Summary

Human induced pluripotent stem cells (iPSCs) and genome editing provide a precise way to generate gene-corrected cells for disease modeling and cell therapies. Human iPSCs generated from sickle cell disease (SCD) patients have a homozygous missense point mutation in the *HBB* gene encoding adult β-globin proteins, and are used as a model system to improve strategies of human gene therapy. We demonstrate that the CRISPR/Cas9 system designer nuclease is much more efficient in stimulating gene targeting of the endogenous *HBB* locus near the SCD point mutation in human iPSCs than ZFNs and TALENs. Using a specific guide RNA and Cas9, we readily corrected one allele of the SCD *HBB* gene in human iPSCs by homologous recombination with a donor DNA template containing the wild-type *HBB* DNA and a selection cassette that was subsequently removed to avoid possible interference of HBB transcription and translation. We chose targeted iPSC clones that have one corrected and one disrupted SCD allele for erythroid

differentiation assays, using an improved xeno-free and feeder-free culture condition we recently established. Erythrocytes from either the corrected or its parental (uncorrected) iPSC line were generated with similar efficiencies. Currently ~6%-10% of these differentiated erythrocytes indeed lacked nuclei, characteristic of further matured erythrocytes called reticulocytes. We also detected the 16-kD β-globin protein expressed from the corrected *HBB* allele in the erythrocytes differentiated from genome-edited iPSCs. Our results represent a significant step towards the clinical applications of genome editing using patient-derived iPSCs to generate disease-free cells for cell and gene therapies.

Human iPSCs; genome editing; erythroid cells; globin switching

Introduction

Patient-derived human induced pluripotent stem cells (iPSCs), which can be expanded unlimitedly in culture while maintaining pluripotency, provide advantages for selecting and expanding rare cells whose genome is precisely edited or engineered by homologous recombination (HR). HR as well as another form of DNA repair, non-homologous end joining (NHEJ) independent of a DNA template, are the two major mechanisms for a mammalian cell to repair a DNA double strand break (DSB). In the past decade, scientists developed tools to induce a specific DSB that triggers DNA repair machinery and greatly stimulate either NHEJ or HR at a predetermined DNA sequence in human and other mammalian cells [1–5]. NHEJ does not need a template for DNA repair but rather simply and promiscuously joins the DNA ends together in an error-prone process, often resulting in small deletions or insertions (indels) at the rejoining junction. In contrast, HR requires a DNA template to replace the DNA sequence surrounding the DSB site. HR-mediated precise gene targeting is much less efficient than NHEJ even in the presence of exogenous donor DNA template [1, 2]. To increase the efficiency of either form of gene targeting, designer DNA endonucleases such as zinc finger nucleases (ZFNs) have been engineered and used in various cell types such as human iPSCs and embryonic stem cells (ESCs) [1–7]. In addition to making targeted insertion, ZFNs were also used to correct a point mutation in human iPSCs derived from adult patients of sickle cell disease (SCD), which harbor the homozygous β^S mutation in the *HBB* gene [8, 9]. This was achieved by HR-mediated gene targeting with a donor DNA that provides a correct *HBB* DNA sequence and an expression cassette rendering drug selection of rare clones after HR-mediated DNA replacement resulting in a targeted insertion. However, the reported efficiencies of gene targeting in these two early studies were low even among the vastly enriched clones after drug-selection: 1.3% and 9.8% of selected clones, respectively [8, 9]. This was not totally surprising, because the *HBB* gene is not expressed in human ESCs or iPSCs, and it is challenging to find a pair of ZFNs that efficiently and specifically cut the *HBB* gene without affecting the nearby and highly homologous genes *HBD*, *HBE* or *HBG* (the later two encoding embryonic and fetal forms of hemoglobin β subunits). Importantly, the two studies did not show the production of the corrected HBB protein, after hematopoietic differentiation of the gene-corrected iPSCs [8, 9]. The lack of evidence in producing HBB protein after iPSC gene correction and

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

differentiation could be due to: 1) defects in the donor vector that is unable to express the corrected gene from the endogenous regulatory element after genome targeting; 2) defects in the iPSC lines in these earlier studies that were derived from adult fibroblasts by vectors inserting and disputing the native human genome; 3) lack of an efficient differentiation method to generate mature erythrocytes that produce the adult form of beta-globin encoded by the *HBB* gene; or 4) combinations of the above.

Recently, several groups used TALENs and CRISPR/Cas9 to develop better designer nucleases that target the *HBB* gene near the SCD point mutation (nt. 69A>T in exon 1). Although these studies reported greater efficiencies measuring both NHEJ and HR rates in human iPSCs and simpler cell models such as cancer cell lines [10–13], the specificity as well as efficiencies of these TALENs and CRIPSR/Cas9 nucleases remained to be fully analyzed. An ultimate test would be to efficiently and specifically target the SCD mutation in high quality iPSCs (such as those free of vector insertion), differentiate them into erythrocytes expressing a high-level of *HBB* mRNA, and demonstrate the production of *HBB*-encoded protein from the corrected allele. In this report, we demonstrated that we achieved these objectives, and established a method that is applicable to other human diseases such as β-thalassemia.

Methods

Approvals of Using Human iPSCs and Primary Cells from Anonymous Donors

The experiments using human iPSCs were approved by the Institutional Stem Cell Research Oversight (ISCRO) committee in the Johns Hopkins University. Use of anonymous human samples for laboratory research was approved by the Institutional Review Board of the Johns Hopkins University.

