Abstract: We present a facile and effective method for fabrication of the localized surface plasmon resonance (LSPR) optical fiber sensor assisted by two polydopamine (PDA) layers with enhanced plasmonic sensing performance. The first PDA layer was self-polymerized onto the bare optical fiber to provide the catechol groups for the reduction from Ag^+ to Ag^0 through chelating and redox activity. As the reduction of Ag^+ proceeds, Ag nanoparticles (NPs) were grown in-situ on the PDA layer with uniform distribution. The second PDA layer was applied to prevent Ag NPs from oxidating and achieve an improvement of LSPR signal. The PDA/Ag/PDA-based optical fiber sensor has an enhanced LSPR sensitivity of 961 nm/RIU and excellent oxidation resistance. The stable PDA/Ag/PDA-based LSPR sensor with high optical performance is very promising for future application in optical sensing field.

Keywords: LSPR; optical fiber; polydopamine; in-situ growth; silver nanoparticles

1. Introduction

Localized surface plasmon resonance (LSPR), a phenomenon occurs when electromagnetic field of oscillating electrons on the surface of nanoparticles (NPs) matches that of incident light, creates prominent spectral absorption and scattering peaks along with strong electromagnetic near-field enhancement. LSPR is normally associated with noble metal nanostructures and has been widely applied in drug screening, biological detection, and

disease diagnosis [1–4], due to its high sensitivity of localized electromagnetic field around the metal surfaces upon the change in environmental refractive index (RI).

Up to date, there are four approaches to fabricate LSPR sensors, i.e., electron-beam lithography, physical evaporation, electrostatic self-assembly (ESSA), and in-situ synthesis. Duyne *et al.* reported the use of nanosphere lithography for building silver nanospheres with regular arrangement [5–7]. They

Article type: Regular

utilized the self-assembly of size-monodisperse polystyrene nanospheres as the uniform deposition mask. With thermal or electron beam evaporation, metal was deposited through the mask. Then, the metal NPs remained on the substrates in order after removing the polystyrene nanospheres. Jia *et al.* fabricated Au/Ag bimetallic NPs by evaporating silver onto gold modified glass through a transmission electron microscopy (TEM) copper grid to build well-ordered patterns [8]. ESSA is another method to build LSPR sensors by achieving the interactions between negatively charged NPs and positively charged glass substrates. The experimental conditions including pH, temperature, solution concentration, and fabrication times together with the size and shape of NPs could contribute to the differences of sensitivity, the limit of detection, and the resolution of optical fiber sensors [9–17].

Dopamine (DA) is an organic chemical of phenethylamine and catecholamine families that can aggregate and form a polydopamine (PDA) layer and then interact with almost all types of substrates [18]. Since the mechanism of PDA formation is still not well known, some evidences have suggested two possible routes including noncovalent self-assembly and covalent polymerization [19]. It was generally accepted that the covalent polymerization plays a key role in the initial stages of deposition. As the aggregation continues, noncovalent interactions become more dominant [20]. Usually, a short time is sufficient for the deposition of the PDA layer in a stirred solution, and the deposition promotes a morphologically uniform and continuous PDA film for further surface-mediated reactions [21].

Considering the strong adhesion and quick deposition capability of PDA [22], along with the high plasmonic activities of silver nanostructures on account of their appropriate dielectric functions and electronic structures [2, 23], we developed an effective strategy to prepare PDA/Ag/PDA-based

LSPR optical fiber sensor. In our work, the first PDA layer serves as reductant for the reduction from free Ag^+ in solution to Ag NPs on substrate. Then the second PDA layer was deposited on the Ag NPs-modified surface to prevent oxidation and increase the sensitivity of the sensor.

2. Experimental section

2.1 Materials

Multimode optical fibers with a 0.22-numerical aperture and a 400- μm core diameter were purchased from Ocean Optics Inc. Dopamine hydrochloride was purchased from Sigma-Aldrich. Silver nitrate (AgNO_3) and tris (hydroxymethyl) aminomethane were purchased from Aladdin Reagent Co., Ltd. (China). All of the other chemicals used were of analytical grade.

2.2 Experimental setup

The bifurcated optical fiber (SPLIT-400-VIS-NIR, Ocean Optics) served as a connection to the LSPR sensor on one of its terminals and a tungsten-halogen light source (DH-2000-BAL, Ocean Optics) along with a mini-spectrometer (USB2000, Ocean Optics) on the bifurcated side. The other terminal of the sensor, which has been fabricated with sensing layer, was dipped into a certain solution. The device was operated by the following way, i.e., a white light emits from the light source to excite the LSPR effect of the sensor and the spectrometer assists in capturing the optical signal reflected by the silver layer of the sensor. Finally, a computer linked with the spectrometer was used to monitor the optical signal.

