# Parallel Cellular Automata: <br> A Model Program for Computational Science ${ }^{1}$ PER BRINCH HANSEN 

Syracuse University, Syracuse, New York 13244

September 1992

We develop a model program for parallel execution of cellular automata on a multicomputer. The model program is then adapted for simulation of forest fires and numerical solution of Laplace's equation for stationary heat flow. The performance of the parallel program is analyzed and measured on a Computing Surface configured as a matrix of transputers with distributed memory.

## INTRODUCTION

This is one of several papers that explore the benefits of developing model programs for computational science [Brinch Hansen 1990, 1991a, 1991b, 1992a]. The theme of this paper is parallel cellular automata.

A cellular automaton is a discrete model of a system that varies in space and time. The discrete space is an array of identical cells, each representing a local state. As time advances in discrete steps, the system evolves according to universal laws. Every time the clock ticks, the cells update their states simultaneously. The next state of a cell depends only on the current state of the cell and its nearest neighbors.

In 1950 John von Neumann and Stan Ulam introduced cellular automata to study self-reproducing systems [von Neumann 1966, Ulam 1986]. John Conway's game of Life is undoubtedly the most widely known cellular automaton [Gardner 1970, 1971, Berlekamp et al. 1982]. Another well-known automaton simulates the life cycles of sharks and fish on the imaginary planet Wa-Tor [Dewdney 1984]. The numerous applications include forest infestation [Hoppenstadt 1978], fluid flow [Frisch et al. 1986], earthquakes [Bak and Tang 1989], forest fires [Bak and Chen 1990], and sandpile avalanches [Hwa and Kardar 1989].

Cellular automata can simulate continuous physical systems described by partial differential equations. The numerical solution of, say, Laplace's equation by grid relaxation is really a discrete simulation of heat flow performed by a cellular automaton.

Cellular automata are ideally suited for parallel computing. Our goal is to explore programming methodology for multicomputers. We will illustrate this theme by developing a model program for parallel execution of cellular automata on a multicomputer with a square matrix of processor nodes. We will then show how easy it is to adapt the model program for two different applications: (1) simulation of a forest fire, and (2) numerical solution of Laplace's equation for stationary heat flow. On a Computing Surface with transputer nodes, the parallel efficiency of the model program is close to one.

## 1. CELLULAR AUTOMATA

A cellular automaton is an array of parallel processes, known as cells. Every cell has a discrete state. At discrete moments in time, the cells update their states simultaneously. The state transition of a cell depends only on its previous state and the states of the adjacent cells.

We will program a two-dimensional cellular automaton with fixed boundary states (Fig. 1).

Fig. 1 A cellular automaton
The automaton is a square matrix with three kinds of cells:

1. Interior cells, marked "?", may change their states dynamically.
2. Boundary cells, marked " + ", have fixed states.
3. Corner cells, marked "-", are not used.

Figure 2 shows an interior cell and the four neighbors that may influence its state. These five cells are labeled $c$ (central), $n$ (north), $s$ (south), $e$ (east), and $w$ (west).

Fig. 2 Adjacent cells
The cellular automaton will be programmed in Pascal, extended with statements for parallel execution and message communication.

The execution of $k$ statements $S_{1}, S_{2}, \ldots, S_{k}$ as parallel processes is denoted

$$
\text { parbegin } S_{1}\left|S_{2}\right| \ldots \mid S_{k} \text { end }
$$

The parallel execution continues until every one of the $k$ processes has terminated.
The parallel for statement
parfor $i:=1$ to $k$ do $S(i)$
is equivalent to

$$
\text { parbegin } S(1)|S(2)| \ldots \mid S(k) \text { end }
$$

We assume that parallel processes communicate through synchronous channels only. The input and output of a value $x$ through a channel $c$ are denoted

$$
c ? x \quad c!x
$$

A cellular automaton is a set of parallel communicating cells. If we ignore boundary cells and communication details, a two-dimensional automaton is defined as follows:

$$
\begin{aligned}
& \text { parfor } \mathrm{i}:=1 \text { to } \mathrm{n} \text { do } \\
& \quad \text { parfor } \mathrm{j}:=1 \text { to } \mathrm{n} \text { do } \\
& \quad \text { cell }(\mathrm{i}, \mathrm{j})
\end{aligned}
$$

After initializing its own state, every interior cell goes through a fixed number of state transitions before outputting its final state:

```
initialize own state;
for \(\mathrm{k}:=1\) to steps do
    begin
        exchange states with
                adjacent elements;
            update own state
    end;
output own state
```

The challenge is to transform this fine-grained parallel model into an efficient program for a multicomputer with distributed memory.