Human iPSC maintenance and expansion

Human iPSC lines BC1 and TNC1, derived from human adult hematopoietic cells by transient expression of one or two episomal vectors [14, 15], were used in this study. While TNC1 was derived from cultured erythroblasts after selective expansion of a SCD patient's peripheral blood (PB) mononuclear cells (MNCs), BC1 was derived from expanded hematopoietic progenitors in bone marrow (BM) of an adult healthy donor [14, 15]. They lack overt genomic alteration or V(D)J rearrangement associated with lymphocytes [14, 15]. Although they were initially derived and expanded on mouse embryonic fibroblasts, these human iPSCs (around passages 20–25) were subsequently cultured under a feeder-free and xeno-free condition with a simplified culture medium E8 as described before [16–18].

Designing CRISPR/Cas9 vectors for targeting the endogenous *HBB* locus

We used the CRIPSR/Cas9 system previously described [18, 25], for which an expression vector encoding humanized (h) Cas9 protein was obtained from Addgene.org (Plasmid #41815). 455-bp guide RNA (gRNA) expression cassettes including a 20-bp target-specific sequence targeting the human *HBB* gene in the first exon were synthesized (Integrated DNA Technology), and cloned into Zero-blunt TOPO vector (Life Technologies). Alternatively, two 60-bp oligonucleotides that are complementary at the 20-bp target sequence were used

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

as a template encoding a guide RNA, and cloned by Gibson assembly into a guide RNA vector (Addgene plasmid #41824) linearized with AflII [25]. The tests of CRIPSR gRNA and Cas9 in human 293T and iPSCs, including Miseq analyses, were described in details in the supplemental materials as recently published [18].

Gene targeting in human iPSCs

Gene targeting in various human iPSC lines including TNC1 was conducted as described [18]. Briefly, two million iPSCs were re-suspended in 100 μl P3 Primary Cell Solution (for 4D Nucleofector, Lonza) and mixed with 10 μg DNA. To target the SCD mutation in TNC1 iPSCs, we used the donor vector (briefed as MGH) that was made previously by MGH investigators and a gift from Dr. J. Keith Joung [9]. The MGH donor vector provides a wild-type HBB DNA template and a PGK-puromycin expression cassette to be inserted into the intron 1 for HR-mediated replacement [9]. In addition to 5 μg MGH donor vector, the mixture also contained 2.5 μg hCas9 plasmid, and 2.5 μg of guide RNA, or 2.5 μg each of the two plasmids expressing of ZFN or TALEN pairs. The nucleofected iPSCs were plated onto Matrigel- or vitronectin-coated 6-well plates immediately following nucleofection. Ten μM ROCK Inhibitor Y-27632 was added in the E8 medium for the first 24-hour. Starting at 72–96 hours post nucleofection, puromycin (0.5 μg/ml) was added to the medium for the selection of targeted events. After puromycin selection, colonies were manually picked from different wells and expanded. Genomic DNAs were isolated from the expanded clones and analyzed for targeted integration [18]. To excise loxP flanked PGK-puromycin selection cassette, iPSCs were transfected with a pCAG-Cre-IRES2-GFP plasmid ([19], plasmid # 26646 in Addgene.org) and plated in low density in 6-well plates for clonal selection. Individual clones were picked, expanded, screened for excision by genomic PCR that amplifies the DNA fragment with shortened insertion in intron 1.

Hematopoietic and erythroblast differentiation of human iPSCs

Hematopoietic and erythroblast differentiation of BC1, TNC1 and targeted iPSCs were done as described previously [17, 20].

Erythroid terminal maturation of erythroblasts generated from iPSCs

We counted the erythroblast cell number at day 10 of erythroblast differentiation and expansion culture and washed erythroblasts twice with PBS after we confirmed the normal erythroblast phenotype by flow cytometry. We then seeded erythroblasts in erythroid terminal maturation medium (TM) at 1 million per ml at 37°C in a humid atmosphere of 5% CO_2 in air. The erythroid TM medium is made by mixing with IMDM (Invitrogen) plus 3 U/ml Epo (R&D Systems), 500 μg/ml human holo-transferrin (R&D systems), 4 U/ml heparin (Sigma), 10 μg/ml insulin (Sigma), and 10% pooled normal adult human peripheral blood plasma (innovative-research, Cat# IPLA-N). Fresh medium with cytokines was added every 2 to 3 days. The cell density is maintained below 4 million per ml. The maturating cells were taken for analysis at different days up to ten days from the beginning of terminal maturation.

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

Flow cytometry of differentiated hematopoietic cells

For flow cytometry analysis of HSPCs and erythroblasts differentiated from human iPSCs, we harvested ~200,000 cells, washed with PBS, and re-suspended the cell pellet in PBS +1%FBS for antibody staining. We used CD34-APC (BD Biosciences), CD45-AF488 or CD45-APC (Invitrogen), CD235a-FITC (Invitrogen), Band3-FITC or Band3-APC (kindly provided by Dr. Xiuli An at NYBC), CD49d-FITC or CD49d-PE (Miltenyi Biotec, San Diego, CA) to characterize expanded and differentiated cells. Dead cells were excluded from analysis by positive staining 7-AAD (Viaprobe, BD Biosciences).