2.3 Fabrication of the LSPR sensor

Figure 1 demonstrates the fabrication process of the PDA/Ag/PDA-based LSPR optical sensor. Firstly, the bare optical fiber was immersed in piranha solution (7:3 mixture of concentrated H_2SO_4 and 30% H_2O_2) for 30 min at 90 °C and then it was rinsed with deionized (DI) water and dried in N_2

stream. After that, the piranha-cleaned optical fiber was functionalized by DA through a polymerization reaction, during which optical fiber was immersed in freshly prepared DA solution (1 mg/mL in 10 mM Tris buffer, pH 8.5) under stirring with a speed of 500 rpm for 10 min. Then this optical fiber was immediately rinsed again with DI water and dried with N₂ stream. Secondly, the PDA-fabricated optical fiber was immersed in AgNO₃ solution

(10 mM) for 18 h. In this step, Ag⁺ was reduced to Ag⁰ by catechol groups in PDA and the color of optical fiber surface changed from transparent to yellowish. Thirdly, the Ag NPs-based optical fiber was modified by PDA again using the same procedure as that of the first PDA layer. At last, a thick layer of Ag (~200 nm) was coated on the end of sensing area through silver mirror reaction to promote reflecting the light to the spectrometer.

Fig. 1 Schematic of the fabrication process of PDA/Ag/PDA-based LSPR sensor in this work.

2.4 Numerical Method

The electric field distributions of the Ag NPs were calculated by the 3D finite-difference time-domain (FDTD) method [24], and their geometric parameters are determined based on the scanning electron microscopy (SEM) images of the fabricated sensors. All the dielectric functions of Ag and glass were obtained from Palik database [25]. Override mesh region with 0.8 nm mesh size is used to enclose the whole NP to get accurate results. To verify the accuracy and stability of the calculations, convergence testing was done before all the simulations. All the calculations of electric field distributions for the Ag NPs were done at their corresponding resonant wavelengths. In this study, all the calculations were performed using the FDTD simulation program (FDTD solutions 8.6, Lumerical solutions, Inc., Vancouver, Canada).

3. Results and discussion

3.1 In-situ synthesis of Ag NPs on PDA-modified optical fiber surface

Since DA can self-polymerize to PDA on almost

all the material surfaces in weakly alkaline and aerobic conditions [15], we utilized a PDA layer to modify a bare optical fiber. In the AgNO₃ solution, the catechol groups in PDA reduced the Ag⁺ to Ag⁰. As a result, Ag NPs were formed on optical fiber from the aggregated neighboring Ag⁰ clusters, leading to the fabrication of PDA/Ag-based sensor. The SEM image in Fig. 2(a) shows a number of separate Ag NPs on the sensor surface and help identify the morphology of the silver film. The Ag NPs appeared to distribute in a relatively uniform size. Moreover, there was no apparent aggregation of Ag NPs on optical fiber. Figure 2(b) shows the statistical graph of the Ag NPs distribution on the LSPR sensor surface. With the help of the Nano Measure (a software), we obtained the statistics of particle distribution (200 points picked at random). According to the statistical result, the NPs distributed in an almost uniform size between 20 nm–30 nm, which can contribute to the excellent signal of the final sensor.

To study the sensing ability of the fabricated PDA/Ag-based LSPR sensor, we measured the reflectivity spectra of the sensor in various solvents

