

22 Germany, France and North of Spain. North of this line, floods are projected to decrease in most of
23 Finland, NW Russia and North of Sweden, with the exception of southern Sweden and some coastal
24 areas in Norway where floods may increase. The results concerning extreme droughts are less robust,
25 especially for drought duration where the spread of the results among the members is quite high in
26 some areas. Anyway, drought magnitude and duration may increase in Spain, France, Italy, Greece, the
27 Balkans, south of the UK and Ireland. Despite some remarkable differences among the hydrological
28 models' structure and calibration, the results are quite similar from one hydrological model to another.
29 Finally, an analysis of floods and droughts together shows that the impact of a +2°C global warming will
30 be most extreme for France, Spain, Portugal, Ireland, Greece and Albania. These results are particularly
31 robust in southern France and northern Spain.

32

33 1. Introduction

34 In Europe, freshwater resources are of crucial importance for many sectors including agriculture,
35 hydropower generation, cooling water for power plants and domestic and industrial water supply. At
36 the same time, water can have a direct impact on safety and livelihoods through floods that can lead to
37 disastrous human and economic losses (e.g. the 2013 floods in Central Europa resulted in a loss of more
38 than €12bn¹). During the last decades, several studies have underlined that water resources and
39 especially river flows have had strong variations across Europe (Kovats et al., 2014) due to climate,
40 water extractions and land use change (Sterling et al., 2013). Even if the relative share of these three
41 driving factors is difficult to assess over the past, it is clear that the strong climate changes expected in
42 Europe for the 21st century will have a significant impact on river flows (Jiménez Cisneros et al., 2014).

¹ <http://www.munichre.com/en/media-relations/publications/press-releases/2013/2013-07-09-press-release/index.html>

43 Thus, a first step in order to make relevant mitigation and adaptation policies is to develop a clear
44 picture of the potential future stream flows extremes.

45 Changes in river flow extremes at a +2°C global warming are currently of central interest as this is
46 the global target defined by policymakers to lower international greenhouse gases emissions (European
47 Commission, 2007). Therefore, in this study, we do not select a specific time period; rather we focus on
48 defining the hydrological impacts in a world with a +2°C global warming relative to pre-industrial levels
49 (Vautard et al., 2014). Describing the impacts of a +2°C global warming on topics such as water
50 resources, agriculture or infrastructures is the main aim of the FP7 project IMPACT2C under which this
51 study was conducted.

52 Future changes in hydrological extremes are still highly uncertain. There is a general consensus that
53 in most part of the world climate change will result in more rainfall extremes (IPCC, 2012). However, to
54 what extent this will affect hydrological extremes is still highly uncertain and differs from region to
55 region. To address this uncertainty many previous studies have used multiple climate models to force a
56 single hydrological model (e.g. Dankers and Feyen (2009); Feyen et al. (2009)). However recent work,
57 mainly at global scale, has shown that not only the choice of the climate models affect future change in
58 hydrological extremes: different hydrological models give sometimes very different results too
59 (Haddeland et al. (2011); Schewe et al. (2014); Prudhomme et al. (2014); Dankers et al. (2014)). Many
60 multiple climate and hydrological models impact assessments have used global climate models. These
61 global climate models tend to have significant biases in the representation of precipitation extremes.
62 The aim of this study is to improve the assessment of hydrological extreme impacts at the European
63 continent scale including a better description of uncertainties through the use of multiple hydrological
64 models and state-of-the art climate projections from the high-resolution CORDEX project. We first focus
65 on the skill of each hydrological model to simulate extreme floods and hydrological drought (section 3.1)

66 and we next assess the impact that a +2°C warming would have on meteorological variables which are
67 relevant for flood and drought generation (section 3.2) and on extreme flows (return periods are 10 and
68 100 years, section 3.3 and 3.4). We finally summarize the results about flood magnitude, droughts
69 magnitude and drought duration for twelve European cities and with a final assessment on which
70 European region will be the most affected by extreme flows at +2°C warming.