For flow cytometric analysis of erythroid terminal maturation of erythroblasts, we harvested suspension cells from terminal maturation culture at different time points of maturation, washed with PBS, and re-suspended in PBS+1%FBS and stained with appropriate combinations of CD235a-FITC, Band3-FITC or APC, CD45-APC and CD49d-FITC (BD BioSciences and Life Technologies), and DRAQ5, a cell permeable dye for DNA staining (Cell Signaling Technology, Danvers, MA). Intracellular hemoglobin staining was done as described before [21].

Morphological analysis of cells spun on slides

Cytospin and histology staining were done as described before [21].

RNA extraction and quantitative RT-PCR to measure gene expression

RT-PCR analysis of globin gene expression was done as described before [21]. All experiments were performed in triplicate and a non-template control (lacking cDNA template) was included in each assay. Relative gene expression was normalized to the housekeeping gene GAPDH.

Western Blot of HBB protein production

Western blot for analyzing HBB protein level in differentiated cells is carried out using a monoclonal antibody against human HBB (Santa Cruz Biotechnology, sc-21757) and GAPDH (Cell Signaling Technology, Cat. 5174), according to the manufacturer's instructions. We used the protein extract from the same number of cells at different stages of differentiation to estimate HBB content in differentiated cells.

O_2 binding capacity and affinity

O_2 equilibrium curves of day 8 erythrocytes after terminal maturation (TM8) differentiated from iPSCs or fresh human CB as a control were determined using a Hemox-Analyzer (TCS Scientific, New Hope, PA) in accordance to manufacturer's recommendations as previously described [21].

Results

Generation of enucleated erythrocytes from human iPSC lines derived from blood

Recently we developed a method to generate human iPSC lines that are free of vector insertion in the genome from hematopoietic cells in cord blood (CB), adult PB or BM [14,

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

15]. For example, we used PB MNCs from an adult SCD patient and established a proliferative erythroblast culture that was reprogrammed to iPSCs by one to two plasmids [14]. One of such established iPSC lines, TNC1, contains the homozygous SCD mutation (nt. 69A>T) in the *HBB* gene [14]. After extensive expansion under a feeder-free culture condition such as one with the E8 culture medium on vitronectin as substrates, the TNC1 and BC1 iPSCs maintain pluripotency and are karyotypically stable [17]. We also analyzed the hematopoietic and erythrocytic differentiation potential of blood-derived iPSCs by first generating definitive CD34+CD45+ hematopoietic progenitor cells (HPCs) followed by erythrocyte production ex vivo. In the first step, we used an improved method of forming individual embryoid bodies (EBs) followed by hematopoietic differentiation (Fig. 1A), under a feeder-free and serum-free condition previously described [17]. Many hematopoietic cells released from EBs to culture medium by day 11–14 (Fig. 1B). We found that 55–65% of the cells harvested from culture suspension co-expressed CD45 and CD34, characteristic phenotypes of definitive HPCs (Fig. 1C). Compared to the input number of iPSCs, this was >3-fold expansion (Fig 1D).

Next, the harvested cells from culture suspension at day 14 after EB formation or the purified CD45+CD34+ cells were expanded in erythroid differentiation (ED) culture in the presence of SCF, EPO, IL-3 and holo-transferrin (Step II in Fig. 1A). After 10 days, the total cells expanded ~40-fold (Fig. 1E), turned reddish gradually (Fig. 1F), expressed erythroblast markers such as CD36 and CD235a (Glycophorin A) and CD45 (not shown) at day 9–10 (Fig. 1G), and displayed erythroblast morphology (Fig. 1H). The erythroblast-like cells were allowed to terminally differentiate in culture with EPO, heparin, insulin and a high concentration of holo-transferrin (Step III in Fig. 1A). We also found that adding human plasma, which enhanced erythrocyte enucleation of erythroblasts derived from primary CD34+ cells [22], also stimulated terminal differentiation of human iPSC-derived erythroblasts as reported recently [23, 24]. Upon terminal differentiation, the cells expanded for another 10-fold (>3 cell divisions) after 7–8 days before ceasing cell proliferation. The differentiated cells at this stage turned reddish, lost CD45 expression in the majority of cells (>98%), continued CD235a expression, and gained the expression of a maturation marker Band3 in both nucleated and enucleated (~10.6%) cells (Fig. 1I to 1L). In addition to the Band3+ and CD235a+ erythrocytes (>98%), we consistently observed a small population (0.2% to 1.6%) of nucleated cells in the harvested suspension cells after 6–8 days of terminal differentiation that express CD45, but lack CD235a and Band 3 expression (Fig. 1K). Morphological staining suggests that these residual nucleated CD45+ cells resemble monocytes or macrophages (data not shown). Using quantitative RT-PCR analysis, we observed that the *HBB* gene expression in erythroblasts (ED10) and erythrocytes (TM8) from either TNC1 iPSCs or CB CD34+ cells under the same improved culture condition, while the *HBG* gene expression is ~10–fold than *HBB* (Fig. 1N). We further confirmed that enucleated cells expressed hemoglobin as stained by benzidine (Fig. 1O). Similar data were obtained using the BC1 iPSC line (Supplemental Fig. S1), with an enucleation rate of 4.7% ± 2.8% (n=21) and producing erythrocytes that express HBB as well as HBG proteins. Thus, we demonstrated that we can generate a population of human erythrocytes from blood cell-derived iPSCs using an improved (free-free and xeno-free) culture condition.