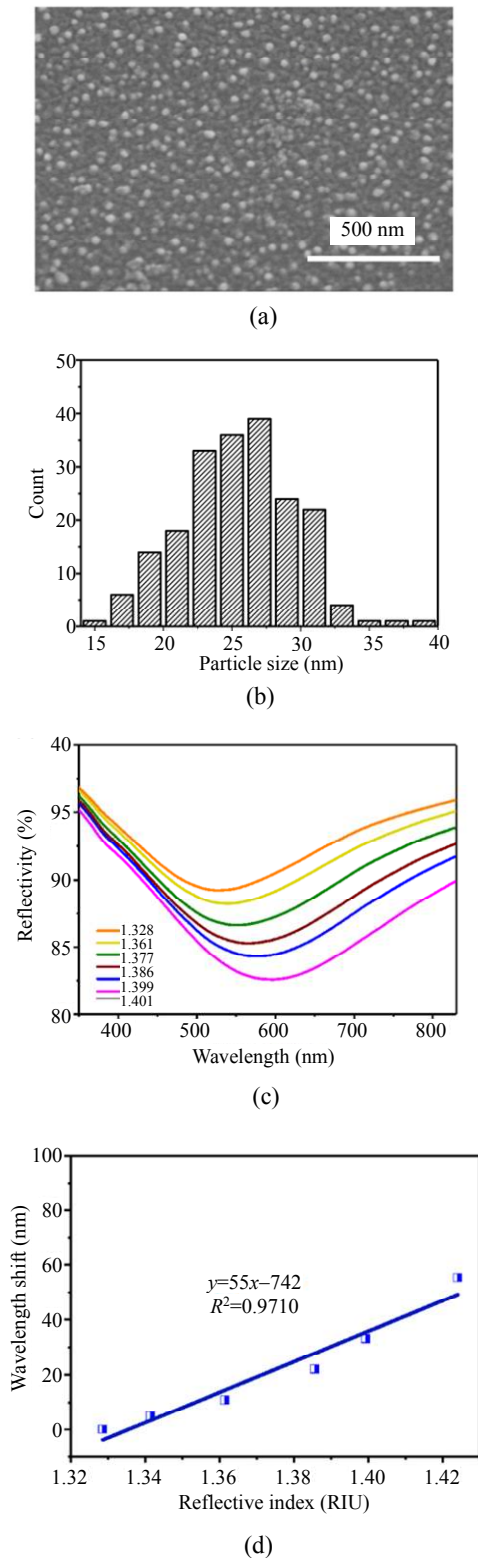

Fig. 2 Characterizations of the as-prepared sensor: (a) SEM images of Ag NPs coated on optical fiber, (b) histogram showing the corresponding particle size distribution of Ag NPs, (c) the reflective spectra of the PDA/Ag-based LSPR sensor in different alcoholic solution, and (d) changes in the LSPR wavelength shift of the as-prepared sensor to the RI.

with RI ranging from 1.328 to 1.401. Table 1 shows the detailed solvents and corresponding RI. As shown in Figs. 2(c) and 2(d), the resonant wavelength redshifted with an increase in the RI, and a linear relationship is obtained between the resonant wavelength shift and the solvent RI. The refractive index sensitivity (RIS) was calculated by $S_n = \delta\lambda_{res}/\delta n_s$, where δn_s is the refractive index change of the solution, and $\delta\lambda_{es}$ is the corresponding resonance wavelength shift. As shown in Fig. 2(d), the sensor shows a sensitivity up to 555 nm/RIU. This sensitivity was higher than that of the Ag NPs prepared by photodeposition, physical lithography, and electrostatic self-assembly [26–29], as shown in Table 1.

To confirm the high sensitivity of the as-prepared Ag NPs-based optical sensor, we calculated the electric field distributions of the Ag NPs on an optical fiber under resonance conditions by using the FDTD method. The diameter and height were set to 25 nm and 12.5 nm, respectively, according to the mean geometric values measured in the experiments. As shown in Fig. 3(a), strongly enhanced electric fields were generated close to the Ag NPs surface, especially in the space near the marked optical fiber. The LSPR peak of the simulated Ag NP arrays was at 502 nm in water, which was in agreement with the measured spectrum in experiment. Moreover, the SEM image in Fig. 2(a) shows that some Ag NPs were close to each other, which might generate interparticle coupling. Hence, we further calculated the electric field distributions of the dimers with gap sizes of 0 nm, 10 nm, and 15 nm. As shown in Figs. 3(b)–3(d), interparticle junction in the dimers generated greater enhancement of electric fields, which indicated strong interparticle coupling. For dimers with 0 nm, 10 nm, and 15 nm gaps, the greatest electric field enhancements at the gap area were 4×10^3 , 2.8×10^3 , 2.8×10^3 , respectively, all of which were larger than that of the single Ag NPs with the value of 1.4×10^3 .

Table 1 Sensitivity comparisons of the fabricated PDA/Ag/PDA-based LSPR sensor with other Ag sensors.

