, 9) Although the link between obesity and cancer is well-documented (8), most studies investigating this association are based on single measurements of height and weight at one point in life and evidence on the cumulative effects of overweight during the life course on disease risk remains scarce. Yet recent studies have shown that obesity duration is an important and independent predictor of type 2 diabetes (10), cardio-vascular disease (11) and all-cause mortality (12). Given that a longer exposure to overweight increases the risk and severity of insulin resistance, chronic inflammation, oxidative DNA damage and alterations in endogenous hormone levels (13) – all of which are thought to be cancer promotive – overweight duration may be an important, but also yet understudied, predictor of the risk of cancer development.

In this study, we assessed the impact of overweight duration and intensity on cancer risk in more than 300,000 older adults in a pooled dataset of seven European and one US prospective cohort studies. In secondary analyses, we evaluated the effects of important effect modifiers and confounders including sex, smoking status, diabetes and HT.

MATERIALS AND METHODS

Study design and participants

This study uses repeated anthropometric assessments obtained from seven European (EPIC Elderly Denmark, Greece, Netherlands, and Spain; ESTHER, Germany; PRIME Belfast, Northern Ireland; Tromsø, Norway) and one American cohort study (NIH AARP), pooled as part of the Consortium of Health and Aging: Network of Cohorts in Europe and the United States (CHANCES, www.chancesfp7.eu). A selection of the cohorts' key characteristics is shown in **Table 1**. Additional information on the individual cohorts has been described elsewhere.⁽¹⁴⁾ All CHANCES cohort studies are conducted in accordance with the Declaration of Helsinki. For each study, investigators satisfied the local requirements for ethical research, including obtaining informed consent from participants.

Patients with a history of cancer at baseline (n=11,710) or an unknown study exit (n=418) were excluded. Furthermore, for inclusion in this study, participants were required to have at least two valid BMI assessments during follow-up, including baseline and excluding assessments after or in the year preceding cancer diagnosis. For NIH AARP, participants with a retrospective self-reported BMI at age 50 and height and weight assessments at baseline were included. Missing data on either smoking or physical activity status at baseline were excluded (n=16,398). The derivation of the final number of included persons by study is portrayed in **Figure 1**.

Outcomes

Incident cancer cases were identified through linkage to cancer registries (EPIC NL, EPIC DK, NIH AARP, Tromsø) or through self-reports that were confirmed by medical records and/or pathology reports (ESTHER, PRIME Belfast) or both (EPIC Spain, EPIC Greece). Analyses were conducted for cancer sites where convincing evidence of a positive association with excess BMI was reported.^(8, 15) We examined invasive breast cancer (ICD-O-3 C50) at postmenopausal ages, colorectal cancer (C18-21), as well as a combined obesity-related cancer category that also included cancer of the lower oesophagus (C15.5, as a proxy for oesophageal adenocarcinoma in the absence of histological data), gastric cardia (C16.0), liver (C22), gallbladder (C23), pancreas (C25), , endometrium (C54), ovary (C56) and kidney (C64)

Exposure variables

Overweight was defined as having a BMI above 25 kg/m². BMI values below 15 kg/m² and above 45 kg/m² were considered highly unlikely and hence considered as missing. For all European studies except

ESTHER, where only self-reported anthropometry was available, BMI at baseline was calculated based on measured height and weight. At re-contact, data on height and weight were self-reported in all cohorts, except PRIME Belfast and Tromsø where BMI at follow-up was based on measured anthropometry. In NIH AARP, height and weight were self-reported at age 50 (retrospectively) and at baseline. Supplementary Figure 1 provides an overview of the study-specific timing of repeated anthropometric measurements by cohort.

Covariates

Baseline information on all covariates except alcohol consumption (continuous, grams/day) were available as categorical variables as follows: (daily) smoking status (never smoker/former smoker/current smoker), vigorous physical activity (yes/no, for performing intense exercise at least once a week), highest level of education (primary or less/more than primary but less than college or university/college or university), HT use (never/ever). Other information on reproductive history and diet were not consistently available in all cohorts and could not be taken into account in our analyses.