Efficient and specific targeting of the SCD HBB locus in human iPSCs derived from blood cells

Previously, we and others have used a pair of ZFNs or TALENs to target the SCD point mutation in human iPSCs and cancer lines [8–13]. Several groups have achieved HR-mediated gene correction of the SCD *HBB* allele in human iPSC lines that were derived from fibroblasts using genome-inserting vectors, although the HR efficiencies were typically low [8, 9, 13]. To improve the *HBB* gene targeting in blood-derived SCD iPSCs that were generated by transient plasmid expression and showed better erythroid differentiation (Fig. 1), we used the CRISPR/Cas9 endonuclease system [25]. Three different guide RNAs (gRNAs), targeting the *HBB* DNA sequence between the SCD mutation and an intended targeting insertion in intron 1, were made (Supplemental Fig. S2). In the preliminary studies using the 293T cell lines, guide gRNA-a and gRNA-c showed a high level of targeting at the *HBB* sequence (data not shown), and therefore were used for subsequent analyses. Because the gene targeting efficiency in human iPSCs is >10-fold lower than in 293T cells by either HR or NHEJ mechanisms, we employed a Next-Gen sequencing (MiSeq)-based method (Fig. S2C) as previously described [18, 25]. The level of CRISPR/Cas9 stimulated NHEJ events that often result in mis-repairs and indels can be measured as mutation (indel) rates (Fig. S2C). We also evaluated efficiency and specificity of gRNA in conjunction of Cas9 at targeting the endogenous *HBB* locus, in comparison with the ZFNs and TALENs published previously [8–10]. Although the ZFNs and TALENs targeted efficiently at the *HBB* reporter transgene and in 293T cells at the endogenous *HBB* locus, they were significantly less efficient in human iPSCs than gRNA-a/Cas9 in making a DSB that triggers NHEJ-mediated indel formation (Fig. S2D). Using the same assay, we also examined levels of off-targeting mediated by either gRNA-a or gRNA-c at the nearby HBD locus (Fig. S2E), which is highly homologous to the *HBB* sequence (Fig. S2B). Additionally we examined 14 bioinformatically predicted off-targets of gRNA-a (Fig. S2F–G). We found that gRNA-a is highly specific in both human iPSCs (Fig. S2F) and to a lesser extent in 293T cells (Fig. S2G).

Next, we targeted the endogenous *HBB* locus in SCD iPSCs, by using the Cas9 and the gRNA-a that targets *HBB* 20-bp downstream to the β^s mutation (Fig. S2B and Fig. 2A). The TNC1 iPSCs containing the homozygous β^s mutation were transfected with the donor plasmid (Fig. 2B), gRNA-a, and Cas9 vector. The donor vector provides the wild-type HBB DNA to correct the β^s point mutation and a puromycin-resistance selection cassette that is inserted into the *HBB* intron 1 and useful in selecting a HR product (Fig. 2A). The drug-resistant iPSC colonies were picked and screened for a HR product by PCR amplification of genomic DNA using two pairs of primers (Fig. 2C). Each pair has one primer sequence inside the puromycin selection cassette (TP1R and TP2F) and the other at the genomic sequence outside the homologous arms (TP1F and TP2R) of the donor plasmid (Fig. 2F; Fig S2D–E). Of the ten clones first screened, four (40%) showed HR detected by both pairs of primers (Fig. 2F). More are shown in Fig. S3D–E. The targeted clones that were positive for both primer pairs were selected for further analysis (Table 1).

We further confirmed the correction of the SCD mutation in targeted and integrated allele by various methods, in 12 out of the first 24 clones that scored positive for at least one targeted

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

insertion (Table 1). We also eliminated clones (such as SC2) that have a copy of undesired insertion of the donor vector. Among the four clones that showed at least one allele of targeted insertion and no sign of random vector insertion in the genome, we determine the presence and nature of the other allele, e.g., the un-intended or non-integrated allele in targeted TNC1 iPSCs (Fig. 2G). These 4 clones (SC6, SC12, SC15 and SC20) were heterozygous: each has one copy of the targeted insertion and one copy of the HBB locus similar to the wild-type or β^S *HBB* allele. We sequenced the 364-bp PCR product of the non-integrated allele from the 4 clones to examine if there was any genetic modification. We found that SC15 has a single nucleotide insertion in the HBB exon 1 (Fig. S4A) in the gRNA-a recognition site. This insertion introduced a pre-mature stop codon in exon 1, so the predicted protein product is ~2.3-kD if it is ever produced. The clone SC20 has no genetic modification in the non-integrated *HBB* allele in this genomic region (Supplemental Fig. S4B). In our case, the disruption of the second β^S HBB allele by the same Cas9/gRNA-a that also achieved a desired HR-mediated targeting is actually advantageous, because only the corrected allele that converts to the wild-type *HBB* gene can make a full-length HBB protein from iPSC clones such as SC15. We focused on the SC15 iPSC clone for subsequent analyses.

Because the PGK-puromycin gene selection cassette may interfere with expression of the corrected *HBB* allele [8], we excised the loxP-flanked PGK-puromycin cassette using transient transfection of a Cre-expressing plasmid [19]. We selected SC15 for Cre excision, and picked 9 individual clones to screen for excision of the LoxP DNA segment (Fig. 2H). Because the Cre excision will leave a 118-bp loxP-containing “footprint” sequence in the intron 1 of HBB locus, genomic PCR using the same primers that amply the 364-bp endogenous HBB allele (Fig. 2G) produced an additional and larger 482-bp product after Cre-mediated excision (Fig. 2H). We sequenced the 482-bp PCR product of several excised clones and confirmed the correction of SCD mutation and insertion of 118-bp “footprint” sequence in the first intron, but no other extra modifications (Supplemental Fig. 4C).