Samples	Methods	Applications	LSPR sensitivity (nm/RIU)	Reference
Ag NPs	Photodeposition	LSPR	387 ($RI=1.333-1.442$)	[26]
Ag NPs	Photodeposition	LSPR	68 ($RI=1.0-1.5$)	[27]
Ag nano-disks	Lithography	LSPR	325 ($RI=1.333-1.378$)	[28]
Ag NPs	Electrostatic self-assembly	LSPR	387 ($RI=1.33-1.40$)	[29]
PDA/Ag-based	In-situ reduction	LSPR	555 ($RI=1.33-1.40$)	This work
PDA/Ag/PDA-based	In-situ reduction+ PDA modification	LSPR	961 ($RI=1.33-1.40$)	This work

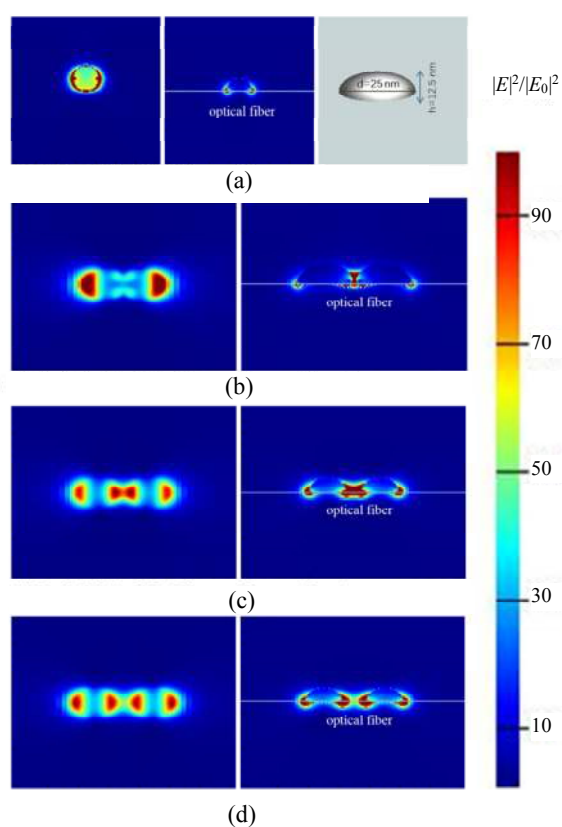

Fig. 3 Calculated electric field distributions ($|E|^2/|E_0|^2$) of the Ag NPs on the optic fiber surface when the particles existed as (a) a single NPs, (b) a dimer without gap, (c) a dimer with a 10 nm gap, and (d) a dimer with a 15 nm gap (the left demonstrates the top view; the right shows the side view).

Therefore, the good sensing performance of the PDA/Ag-based sensor might be partly ascribed to the interparticle coupling of the dimers. Based on the simulation results, constructed Ag NPs arrays

present LSPR peaks at 562 nm, 548 nm, and 534 nm for the regions of dimers with 0 nm, 10 nm, and 15 nm gaps in water, respectively, which is in good agreement with the experiment.

To further confirm the coupling effect of the dimers, we simulated the spectra of single AgNPs and dimers on optical fiber in different alcoholic solutions. The simulation of single AgNPs and dimers in solutions were carried out while RI ranging from 1.328 to 1.401. The resonance wavelength shifts 38 nm from 502 nm to 540 nm for single NPs and the dimers without gap shows 49 nm shift from 562 nm to 611 nm in the same environmental RI range. Moreover, as shown in Fig. 2(b), the sensitivity of the sensor fabricated in experiment is 555 nm/RIU, which is between 511 nm/RIU and 574 nm/RIU. As a result, the simulated work confirmed that dimers may exist on the PDA/Ag-based optical fiber sensor, which can contribute to the improvement of sensitivity.

3.2 LSPR performance and stability of PDA/Ag/PDA optical fiber sensor

To further protect Ag NPs and increase the sensitivity of PDA/Ag-based optical fiber sensor, the second PDA layer was modified on the fiber surface.

We immersed the sensing area of our sensor in various solvents with RI ranging from 1.328 to 1.401 to examine the sensitivity of PDA/Ag/PDA-