## 2. INITIAL STATES

Consider a cellular automaton with 36 interior cells and 24 boundary cells. In a sequential computer, the combined state of the automaton can be represented by an $8 \times 8$ matrix, called a grid (Fig. 3). For reasons that will be explained later, the grid elements are indicated by 0 's and 1 's.

| - | 1 | 0 | 1 | 0 | 1 | 0 | - |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 1 | 0 | 1 | 0 | 1 | 0 | 1 | 0 |
| 0 | 1 | 0 | 1 | 0 | 1 | 0 | 1 |
| 1 | 0 | 1 | 0 | 1 | 0 | 1 | 0 |
| 0 | 1 | 0 | 1 | 0 | 1 | 0 | 1 |
| 1 | 0 | 1 | 0 | 1 | 0 | 1 | 0 |
| 0 | 1 | 0 | 1 | 0 | 1 | 0 | 1 |
| - | 0 | 1 | 0 | 1 | 0 | 1 | - |

Fig. 3 A square grid
Figure 4 shows the initial values of the elements. The boundary elements have fixed values $u_{1}, u_{2}, u_{3}$, and $u_{4}$. Every interior element has the same initial value $u_{5}$.

Fig. 4 Initial values
In general, a grid $u$ has $n \times n$ interior elements and $4 n$ boundary elements:

$$
\begin{aligned}
& \text { const } \mathrm{n}=\ldots ; \\
& \text { type state }=(\ldots) ; \\
& \quad \text { row }=\text { array }[0 . . \mathrm{n}+1] \text { of state; } \\
& \text { grid }=\text { array }[0 . . \mathrm{n}+1] \text { of row; } \\
& \text { var } \mathrm{u}: \text { grid; }
\end{aligned}
$$

Since the possible states of every cell vary from one application to another, we deliberately leave them unspecified. The grid dimension $n$ and the initial states $u_{1}$, $u_{2}, u_{3}, u_{4}$, and $u_{5}$ are also application dependent.

On a sequential computer, the grid is initialized as follows:

$$
\begin{aligned}
& \text { for } \mathrm{i}:=0 \text { to } \mathrm{n}+1 \text { do } \\
& \quad \text { for } \mathrm{j}:=0 \text { to } \mathrm{n}+1 \text { do } \\
& \mathrm{u}[\mathrm{i}, \mathrm{j}]:=\text { initial }(\mathrm{i}, \mathrm{j})
\end{aligned}
$$

Algorithm 1 defines the initial value of element $u[i, j]$. The values of the corner elements are arbitrary (and irrelevant).

```
function initial( \(\mathrm{i}, \mathrm{j}\) : integer)
    : state;
begin
    if \(\mathrm{i}=0\) then
        initial \(:=u 1\)
    else if \(\mathrm{i}=\mathrm{n}+1\) then
        initial \(:=\mathrm{u} 2\)
    else if \(\mathrm{j}=\mathrm{n}+1\) then
        initial \(:=\mathrm{u} 3\)
    else if \(\mathrm{j}=0\) then
        initial \(:=u 4\)
    else
        initial \(:=u 5\)
end
```

Algorithm 1

## 3. DATA PARALLELISM

For simulation of a cellular automaton, the ideal multicomputer architecture is a square matrix of identical processor nodes (Fig. 5). Every node is connected to its nearest neighbors (if any) by four communication channels.

Fig. 5 Processor matrix

Figure 6 shows a grid with 36 interior elements divided into 9 subgrids. We now have a $3 \times 3$ matrix of nodes and a $3 \times 3$ matrix of subgrids. The two matrices define a one-to-one correspondence between subgrids and nodes. We will assign each subgrid to the corresponding node and let the nodes update the subgrids simultaneously. This form of distributed processing is called data parallelism.

| - | 1 | 0 | 1 | 0 | 1 | 0 | - |

Fig. 6 A subdivided grid
Every processor holds a $4 \times 4$ subgrid with 4 interior elements and 8 boundary elements (Fig. 7). Every boundary element holds either an interior element of a neighboring subgrid or a boundary element of the entire grid. (We will say more about this later.)