Production of human erythrocytes from corrected iPSC clones and parental TNC1 iPSCs

Using the three-step feeder-free and xeno-free procedure for differentiating human iPSCs to erythrocytes that we recently developed (Fig. 1A), we evaluated erythrocytes production of gene corrected iPSC clones such as SC15 and SC15-Cre2, in comparison with the parental TNC1 iPSCs containing the homozygous β^S mutation. The SC15-Cre2 clone behaved similarly to the TNC1 iPSCs at various stages of differentiation. After the terminal differentiation (Fig. 3A), the cells gradually lost the markers of CD45 and CD49d, maintained CD235a expression, and gained the expression of Band3 as previously described for erythrocytes from primary CB CB34+ cells [22]. Among the mature erythrocytes that are Band3+ but CD45- and CD49d-, ~5–8% of cells lacked DNA staining by DRAQ5 (Fig. 3A and 3B). Many of the enucleated cells remained metabolic active with an intact cell membrane, because they were positive when probed by Calcein AM (a fluorogenic substrate of cellular esterases) (Fig. 3C). The enucleated cells (more abundant at day 8) also expressed hemoglobin as stained positive for benzidine (Fig. 3D).

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

Production of corrected HBB proteins in erythrocytes derived from genome-edited SCD iPSCs

We specifically measured the level of corrected HBB gene expression and protein in *ex vivo* generated erythrocytes (TM8) from the gene-edited SC15-Cre2 clones, in comparison to the parental TNC1 that expressed the β^S protein (Fig 4). The RT-PCR primers and the HBB antibody would not distinguish the wild-type and β^S forms, allowing us to quantitatively compare the level of HBB mRNAs or proteins in erythrocytes from the corrected SC15-Cre2 or parental TNC1 iPSCs. By RT-PCR, the level of HBB mRNA in SC15-Cre2 after terminal differentiation (TM8) increased further over those at earlier stages, but appeared >10-fold lower than those in erythrocytes from CB or TNC1 iPSCs (Fig. 4A). By Western blot, the HBB protein level in the erythrocyte culture from the SC15-Cre2 iPSCs is comparable to that from the parental TNC1 iPSCs (Fig. 4B). The HBB protein level in the erythrocytes derived from the corrected and excised SC15-Cre2 iPSCs appeared to be higher than that from the SC15 iPSCs, the genome-edited clones without the removal of the PGK-puromycin selection cassette located in the *HBB* intron 1. The data corroborated with the early observations that it is important to remove the expression cassette for selection even if it is located in an intron [26].

We also measured the HBB and HBG proteins in the native form of hemoglobin tetramers in individual cells by flow cytometric analysis (Fig. 4C). We detected >85% and >98% of cells expressed HBB and HBG proteins, respectively. However, the level of HBB proteins appears ~10-fold lower that that of HBG (Fig. 4C): nearly all the HBB-expressing cells also express HBG (Supplemental Fig. 1I).

We also measured the functionality of O_2 binding by hemoglobin produced in the erythrocyte generated from iPSCs, in comparison with primary CB erythrocytes (Fig. 4D). The iPSC-generated cells have an O_2-binding curve similar to that of cord blood, except that the affinity is slightly higher (p50 is 16.6 in SC15-Cre2 vs. 22.9 for CB). This may reflect the fact that HbF (containing HBG), which has a higher affinity for oxygen, are more abundant in the erythrocytes derived the iPSCs.

Discussion

In this study, we demonstrate that the sickle point mutation in the *HBB* allele in patient-specific iPSCs can be corrected efficiently by genome editing, which allows the expression of normal HBB proteins in erythrocytes after hematopoietic differentiation of gene-corrected iPSCs. This study has broad implications for studies using human iPSCs for disease modeling, and for developing combined gene and (stem) cell therapies. First, this study corroborates with other recent studies showing that CRISPR/Cas9 can be both efficient and specific in human iPSCs for gene targeting, even for correcting a point mutation [14, 27–29]. Second, the CRISPR/Cas9-mediated genome editing has little adverse effect on the integrity of targeted iPSCs, since they can differentiate into mature progeny such as enucleated erythrocytes that express the corrected *HBB* gene in SCD iPSCs. The level of HBB protein expression is similar to that of erythrocytes differentiated from untargeted iPSCs (Fig. 4).

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

Our study showing HBB protein expression in human erythrocytes differentiated from corrected iPSCs would not have been possible, if the HBB mRNA expression and protein synthesis had remained at low levels as previously observed [8, 9, 30–35]. Previously, HBB protein expression was not detected in erythrocytes generated from human iPSCs or ESCs ex vivo, unless transgene expression promoting erythroid formation [36–38] or co-culture with mouse stromal cell lines such as OP9 or MS5 were used [24, 33, 39]. Compared to these pioneering studies, we achieved much higher levels of HBB mRNA expression under the culture condition for producing erythrocytes generated from iPSCs such as TNC1 and their corrected progeny (Figure 4). In addition, we also observed the presence of enucleated erythrocytes under the feeder-free and xeno-free culture condition, although the percentage was not high (typically 5–10%) compared to that derived from CB CD34+ cell cultures (30% or higher as reported).