Statistical analysis

The analysis was carried out in three steps. First, a quadratic growth model with a random intercept and random slope was used to predict individual BMI trajectories for each study participant.(16, 17) This model was developed and adjusted in a step-wise manner by adding study, sex, smoking status, physical activity and an interaction term for study and contact age to the fixed effects part of the model. The obtained predicted BMI values for all ages between study entry (baseline) and study exit were then used to estimate overweight ($BMI \geq 25$) duration in years. Weighted cumulative overweight years (OWY) were computed by multiplying the duration of overweight in years by the difference (in BMI units) above normal BMI ($BMI \geq 25$) for each increment of age. This measure takes into account the degree of overweight over time and is comparable to pack-years in relation to tobacco smoking. For example, when considering 10 years of follow-up, a person with $BMI=26$ would accumulate 10 OWY ($26-25*10$) and 10 years of overweight duration; a person with a $BMI=35$ would accumulate 100 OWY ($35-25*10$). Overweight duration was assessed per 10-year increment and cumulative OWY per 100 units.

Secondly, Cox proportional hazard models with age as time metric were used to estimate hazard ratios (HR) and 95% confidence limits (CI) to describe the relation between overweight duration, cumulative OWY and the risk of developing cancer. Overweight duration and cumulative OWY were treated as continuous, time-dependent covariates in the model. Baseline information was used for all other

covariates. Subjects were censored at death, lost to follow-up (i.e. emigration, opt-out), any cancer excluding non-melanoma skin cancer (C44) diagnosis other than the site of interest or cohort-specific end-of-follow up, whichever occurred first. For all outcomes, three models with different sets of adjustments were fitted. In model 1, adjustments were made for sex. Model 2 was additionally adjusted for smoking status and physical activity. In model 3, further adjustments were made for education and alcohol consumption. The proportional hazard assumptions were assessed by visual inspection of log-log plots and by statistical tests using Schoenfeld residuals. Any covariates for which proportional hazards were unlikely were stratified, but the final results were not materially different from the unstratified models.

All analyses were carried out for each study separately and the results were then combined using random-effects meta-analysis in order to limit the influence of study size (especially with regard to the NIH AARP cohort). (18) Data from all cohorts were then pooled to describe the dose-response relationship between overweight duration, intensity and cancer risk and to assess interactions in stratified analyses by sex, smoking status, HT use and diabetes history. We used restricted cubic splines with four knots at Harrell's default percentiles to model non-linear relations between obesity duration, OWY and cancer risk. Analyses of the pooled data were additionally adjusted for study.

Lastly, and based on the assumption that the association between overweight and the cancer sites included in our study is causal (19), population attributable fractions (PAF) and their 95% CIs were calculated (20, 21) using the maximum likelihood method (22) and the 'punaf' command in Stata. PAFs represent the proportion of obesity-related cancer cases that could have been avoided if participants were never overweight during follow-up.

All statistical analyses were performed using Stata 12.

RESULTS

In total, 329 576 participants were included in this study, with 16 520 obesity-related cancer cases occurring during follow-up (**Table 1**). Study participants were recruited between 1991 and 2003, with a mean age at study entry ranging from 54 years in Northern Ireland (PRIME Belfast) cohort to 67 years in Greece (EPIC elderly). Education level (highest attained degree) was particularly high in the US (NIH AARP) (75% with college or university degree), while more than 85% of the Spanish participants (EPIC elderly) had only primary education or less. Mean BMI at baseline ranged between 25.8 kg/m² in the Netherlands to 29.5 kg/m² in Spain, where 42% of the study participants were classified as obese (BMI \geq 30). While 75% of all participants from Denmark (EPIC elderly) reported to be physically active, this applied to only 5% in Spain. Alcohol intake was highest in Denmark (20.2 g/d) and lowest in Norway (Tromsø – 3.6 g/d), in contrast with smoking, where Norway had the highest and Greece the lowest proportion of current daily smokers (31% and 12% respectively). Median follow-up ranged between 10.4 years in Germany (ESTHER) and 18.0 years in Northern Ireland (PRIME Belfast). Age-standardized incidence rates of obesity-related cancers ranged between 351 per 100 000 person-years in the US to 45 per 100 000 in Greece.