Fig. 7 A subgrid

## 4. PROCESSOR NODES

With this background, we are ready to program a cellular automaton that runs on a $q \times q$ processor matrix.

The nodes follow the same script (Algorithm 2).

```
procedure node(qi, qj: integer;
    n, s, e, w: channel);
var \(u\) : subgrid; k: integer;
begin
    newgrid(qi, qj, u);
    for \(k:=1\) to steps do
        \(\operatorname{relax}(\mathrm{qi}, \mathrm{qj}, \mathrm{n}, \mathrm{s}, \mathrm{e}, \mathrm{w}, \mathrm{u})\);
    output(qi, qj, e, w, u)
end
```

## Algorithm 2

A node is identified by its row and column numbers $\left(q_{i}, q_{j}\right)$ in the processor matrix, where

$$
1 \leq q_{i} \leq q \text { and } 1 \leq q_{j} \leq q
$$

Four communication channels labeled $n, s, e$, and $w$ connect a node to its nearest neighbors (if any).

Every node holds a subgrid with $m \times m$ interior elements and $4 m$ boundary elements (Fig. 7):

```
const \(\mathrm{m}=\ldots\);
type subrow \(=\) array \([0 . . \mathrm{m}+1]\) of state;
    subgrid \(=\) array \([0 . . m+1]\) of subrow;
```

The grid dimension $n$ is a multiple of the subgrid dimension $m$ :

$$
n=m * q
$$

After initializing its subgrid, a node updates the subgrid a fixed number of times before outputting the final values. In numerical analysis, grid iteration is known as relaxation.

Node $\left(q_{i}, q_{j}\right)$ holds the following subset of the complete grid $u[0 . . n+1,0 . . n+1]$ :

$$
u\left[i_{0} . . i_{0}+m+1, j_{0} . . j_{0}+m+1\right]
$$

where

$$
i_{0}=\left(q_{i}-1\right) m \text { and } j_{0}=\left(q_{j}-1\right) m
$$

The initialization of a subgrid is straightforward (Algorithm 3).

```
procedure newgrid(qi, qj:
    integer; var u: subgrid);
\(\operatorname{var} \mathrm{i}, \mathrm{i} 0, \mathrm{j}, \mathrm{j} 0\) : integer;
begin
    \(\mathrm{i} 0:=(\mathrm{qi}-1) * \mathrm{~m} ;\)
    \(\mathrm{j} 0:=(\mathrm{qj}-1) * \mathrm{~m}\);
    for \(\mathrm{i}:=0\) to \(\mathrm{m}+1\) do
        for \(\mathrm{j}:=0\) to \(\mathrm{m}+1\) do
            \(\mathrm{u}[\mathrm{i}, \mathrm{j}]:=\operatorname{initial}(\mathrm{i} 0+\mathrm{i}, \mathrm{j} 0+\mathrm{j})\)
end
```

Algorithm 3

## 5. PARALLEL RELAXATION

In each time step, every node updates its own subgrid. The next value of an interior element is a function of its current value $u_{c}$, and the values $u_{n}, u_{s}, u_{e}$, and $u_{w}$ of the four adjacent elements (Fig. 2). Every application of a cellular automaton requires a different transition function (Algorithm 4).
function next(uc, un, us,
ue, uw: state): state;
begin next $:=\ldots$ end

## Algorithm 4

Parallel relaxation is not quite as easy as it sounds. When a node updates row number 1 of its subgrid, it needs access to row number $m$ of the subgrid of its northern neighbor (Fig. 6). To relax its subgrid, a node must share a single row or column with each of its four neighbors.

The solution to this problem is to let two neighboring grids overlap by one row or column vector. Before a node updates its interior elements, it exchanges a pair of vectors with each of the adjacent nodes. The overlapping vectors are kept in the boundary elements of the subgrids (Fig. 7). If a neighboring node does not exist, a boundary vector holds the corresponding boundary elements of the entire grid (Figs. 4 and 6).

The northern neighbor of a node outputs row number $m$ to the node, which inputs it in row number 0 of its own subgrid (Fig. 7). In return, the node outputs row number 1 to its northern neighbor, which inputs it in row number $m+1$ of its subgrid. Similarly, a node exchanges rows with its southern neighbor, and columns with its eastern and western neighbors (Fig. 5).