The much improved erythrocyte maturation and HBB protein expression from human iPSCs that we reported here could be due to at least the following two possibilities, which are not mutually exclusive. The first one is that we improved culture condition for terminal differentiation: we added human plasma that is known to promote enucleation, and omitted dexamethasone that promotes stressed erythropoiesis and fetal globin expression. The second one is that we used blood-derived iPSCs that have some residual epigenetic memory inherited from parental cells (TNC1 was derived from PB erythroblasts and BC1 was from adult BM hematopoietic cells). This notion is also supported by a recent study showing that blood-derived iPSCs tend to have better erythroid differentiation potential than fibroblast-derived iPSCs [37]. Together, these studies provide additional strong evidence that residual epigenetic memory found in these blood-derived iPSCs [40–42] favors differentiation back to erythrocytes, especially when the differentiation condition is still sub-optimal. According to this notion, blood MNC-derived iPSCs are a better choice for efficient erythroid differentiation than fibroblast-derived iPSCs and human ESC lines (especially those in the NIH registry that are derived some years ago and in high passage numbers). It is of note, however, that the fibroblast-derived iPSCs could generate enucleated cells and express the HBB proteins under enhanced conditions [23, 24], even though at an efficiency lower than that from blood-derived human iPSCs as we report here. We predict that with improved differentiation conditions, the origin of human iPS cells will be even less critical to the efficient formation of erythrocytes.

Under the current culture conditions, however, the level of HBB expression (at both mRNA and protein levels) is still >10-fold lower than that of the HBG. This may explain the fact that we and others did not observe sickling or defect in erythrocytes generated from iPSCs derived from SCD patients [23]. The high-level of HBG protein may prevent the sickling of $\alpha_2\beta^s{}_2$ complexes, especially under culture conditions with a normoxic level of O_2. In the future, human differentiated erythrocytes generated ex vivo from human iPSCs (with or without genome editing) should also be tested using improved immune-deficient mice and conditioning, to examine in vivo properties of human erythrocyte in the circulation of mouse models.

For future therapeutic uses, it is desirable to correct at least one of the β^s HBB allele in the iPSCs derived from SCD patients, before the iPSC-derived HPCs or erythrocyte can be used

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

for autologous cell transplantation or transfusion. In addition to achieving the elusive objective to develop a robust and reproducible method for generating transplantable HPCs [43, 44], we could also use erythrocytes generated from patient-specific iPSCs, with or without genome-editing to correct the underlying genetic defect, for transfusion medicine. The enucleated erythrocytes generated from iPSC lines, which could be further irradiated to block DNA replication, may have less risk than other nucleated progeny in causing cancers [45–47]. We also envision that we could generate genetically modified erythrocytes from genome-engineered iPSCs, for providing a source of functionally enhanced erythrocytes for cell therapies, not just a source of replacement in transfusion medicine [47]. Future studies are warranted to test efficacy and safety of erythrocytes from genome-edited iPSCs in preclinical models and in clinical trials.

Summary

In this study, we used the human SCD model and demonstrated that a point mutation could be corrected in patient-specific iPSCs by genome editing, which allows the expression of the corrected gene after differentiation into biologically relevant cells. Our result is a significant step towards the goal of generating gene-edited and functionally repaired or enhanced cells after genome editing of patient-specific iPSCs and possible other stem cell types, for disease modeling and future gene therapies.

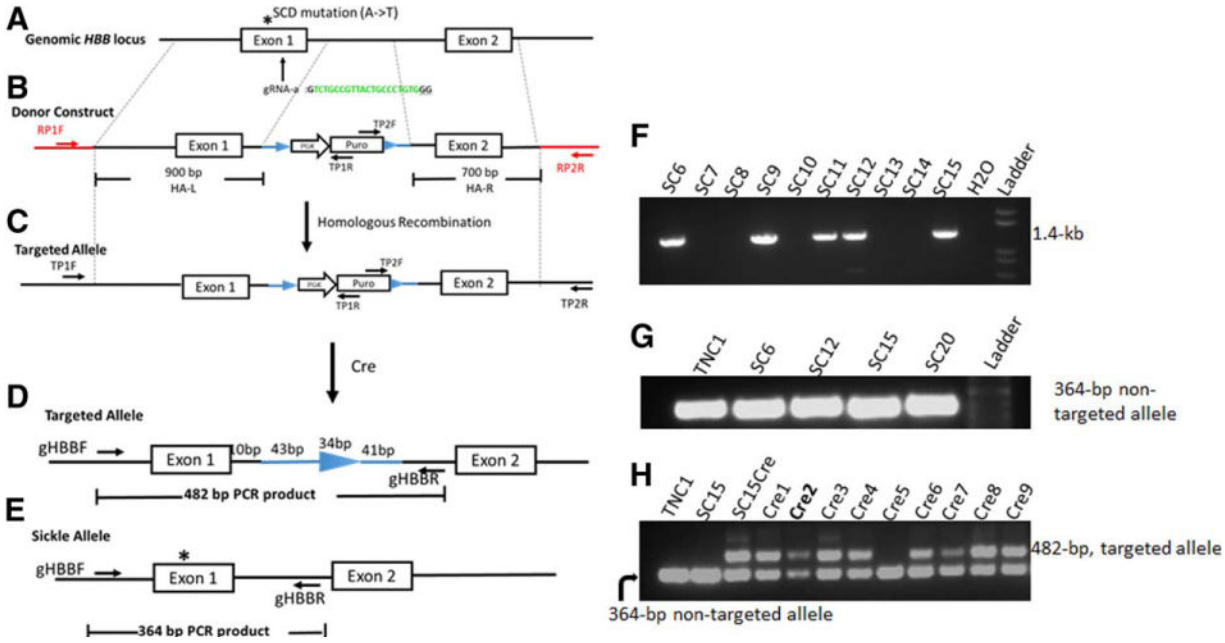

Figure 2. A strategy for site-specific correction of the sickle cell disease mutation in the *HBB* locus using homologous recombination stimulated by Cas9 and a guide RNA