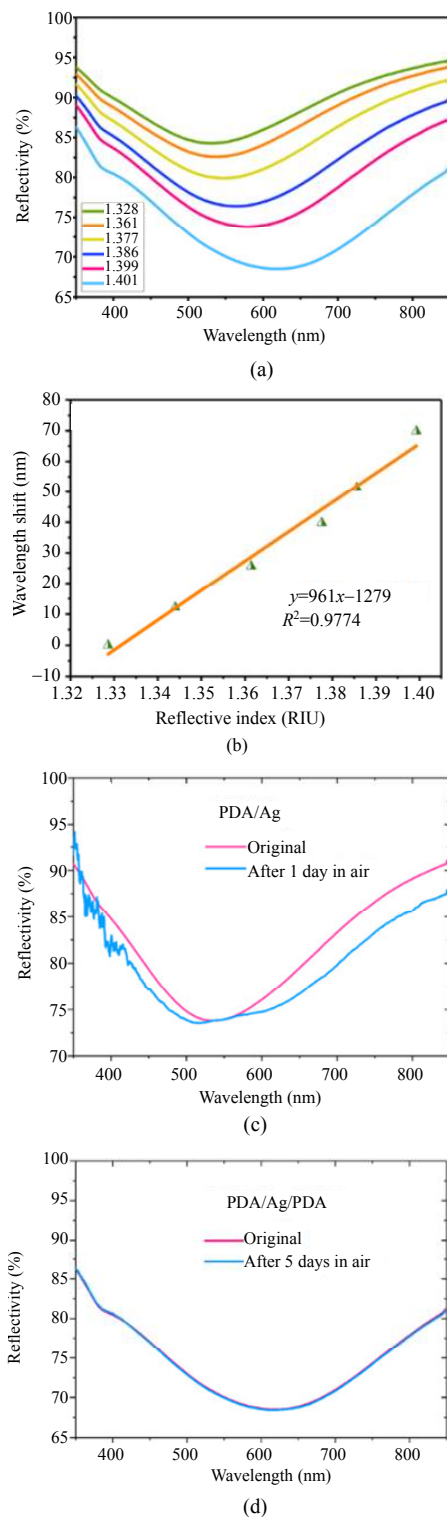

Fig. 4 LSPR performance and stability of PDA/Ag/PDA optical fiber sensor: (a) the reflective spectra of the PDA/Ag/PDA-based LSPR sensors in different alcoholic solutions, (b) changes in the LSPR wavelength shift of the as-prepared sensors to the RI, (c) reflectivity spectra of the PDA/Ag-based LSPR sensor, (c) PDA/Ag/PDA-based LSPR sensor and (d) in butanol before treatment and after storage in the air.

based LSPR sensor. As shown in Fig. 4(a), reflectivity peaks illustrate that PDA/Ag/PDA sensor has stronger LSPR signal. In the RI range of 1.328–1.401, the sensor shows brilliant optical performance with the enhanced sensitivity of 961 nm/RIU. As shown in Table 1, the Ag NPs prepared by photodeposition, physical lithography, and electrostatic self-assembly show lower sensitivity than two constructed sensors in this work [26–29]. Moreover, the sandwich-structured PDA/Ag/PDA-based sensor presents higher sensitivity compared with the PDA/Ag-based sensor. The improved sensitivity is most likely due to the redshift of the resonance wavelength. It has been reported that the redshift of spectrum could enhance the sensitivity of SPR sensors [30]. Therefore, the additional layer of PDA, which contributed to the redshift of the spectra, played an important role in increasing the sensitivity of the optical fiber sensor. As shown in Fig. 4(c), the FWHM of the reflectivity spectra of the PDA/Ag-based LSPR sensor after 1 day in air increased because of the deformation of the Ag NPs resulting from their poor chemical and structural stabilities. In comparison, as shown in Fig. 4(d), the reflectivity spectra of the PDA/Ag/PDA-based LSPR sensor after 5 days in air almost overlapped with the original spectrum. The results proved the excellent oxidation resistance of the PDA/Ag/PDA, indicating that the second PDA layer on Ag NPs prevented them from oxidating. Due to its enhanced sensitivity and stability, PDA/Ag/PDA-based LSPR sensor is very promising in the future application.

4. Conclusions

In summary, we reported a facile method for the fabrication of PDA/Ag/PDA-based LSPR sensor in this work. The method is based on the strong self-polymerization capability of PDA and the in-situ growth of Ag NPs for LSPR sensing. The first PDA layer worked as a reductant and a binder to modify the Ag NPs to the optical fiber surface, whereas the second PDA layer was coated again to

prevent oxidation and increase the sensitivity of the sensor. The prepared PDA/Ag/PDA-based LSPR sensor presented improved LSPR performance and stability owing to the key role of PDA on the fabrication process. Compared with the PDA/Ag-based and other Ag NPs-based LSPR sensors, the PDA/Ag/PDA-based LSPR sensor had an excellent sensitivity of 961 nm/RIU. The sandwich-structured sensor showed an obvious enhancement in sensitivity and stability, which demonstrated that PDA could be of great value to the performance enhancement of optical fiber sensors.