The shared elements raise the familiar concern about time-dependent errors in parallel programs. Race conditions are prevented by a rule of mutual exclusion: While
a node updates an element, another node cannot access the same element. This rule is enforced by an ingenious method [Barlow and Evans 1982].

Every grid element $u[i, j]$ is assigned a parity

$$
(i+j) \bmod 2
$$

which is either even (0) or odd (1) as shown in Figs. 3 and 6. To eliminate tedious (and unnecessary) programming details, we assume that the subgrid dimension $m$ is even. This guarantees that every subgrid has the same parity ordering of the elements (Figs. 6 and 7).

Parity ordering reveals a simple property of grids: The next values of the even interior elements depend only on the current values of the odd elements, and vice versa. This observation suggests a reliable method for parallel relaxation.

In each relaxation step, the nodes scan their grids twice:
First scan: The nodes exchange odd elements with their neighbors and update all even interior elements simultaneously.

Second scan: The nodes exchange even elements and update all odd interior elements simultaneously.

The key point is this: In each scan, the simultaneous updating of local elements depends only on shared elements with constant values! In the terminology of parallel programming, the nodes are disjoint processes during a scan.

The relaxation procedure uses a local variable to update elements with the same parity $b$ after exchanging elements of the opposite parity $1-b$ with its neighbors (Algorithm 5).

```
procedure relax(qi, qj: integer;
    \(\mathrm{n}, \mathrm{s}, \mathrm{e}\), w: channel; var u:
    subgrid);
var \(b, i, j, k\), last: integer;
begin
    for \(b:=0\) to 1 do
        begin
            exchange(qi, qj, \(1-\mathrm{b}\),
                \(\mathrm{n}, \mathrm{s}, \mathrm{e}, \mathrm{w}, \mathrm{u})\);
            for \(\mathrm{i}:=1\) to m do
                begin
                    \(\mathrm{k}:=(\mathrm{i}+\mathrm{b}) \bmod 2\);
                    \(\mathrm{j}:=2-\mathrm{k}\);
                    last \(:=\mathrm{m}-\mathrm{k}\)
                    while \(\mathrm{j}<=\) last do
                        begin
                                    \(\mathrm{u}[\mathrm{i}, \mathrm{j}]:=\operatorname{next}(\mathrm{u}[\mathrm{i}, \mathrm{j}]\),
                                    \(\mathrm{u}[\mathrm{i}-1, \mathrm{j}], \mathrm{u}[\mathrm{i}+1, \mathrm{j}]\),
                                    \(u[i, j+1], u[i, j-1]) ;\)
                                    \(\mathrm{j}:=\mathrm{j}+2\)
                                    end
            end
        end
end
```

## Algorithm 5

## 6. LOCAL COMMUNICATION

The nodes communicate through synchronous channels with the following properties:

1. Every channel used connects exactly two nodes.
2. The communications on a channel take place one at a time.
3. A communication takes place when a node is ready to output a value through a channel and another node is ready to input the value through the same channel.
4. A channel can transmit a value in either direction between two nodes.
5. The four channels of a node can transmit values simultaneously.

These requirements are satisfied by transputer nodes programmed in occam [Cok 1991].

The identical behavior of the nodes poses a subtle problem. Suppose the nodes simultaneously attempt to input from their northern channels. In that case, the nodes will deadlock, since none of them are ready to output through these channels. There are several solutions to this problem. We use a method that works well for transputers.

Before the nodes scan elements of the same parity, they communicate with their neighbors in two phases (Fig. 8).

Fig. 8 Communication phases
In each phase, every node communicates simultaneously on its four channels as shown below. Phases 1 and 2 correspond to the left and right halves of Fig. 8.

| Channel | Phase 1 | Phase 2 |
| :---: | :--- | :--- |
| $n$ | input | output |
| $s$ | output | input |
| $e$ | output | input |
| $w$ | input | output |

Since every input operation on a channel is matched by a simultaneous output operation on the same channel, this protocol is deadlock free. It is also very efficient, since every node communicates simultaneously with its four neighbors.