(A) The *HBB* genomic structure (first two exons), and locations of SCD mutation and gRNA-a targeting *HBB* exon 1. (B) The gene-targeting donor MGH vector with 2 homology arms (900-bp left arm and 700-bp right arm) introduces a homologous recombination (HR) template for T-to-A replacement in the sickle allele and a loxP-flanked drug-selection cassette PGK-puromycin (puro) to be inserted into the *HBB* intron 1. (C) Targeted allele following HR with corrected SCD mutation and inserted PGK-puro cassette in intron 1. We used 2 PCR primers (black arrows: TP1F/TP1R and TP2F/TP2R) for initial screening of targeted insertion (TI) indicative of correct HR. (D) Cre-mediated excision removes the PGK-puro cassette and leaves one copy of the loxP DNA (34-bp) and 84-bp linker DNA in *HBB* intron 1 of the corrected allele. Genomic DNA PCR with primers gHBB-F/gHBB-R produces a 482-bp product from the targeted allele of "Cre" clones. (E) Genomic DNA PCR with primers gHBB-F/gHBB-R produces a 364-bp product from the unintended sickle allele of original and "Cre" clones. (F) PCR screening for targeted integration (TI) by the primer set TP2F/TP2R that detect 3′ TI (1.4-kb). (G) Genomic PCR using the primer set gHBB-F/gHBB-R that amplify the unintended (sickle) allele but not the targeted allele (it is too long to be amplified by PCR with a short extension time) before Cre-mediated excision. (H) PCR screening of Cre-mediated excision of SC15 clones using primer set gHBB-F/gHBB-R. The 482-bp PCR product emerged after Cre-excision as shown in (D).

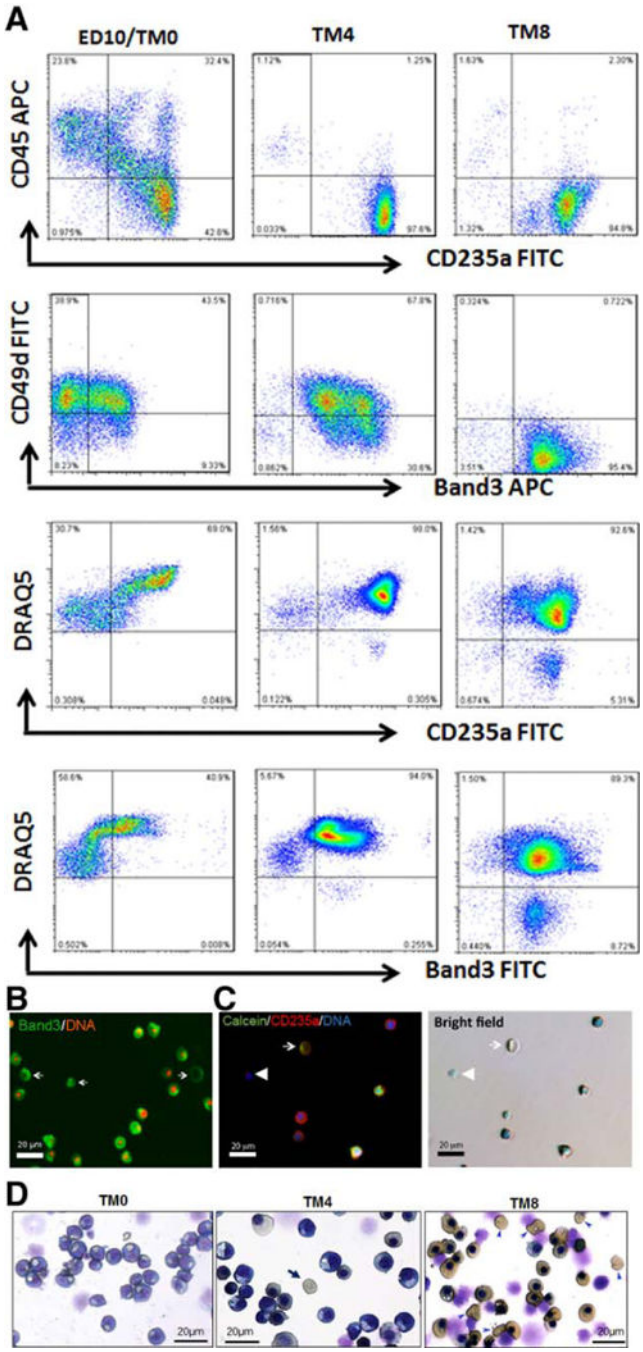

Figure 3. Erythroid terminal maturation of erythroblasts that generated from SC15-Cre2 iPSC clone

The phenotypes of erythroblasts (ED10) from SC15-Cre2 are similar those from TNC1 and BC1 iPSC lines. (A) Cell surface marker expression dynamics during 8 days of terminal maturation (TM). By day 8 of TM (TM8), nearly all the cells expressed CD235a and Band3, and lost the expression of CD45 and CD49d. About 9% of CD235a+ and Band3+ cells were stained negative for DNA by DRAQ5. (B) Fluorescent image of TM8 cells showing Band3 cell surface expression and ~10% lacking DNA staining (red). (C) Fluorescent images of TM8 cells showing cell surface expression CD235a in enucleated cells (lacking blue DAN

staining) that are metabolically active based on Calcein AM staining (green, by arrows). (D) Histology staining and morphology of cells after terminal maturation at day 0 (ED10), day 4 (TM4) and day 8 (TM8) after Wright-Giemsa (blue) and benzidine (brown) staining. Enucleated and hemoglobinized cells are easily identified (arrow). Scale bar: 20μm.