In the meta-analysis of all studies, a longer duration of overweight was significantly associated with an increased risk of obesity-related cancer combined (Hazard Ratio (HR) per 10-yr increment: 1.36; 95%CI: 1.12 to 1.60) and was most pronounced in the German ESTHER cohort (HR: 2.29, 95%CI: 1.66 to 3.14), but not statistically significant in the Spanish and Danish EPIC cohorts and PRIME Belfast (**Figure 2**). When taking the degree of overweight over time into account, risks tended to be slightly more pronounced, especially in the US NIH AARP cohort (**Figure 2**), but also overall (HR per 100-unit increment in OWY: 1.46; 95%CI: 1.14 to 1.77). While results were similar for postmenopausal breast and colorectal cancer, higher risks were found for other obesity-related sites, comprising cancer of the pancreas, kidney, gallbladder and endometrium. HRs for the association between overweight duration and cumulative OWY by cancer site and cohort, for the different models are presented in **Supplementary Table 1**. As adjustments for alcohol consumption and education level in model 3 only marginally altered the results of model 2, the latter simpler model was used when exploring dose-response relationships between increasing overweight duration, intensity and cancer risk. Clear associations were found for all obesity-related cancer sites combined, but also for breast cancer in HT non-users (**Figure 3, panel A**). When taking into account the degree of overweight over time, the risk increase became more pronounced, especially for other obesity-related cancers (**Figure 3, panel B**). This

relationship was mainly driven by kidney and endometrial cancer, showing exponential associations with the combination of overweight duration and intensity over time (data not shown).

The population attributable fraction (PAF) for ever being overweight during follow-up was 8.4% (95%CI: 6.3 to 10.5%) for obesity-related cancers combined (**Table 2**). PAFs were considerably higher in men than in women (20.0% vs 4.6%), in never smokers relative to current and past smokers and in those with a history of diabetes type 2. In women who never used HT, 15.6% (11.8 to 19.2%) of all breast cancers were attributable to ever being overweight during follow-up.

In secondary analyses, we investigated the potential confounding effects of sex, smoking status, HT use and diabetes history in the pooled dataset (**Supplementary Table 2**). Generally, the risks associated with both overweight duration and cumulative OWY were higher in men than in women. After stratification for sex, the risk of colorectal cancer associated with a longer overweight duration and intensity (OWY) reached statistical significance in both men and women. Gradients in risk were found across smoking categories, indicating that the risk of obesity-related cancer due to overweight duration and/or cumulative OWY was highest among never smokers, intermediate among former smokers and low or negligible in current smokers. For breast cancer, significantly increased risks were observed in women who never used HT, with similar effect sizes for both overweight duration (HR: 1.41, 95%CI: 1.25 to 1.58) and cumulative OWY (HR: 1.33, 95%CI: 1.15 to 1.53). Risks of obesity-related cancers were higher in study participants who ever reported type 2 diabetes relative to those who had no diabetes history, especially when the degree of overweight over time was taken into account.

DISCUSSION

Based on a pooling of eight cohort studies, 300 000 participants and more than 16 000 obesity-related cancers, this is the first study to assess the impact of overweight duration on cancer risk in older populations. Overall, we found that a longer duration of overweight was significantly associated with a higher risk of postmenopausal breast and colorectal cancer, as well as for obesity-related cancers combined. Risks associated with a longer overweight duration were higher in men than in women and among non-smokers than in current smokers. For post-menopausal breast cancer, increased risks were confined to women who never used HT. When additionally taking the degree of overweight over time into account, risks increased even further. Overall, 8.4% of obesity-related cancers could be attributed to being overweight at any time point after age 50 (10.7% in never smokers).

These findings are consistent with studies reporting associations between high BMI at one point in time and cancer risk (8, 23) and are in line with evidence on the impact of obesity duration on other health outcomes, including type 2 diabetes, cardiovascular disease and all-cause mortality.(10-12) One of the putative underlying biological mechanisms involves changes in the metabolism of sex-steroid hormones, namely oestrogen, which is mainly produced by fat tissue in postmenopausal women.(24) Hence, a longer overweight duration increases the exposure time to elevated hormone levels, which may in turn increase the risk of developing cancer. In our study, we found that the increased risk of postmenopausal breast cancer related to a longer overweight duration was confined to women who never used HT and risks were similar for overweight duration and OWY. This finding suggests that exogenous oestrogen and hormone levels modify the association between overweight duration and postmenopausal breast cancer, as noted in previous studies.(25, 26) While similar associations have also been reported for endometrial cancer (27, 28), evidence for effect modification for colorectal cancer is inconsistent across studies.(29, 30)