Algorithm 6 defines the exchange of elements of parity $b$ between a node and its four neighbors.

```
procedure exchange(qi, qj, b:
    integer; n, s, e, w: channel;
    var u: subgrid);
begin
    phase1(qi, qj, b, n, s, e, w, u);
    phase2(qi, qj, b, n, s, e, w, u)
end
```

Algorithm 6
Phase 1 is defined by Algorithm 7. The if statements prevent boundary nodes from communicating with nonexisting neighbors (Fig.5).

```
procedure phase1(qi, qj, b:
    integer; n, s, e, w: channel;
    var u: subgrid);
var \(k\), last: integer;
begin
    \(\mathrm{k}:=2-\mathrm{b}\);
    last \(:=\mathrm{m}-\mathrm{b}\);
    while \(\mathrm{k}<=\) last do
        begin
            parbegin
            if \(q i>1\) then \(n ? u[0, k] \mid\)
            if \(q i<q\) then \(s!u[m, k] \mid\)
            if \(q j<q\) then \(e!u[k, m] \mid\)
                    if \(q j>1\) then \(w ? u[k, 0]\)
            end;
            \(\mathrm{k}:=\mathrm{k}+2\)
        end
end
```

Algorithm 7

Phase 2 is similar (Algorithm 8).

```
procedure phase2(qi, qj, b:
    integer; n, s, e, w: channel;
    var u: subgrid);
var \(k\), last: integer;
begin
    \(\mathrm{k}:=\mathrm{b}+1\);
    last \(:=\mathrm{m}+\mathrm{b}-1\);
    while \(\mathrm{k}<=\) last do
        begin
            parbegin
                if \(q i>1\) then \(n!u[1, k] \mid\)
                if \(\mathrm{qi}<\mathrm{q}\) then \(\mathrm{s} ? \mathrm{u}[\mathrm{m}+1, \mathrm{k}] \mid\)
                if \(q j<q\) then \(e ? u[k, m+1] \mid\)
                if \(q j>1\) then \(w!u[k, 1]\)
            end;
            \(\mathrm{k}:=\mathrm{k}+2\)
        end
end
```

## Algorithm 8

We have used this protocol on a Computing Surface with transputer nodes. Since transputer links can communicate in both directions simultaneously, the two communication phases run in parallel. So every transputer inputs and outputs simultaneously through all four links!

If the available processors cannot communicate simultaneously with their neighbors, a sequential protocol must be used [Dijkstra 1982]. This is also true if the overhead of parallelism and communication is substantial. However, the replacement of one protocol by another should only change Algorithms 6-8 and leave the rest of the program unchanged.

## 7. GLOBAL OUTPUT

At the end of a simulation, the nodes output their final values to a master processor that assembles a complete grid. The boundary channels of the processor matrix are not used for grid relaxation (Fig. 5). We use the horizontal boundary channels to connect the nodes and the master into a pipeline for global output (Fig. 9).

Fig. 9 Output pipeline
The boundary elements of the entire grid have known fixed values (Fig. 4). These elements are needed only during relaxation. The final output is an $n \times n$ matrix of interior elements only. Every element defines the final state of a single cell.

So we redefine the full grid, omitting the boundary elements:

$$
\begin{aligned}
& \text { type row = array }[1 . . n] \text { of state; } \\
& \text { grid }=\text { array }[1 . . n] \text { of row; }
\end{aligned}
$$

The master inputs the final grid row by row, one element at a time (Algorithm $9)$.

```
procedure master(inp: channel;
    var u: grid);
var \(\mathrm{i}, \mathrm{j}\) : integer;
begin
    for \(\mathrm{i}:=1\) to n do
        for \(\mathrm{j}:=1\) to n do
        inp? \(\mathrm{u}[\mathrm{i}, \mathrm{j}]\)
end
```

Algorithm 9
The nodes use a common procedure to output interior elements in row order (Algorithm 10).

```
procedure output(qi, qj: integer;
    inp, out: channel; var u:
    subgrid);
var \(i, j\) : integer;
begin
    for \(i:=1\) to \(m\) do
        begin
            for \(\mathrm{j}:=1\) to m do
                out!u[i,j];
            \(\operatorname{copy}((q-q j) * m, i n p\), out \()\)
        end;
    \(\operatorname{copy}((\mathrm{q}-\mathrm{qi}) * \mathrm{~m} * \mathrm{n}, \mathrm{inp}\), out \()\)
end
```

Algorithm 10
Every row of elements is distributed through a row of nodes (Figs. 5 and 6). For each of its subrows, node ( $q_{i}, q_{j}$ ) outputs the $m$ interior elements and copies the remaining $\left(q-q_{j}\right) m$ elements of the same row from its eastern neighbor. This completes the output of the rows of elements, which are distributed through row $q_{i}$ of the processor matrix. The node then copies the remaining ( $q-q_{i}$ ) m complete rows of $n$ elements each.