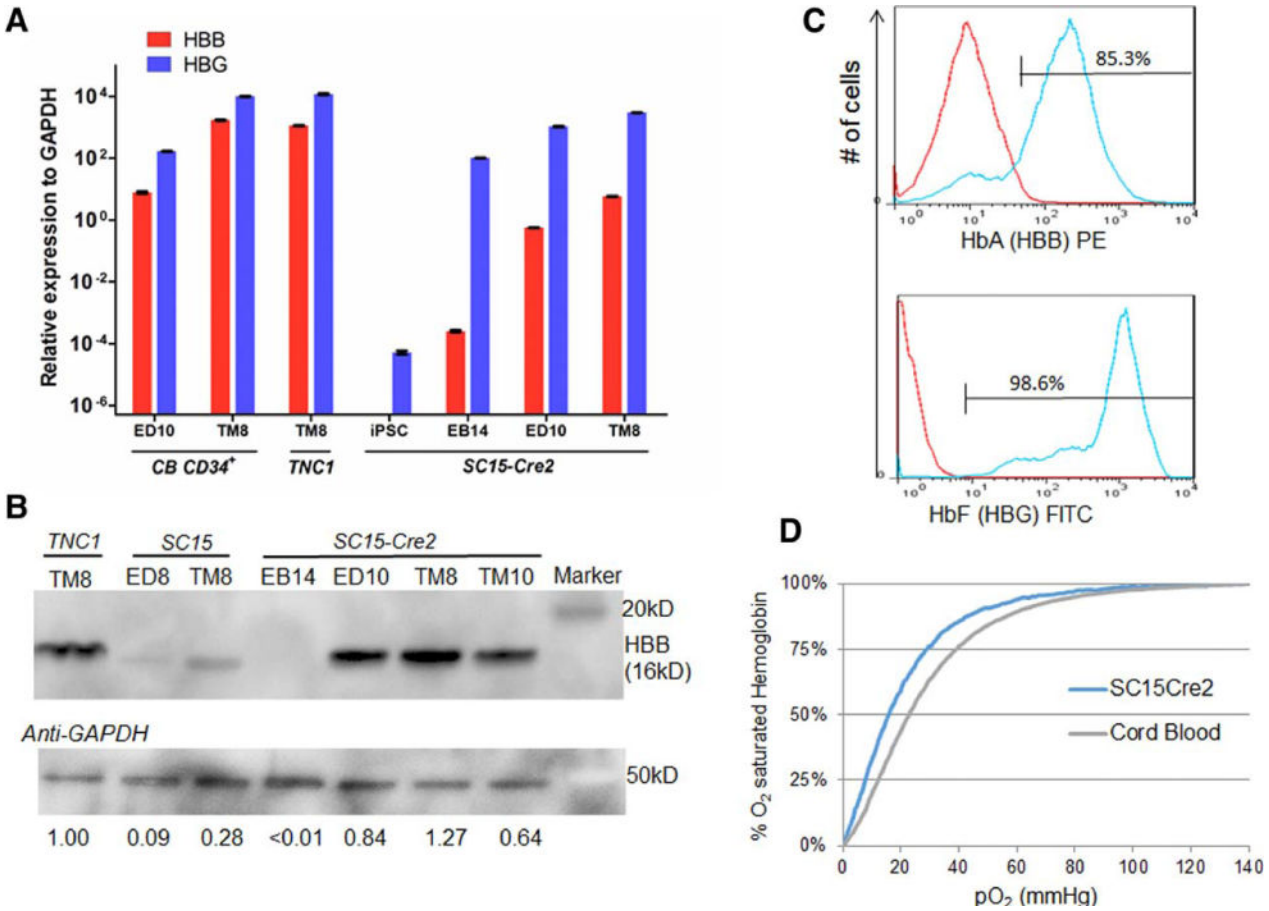

Figure 4. Analysis of globin gene and protein expressions the corrected erythrocytes, and their function

(A) Quantitative RT-PCR analysis of *HBB* and *HBG* gene expression in iPSCs, after hematopoietic differentiation (EB14), erythroid differentiation (ED10) and terminal maturation (TM8) from SC15-Cre2 and parental TNC1 iPSCs and a control of cord blood (CB) CD34+ cells. (B) Western blot analysis of adult hemoglobin beta (HBB) protein level during the differentiation of iPSC clones before and after correction and excision. The relative levels of full-length HBB proteins normalized to the GAPDH control are also indicated. (C) FACS analysis of intracellular adult and fetal hemoglobin protein expression of maturated erythrocytes generated from SC15-Cre2 iPSC clone. (D) Oxygen affinity curves of erythrocytes from SC15-Cre2 after terminal maturation and a cord blood control as measured by a Hemox Analyzer.