We also noted important sex differences in the risk of developing obesity-related cancer associated with increasing overweight duration. Higher risks in men were mainly evident for colorectal cancer and all obesity-related cancers combined. This is consistent with previous studies pointing towards a stronger link between different measures of obesity and colorectal cancer in men, with the association much weaker or absent in women.(31, 32) Increased waist circumference has been suggested to be a better predictor of colorectal cancer risk than BMI that varies markedly by sex.(32, 33) Waist circumference is a proxy for visceral adipose tissue, where leptin and adiponectin are predominantly secreted.

Adiponectin is inversely correlated with body fatness, is anti-inflammatory and inhibits tumour growth

in animals.(34) As circulating levels of adiponectin have been found to be higher in women than men, this may offer an explanation for sex differences in colorectal cancer risk associated with overweight and obesity.(31) When assessing the dose-response relationship between overweight duration and cancer risk, we also noted that peaks in risk differed by cancer site, possibly reflecting early and late promotional effects of adiposity for some cancers. Yet, the site specific numbers of cases were too small to draw firm conclusion from this finding.

Another important confounder was smoking. We found that the effect of increasing overweight duration on the risk of developing obesity-related cancer was stronger in never smokers relative to current smokers. This association was more pronounced when the degree of overweight was taken into account, and is supported by previous findings on the role of smoking in the obesity-cancer pathway. (8, 35, 36) Other factors such as hormones and circulating levels of DNA adducts have been suggested to contribute to lower risks of obesity-related cancers observed in smokers. (8, 37-39) In contrast, history of type 2 diabetes modified the overweight-cancer association in our study in a way that participants with a positive history had the greatest risk. This finding confirms previous findings on the interaction between overweight duration, diabetes and pancreatic cancer.(40)

While our findings were largely consistent across studies, we generally found weaker associations in the US cohort when compared to the European cohorts. The between-study heterogeneity could only marginally be reduced by accounting for sex, HRT use and smoking, suggesting that other (unmeasured) factors must be responsible for the differences observed across studies. At least in parts, this may also be explained by differences in the baseline characteristics between European and US study participants as well as the respective study sizes. In comparison with the combined European cohorts, comprising 38 563 study participants, the US NIH AARP cohort was much larger (291 013 participants), and hence better powered. Additionally, the majority of the US NIH AARP participants were highly educated and less likely to be current smokers or physically inactive than participants of the European cohorts, limiting the generalizability of the findings to the general US population. Yet, given the similar associations found across the studies and the general notion that the effect of obesity on cancer development should not differ between Europeans and North Americans, we believe that our results are valid and most likely a conservative estimate of the true effect.

In the pooled analysis, we were able to include a large number of study participants from several European countries and the US, which enabled an assessment of the dose-response relationship between overweight duration and cancer risk, as well as related sensitivity analyses. However, some

methodological considerations and limitations should be noted. In the first step of our analysis, we used repeated measurements and self-reports of height and weight to model BMI across ages using a growth curve model. With this approach, we were able to estimate each study participant's BMI trajectory and overweight duration during follow-up. When put into context with the observed BMI, the trajectories predicted by the model were fitting well, also owing to the fact that in most individuals BMI typically changes only marginally during adulthood (and if so, only slowly).(41, 42) As the results from the German ESTHER study (where only self-reported height and weight were available) were consistent with those from the other European cohorts (where BMI was calculated based on measured height and weight), we believe that the type of BMI information has not unduly affected our overall findings. When we repeated the analyses with obesity ($BMI \geq 30$) duration, the associations became slightly stronger. Due to the fact that there were no anthropometric data available before baseline (except in NIH AARP), we could only evaluate overweight duration and intensity after study entry, i.e. in the elderly, and could not take into account overweight earlier in life. This might have led to the unexpected shape of the dose-response curves (Figure 3), especially in the first years. Even though our results may not reflect risks on the individual-level (owing to the observational study design), the dose-response curves indicate that risk may be better approximated by taking both overweight duration and intensity into account.