A simple procedure is used to copy a fixed number of elements from one channel to another (Algorithm 11).

```
procedure copy(no: integer;
    inp, out: channel);
var k: integer; uk: state;
begin
    for \(k:=1\) to no do
        begin
            inp?uk; out!uk
        end
end
```

Algorithm 11
In our program for the Computing Surface, we extended the copy procedure with parallel input/output. We also modified Algorithms 2 and 9 slightly to enable the program to output intermediate grids at fixed intervals.

## 8. PROCESSOR NETWORK

Figure 10 illustrates the network that ties the processors together. The network consists of a horizontal channel matrix $h$ and a vertical channel matrix $v$.

Fig. 10 Processor network
The following examples illustrate the abbreviations used:

| $M$ | master |
| :---: | :--- |
| 3,2 | node $(3,2)$ |
| $v_{2,2}$ | channel $v[2,2]$ |
| $h_{3,1}$ | channel $h[3,1]$ |

Algorithm 12 defines parallel simulation of a cellular automaton that computes a relaxed grid $u$. Execution of the parallel statements activates (1) the master, (2) the first column of nodes, and (3) the rest of the nodes.

```
procedure simulate(var u: grid);
type
    line \(=\) array \([1 . . q]\) of channel;
    matrix = array [0..q] of line;
var \(h, \mathrm{v}\) : matrix; \(\mathrm{i}, \mathrm{j}, \mathrm{k}\) : integer;
begin
    parbegin
        \(\operatorname{master}(\mathrm{h}[0, \mathrm{q}], \mathrm{u}) \mid\)
        parfor \(\mathrm{k}:=1\) to q do
            node \((\mathrm{k}, 1, \mathrm{v}[\mathrm{k}-1,1], \mathrm{v}[\mathrm{k}, 1]\),
                \(\mathrm{h}[\mathrm{k}, 1], \mathrm{h}[\mathrm{k}-1, \mathrm{q}])\) |
        parfor \(\mathrm{i}:=1\) to q do
            parfor \(\mathrm{j}:=2\) to q do
                node( \(\mathrm{i}, \mathrm{j}, \mathrm{v}[\mathrm{i}-1, \mathrm{j}]\), v[i,j],
                    \(\mathrm{h}[\mathrm{i}, \mathrm{j}], \mathrm{h}[\mathrm{i}, \mathrm{j}-1 \mathrm{j})\)
    end
end
```

Algorithm 12
This completes the development of the model program. We will now demonstrate how easily the program can be adapted to different applications of cellular automata.

## 9. EXAMPLE: FOREST FIRE

A typical application of a cellular automaton is simulation of a forest fire. Every cell represents a tree that is either alive, burning, or dead. In each time step, the next state of every tree is defined by probabilistic rules similar to the ones proposed by Bak and Chen [1990]:

1. If a live tree is next to a burning tree, it burns; otherwise, it catches fire with probability $p_{1}$.
2. A burning tree dies.
3. A dead tree has probability $p_{2}$ of being replaced by a live tree.

Parallel simulation of a forest fire requires only minor changes of the model program:

1. The possible states are:

$$
\text { type state }=(\text { alive }, \text { burning, dead })
$$

2. The initial states may, for example, be:

$$
u_{1}=u_{2}=u_{3}=u_{4}=\operatorname{dead} \quad u_{5}=\text { alive }
$$

3. Algorithm 4.1 defines state transitions.
```
function next(uc, un, us,
    ue, uw: state): state;
const \(\mathrm{p} 1=0.01 ; \mathrm{p} 2=0.3\);
begin
    if \(\mathrm{uc}=\) alive then
        if (un = burning) or
                ( \(u s=\) burning) or
                (ue = burning) or
                (uw = burning)
            then next := burning
            else if random \(<=\mathrm{p} 1\)
                then next := burning
                else next := alive
        else if \(u c=\) burning then
            next := dead
        else \(\{u c=\) dead \(\}\)
            if random \(<=\mathrm{p} 2\)
                then next \(:=\) alive
                else next \(:=\) dead
end
```

Algorithm 4.1
4. A random number generator is added.

## 10. EXAMPLE: LAPLACE'S EQUATION

A cellular automaton can also solve Laplace's equation for equilibrium temperatures in a square region with fixed temperatures at the boundaries. Every cell represents the temperature at a single point in the region. In each time step, the next temperature of every cell is defined by a simple deterministic rule.

Parallel simulation of heat flow requires the following changes of the model program:

1. The states are temperatures represented by reals.
2. A possible choice of initial temperatures is:

$$
\begin{aligned}
& u_{1}=0 \\
& u_{2}=100 \\
& u_{3}=100 \\
& u_{4}=0 \\
& u_{5}=50
\end{aligned}
$$

3. Algorithm 4.2 defines the next temperature of an interior cell.
```
function next(uc, un, us,
    ue, uw: real): real;
var res: real;
begin
    res := (un + us + ue +
        uw)/4.0 - uc;
    next := uc + fopt*res
end
```

## Algorithm 4.2

In steady state, the temperature of every interior cell is the average of the neighboring temperatures:

$$
u_{c}=\left(u_{n}+u_{s}+u_{e}+u_{w}\right) / 4.0
$$

This is the discrete form of Laplace's equation. The residual res is a measure of how close the temperatures are to satisfying this equation. The correction of a temperature $u_{c}$ is proportional to its residual.
4. A relaxation factor $f_{\text {opt }}$ is added:

For a large square grid relaxed in parity order, the relaxation factor

$$
f_{\text {opt }}=2-2 \pi / n
$$

ensures the fastest possible convergence towards stationary temperatures. In numerical analysis, this method is called successive overrelaxation with parity ordering. The method requires $n$ relaxation steps to achieve 3 -figure accuracy of the final temperatures [Young 1954, Press et al. 1989].

The complete algorithm for parallel simulation of steady state heat flow is listed in the Appendix. The corresponding sequential program is explained in [Brinch Hansen 1992b]. Numerical solution of Laplace's equation on multicomputers is also discussed in [Barlow and Evans 1982, Evans 1984, Pritchard et al. 1987, Saltz et al. 1987, Fox et al. 1988].

## 11. COMPLEXITY

In each time step, every node exchanges overlapping elements with its neighbors in $O(m)$ time and updates its own subgrid in $O\left(m^{2}\right)$ time. The final output takes $O\left(n^{2}\right)$ time. The parallel run time required to relax an $n \times n$ grid $n$ times on $p$ processors is

$$
T(n, p)=n\left(a m^{2}+O(m)\right)+O\left(n^{2}\right)
$$

where $a$ is a system-dependent constant of relaxation and

$$
\begin{equation*}
n=m \sqrt{p} \tag{1}
\end{equation*}
$$

The complexity of parallel simulation can be rewritten as follows:

$$
T(n, p)=n^{2}(a n / p+O(1)+O(1 / \sqrt{p}))
$$

For $1 \leq p \ll n$, the communication times are insignificant compared to the relaxation time, and we have approximately

$$
\begin{equation*}
T(n, p) \approx a n^{3} / p \quad \text { for } n \gg p \tag{2}
\end{equation*}
$$

If the same simulation runs on a single processor, the sequential run time is obtained by substituting $p=1$ in (2):

$$
\begin{equation*}
T(n, 1) \approx a n^{3} \quad \text { for } n \gg 1 \tag{3}
\end{equation*}
$$

The processor efficiency of the parallel program is

$$
\begin{equation*}
E(n, p)=\frac{T(n, 1)}{p T(n, p)} \tag{4}
\end{equation*}
$$

The nominator is proportional to the number of processor cycles used in a sequential simulation. The denominator is a measure of the total number of cycles used by $p$ processors performing the same computation in parallel.

By (2), (3), and (4) we find that the parallel efficiency is close to one, when the problem size $n$ is large compared to the machine size $p$ :

$$
E(n, p) \approx 1 \text { for } n \gg p
$$

Since this analysis ignores communication times, it cannot predict how close to one the efficiency is.