It is furthermore important to note that BMI may not be an ideal measure of body fatness since it can reflect both adiposity and muscularity and is limited in its ability to predict body fatness across ethnic groups and age.(43) Age-related decreases in height might falsely lead to an increase in BMI and with advancing age fat tissue tends to be redistributed towards the abdominal region.(43) Hence, it might have been more appropriate to use one of the measures of central obesity as a surrogate for overweight and obesity as these have been suggested to better predict obesity-related health outcomes when compared to BMI.(44, 45) These measures were however not available longitudinally from the cohorts included in this study. Yet, in a companion paper using data from the same cohorts (except NIH-AARP), we found that the risk associated with a standard deviation increase in baseline BMI and waist circumference were similar for post-menopausal breast, colorectal and obesity-related cancers combined (Heinz Freisling, personal communication).

Further limitations of our study are related to differences in study design between cohorts, including differences in length of follow-up, anthropometric assessment methods and their frequency, as well as the comparability of several variables. In order to harmonize the data and variable definitions across cohorts, some variables such as physical activity were only available in binary form (yes/no). Despite

adjustment for the main confounding factors, namely smoking and physical activity, we cannot rule out confounding by other unmeasured factors, most importantly reproductive risk factors and diet. As these were not consistently available from all cohorts, we were not able to take these into account in our analyses.

Lastly, it is important to acknowledge a number of methodological limitations, which we hope will prompt further research. In the same way that we have estimated cumulative exposure for our main independent variable, overweight duration, it may be surmised that the nature of the confounding or moderating effects of other exposures (such as smoking, alcohol intake or physical activity) might, in uncertain ways, depend on how their own cumulative effects have been modelled. Related to this is the fact that methodologists have recently debated about the correct way to model cumulative effects, when their effects on absolute rather than relative risk scales might differ and when more complex temporal patterns of exposure may not be modelled well on a proportional hazards scale. (46-48)

Implications and conclusions

We report that longer overweight duration increases the risk of cancer in older adults, in both Europe and the US, with 8.4% of obesity-related cancers attributable to overweight at any time point after age 50. Each of the studies included in this analysis was based on a prospective design, with data collection prior to disease onset. Thus, a degree of causality between overweight duration and cancer development can be inferred, although with great caution. These observations lend further credibility to existing clinical recommendations for weight reduction in the obese and the maintenance of healthy weight in the non-obese, irrespective of age. Avoidance of weight gain, engaging in physical activity, and even small amounts of weight loss have been suggested to prevent adverse health consequences of obesity in the elderly.(43, 49) Future studies should further investigate the specific roles of age at onset of overweight and different BMI trajectories on cancer risk.

FIGURE LEGENDS

Fig 1 Flowchart of participant inclusion

Fig 2 Hazard ratios (HR)* and their 95% confidence intervals (95% CI) for overweight (BMI \geq 25) duration and weighted cumulative overweight years (OWY), by cohort and cancer site, men and women combined.

* results from random-effects meta-analysis with adjustments for sex, smoking status, physical activity (yes/no), alcohol consumption and education level (Model 3)

^a breast, colorectum, pancreas, kidney, gallbladder, endometrium, ovary, liver, lower oesophagus, cardia stomach

^b pancreas, kidney, gallbladder, endometrium, ovary, liver, lower oesophagus, cardia stomach

Fig 3 Hazard ratios (HR) and their 95% confidence intervals (95%CI) for the association between (A) overweight (BMI \geq 25) duration, (B) weighted cumulative overweight years (OWY) and cancer risk, men and women combined

^a breast, colorectum, pancreas, kidney, gallbladder, endometrium, ovary, liver, lower oesophagus, cardia stomach

^b pancreas, kidney, gallbladder, endometrium, ovary, liver, lower oesophagus, cardia stomach

The figure shows a 3-knot spline of the relation between overweight duration and cancer risk, allowing for non-linear effects and adjusted for sex, study, smoking status and physical activity (Model 2). Restricted cubic splines were fitted with knots at 0, 1, 5 and 10 years for overweight duration and at 0, 1, 13 and 65 for OWY. P-values are for non-linearity.