In theory, the efficiency can be computed from (4) by measuring the sequential and parallel run times for the same value of $n$. Unfortunately, this is not always feasible. When 36 nodes relax a $1500 \times 1500$ grid of 64 -bit reals, every node holds a subgrid of $250 \times 250 \times 8=0.5$ Mbytes. However, on a single processor, the full grid occupies 18 Mbytes.

A more realistic approach is to make the $O\left(n^{2}\right)$ grid proportional to the machine size $p$. Then every node has an $O\left(m^{2}\right)$ subgrid of constant size independent of the number of nodes. And the nodes always perform the same amount of computation per time step.

When a scaled simulation runs on a single processor, the run time is approximately

$$
\begin{equation*}
T(m, 1) \approx a m^{3} \quad \text { for } m \gg 1 \tag{5}
\end{equation*}
$$

since $p=1$ and $n=m$.
From (1), (3), and (5) we obtain

$$
\begin{equation*}
T(n, 1) \approx p^{3 / 2} T(m, 1) \text { for } m \gg 1 \tag{6}
\end{equation*}
$$

The computational rule we need follows from (4) and (6):

$$
\begin{equation*}
E(n, p) \approx \frac{\sqrt{p} T(m, 1)}{T(n, p)} \quad \text { for } m \gg 1 \tag{7}
\end{equation*}
$$

This formula enables us to compute the efficiency of a parallel simulation by running a scaled-down version of the simulation on a single node.

## 12. PERFORMANCE

We reprogrammed the model program in occam 2 and ran it on a Computing Surface with T800 transputers configured as a square matrix with a master node [Inmos 1988, Meiko 1987, Trew and Wilson 1991]. The program was modified to solve Laplace's equation as explained in Section 10. The complete program is found in the Appendix.

Table I shows measured (and predicted) run times $T(n, p)$ in seconds for $n$ relaxations of an $n \times n$ grid on $p$ processors. In every run, the subgrid dimension $m=250$.

| Table I |  |  |  |  |
| ---: | ---: | :---: | :---: | :---: |
| $p$ | $n$ | $T(n, p)$ | $E(n, p)$ |  |
| 1 | 250 | 278 | $(281)$ | 1.00 |
| 4 | 500 | 574 | $(563)$ | 0.97 |
| 9 | 750 | 863 | $(844)$ | 0.97 |
| 16 | 1000 | 1157 | $(1125)$ | 0.96 |
| 25 | 1250 | 1462 | $(1406)$ | 0.95 |
| 36 | 1500 | 1750 | $(1688)$ | 0.95 |

The predicted run times shown in parentheses are defined by (2) using

$$
a=18 \mu s
$$

The processor efficiency $E(n, p)$ was computed from (7) using the measured run times.

## SUMMARY

We have developed a model program for parallel execution of cellular automata on a multicomputer with a square matrix of processor nodes. We have adapted the model program for simulation of forest fires and numerical solution of Laplace's equation for stationary heat flow. On a Computing Surface with 36 transputers the program performs 1500 relaxations of a $1500 \times 1500$ grid of 64 -bit reals in 29 minutes with an efficiency of 0.95 .

## APPENDIX: COMPLETE ALGORITHM

The complete algorithm for parallel solution of Laplace's equation is composed of Algorithms 1-12.

```
const \(q=6 ; m=250\{\) even \(\} ;\)
    \(\mathrm{n}=1500\{\mathrm{~m} * \mathrm{q}\}\);
type row = array [1..n] of real;
    grid \(=\) array \([1 . . n]\) of row;
procedure laplace(var u: grid; u1, u2,
    u3, u4, u5: real; steps: integer);
const \(\mathrm{pi}=3.14159265358979\);
type subrow \(=\) array \([0 . . \mathrm{m}+1]\) of real;
    subgrid \(=\) array \([0 . . \mathrm{m}+1]\) of subrow;
var fopt: real;
    procedure master(inp: channel;
        var u: grid);
    var \(i, j\) : integer;
        begin
        for \(i:=1\) to \(n\) do
            for \(\mathrm{j}:=1\) to n do
                inp? \(\mathrm{u}[\mathrm{i}, \mathrm{j}]\)
    end;
procedure copy(no: integer;
        inp, out: channel);
        var k: integer; uk: real;