71

72

73 2. Material and data

74

75 2.1 Data

76

77 2.1.1 Forcing data

78 This study uses a sub-ensemble from the latest (as of 2014) ensemble of high-resolution,
79 dynamically downscaled daily climate simulations from CMIP5, 5th Coupled Model Intercomparison
80 Project and CORDEX, A Coordinated Regional Downscaling Experiment (Jacob et al., 2014). The 11
81 ensemble members were chosen to be representative of the larger ensemble and consist of 5
82 GCM/RCM combinations and 3 Representative Concentration Pathways (RCPs) (Moss et al. (2010))
83 (Table 1). One of the main differences with previous impact studies is that rather than focusing on a
84 future time slice, change is quantified at the 30-year period when each driving GCM reaches +2°C in
85 global mean temperature relative to pre-industrial levels (1881-1910, Vautard et al. (2014)). Thus, the
86 ensemble is a representation of a world where greenhouse gas emissions have caused a +2°C global
87 warming. The climate variables were regridded to a 0.25° resolution grid. As climate models are known
88 to be affected by some biases that can clearly affect the results (Chen et al., 2013), daily climate

89 variables (precipitation, maximum, minimum and average temperature, dew point temperature,
90 shortwave and longwave downward radiations) were bias-corrected using quantile mapping (Themeßl
91 et al. (2011), Themeßl et al. (2012) and Wilcke et al. (2013)). Bias-correction was made using the E-OBS
92 gridded observational dataset (Haylock et al., 2008) as a reference. These bias corrected data were then
93 used to run the three hydrological models (1971-2100). Climatic changes were subsequently assessed by
94 comparing the +2°C period with the baseline period 1971-2000 (Table 1).

95 2.1.2 Observed discharge data

96 In order to assess the skills of the hydrological models in representing specific floods and
97 droughts, we used 428 discharge stations over Europe selected from the Joint Research Center database
98 which gathers several sources like the Global Runoff Data Centre (2013) data or other publicly available
99 datasets (e.g., HYDROBanque, CEDEX, Norwegian Water Resources and Energy Directorate, National
100 river flow archive, Waterinfo.be , eHyd). The original database was filtered to include only stations with
101 data for the time period 1971-2000 and with no day with missing data in order to not to miss any
102 extreme discharges. Model performance was validated using the median of the values from each
103 hydrological model forced by the ensemble of climate models over the 30 years control period.

104

105 2.2 Summary of models

106 Three pan-European hydrological models were used to simulate daily discharge: Lisflood (Burek
107 et al., 2013), E-Hype (Donnelly et al., 2015) and VIC (Liang et al., 1994). The models differ in both
108 complexity of process description, input data and setup. For example, differences include spatial
109 resolution (one model is subbasin rather than grid based), description of evapotranspiration and snow
110 processes, the number of soil layers and depth assumptions and the calibration procedure. A summary
111 of these models can be found in the Appendix and more details are available in Greuell et al. (2015).

112 Because each of these models has a different output resolution (and in the case of E-HYPE, a high-
113 resolution subbasin rather than grid output), the output from each model was regridded to a
114 comparable 0.5°*0.5° grid.

115

116

117 2.3 Methodology for extreme value analysis

118

119 2.3.1 High flows

120 We focus here on the discharge magnitude of the 1 in 10 and 1 in 100 year floods (QRP10 and
121 QRP100). These two return periods were chosen as the first one represents an extreme event occurring
122 often enough that it is remembered by individuals and communities and the other one is a standard
123 value used in some countries to design flood protection. In order to compute QRP10 and QRP100 for
124 each pixel of the grid, we followed a typical extreme value analysis fitting methodology (see e.g. Roudier
125 and Mahé (2010)). First, the daily maximum discharge was selected for each year of the 30 years long
126 period, then fitted a Generalized Extreme Value (GEV) distribution using the L-moments and finally, we
127 calculated QRP10 and QRP100 using the fitted function. The goodness-of-fit was also checked using the
128 Anderson-Darling test (at 5%), as recommended by Meylan et al. (2008). For each of the 3 hydrological
129 models, and each of the 11 climate runs, the relative QRP10 and QRP100 change between the +2°C
130 period and the baseline was computed, resulting in a set of 33 relative changes. To describe this set, in
131 this paper the median of all the ensemble members is used (the combined climatological and
132 hydrological model ensemble) rather than the mean, in order to avoid giving excessive weight to
133 potential outliers. The significance of changes is also assessed using a Wilcox test (5% threshold)
134 between future period and baseline. Therefore, in all relative change plots, we set as missing values

135 pixel that do not pass the test. Moreover, those that do not pass the goodness-of-fit test were also set
136 as missing value.

137

138

139

140 2.3.2 Low flows

141 We focus for low flows on the same return periods as for the high flow analysis, following the
142 methodology used by Feyen and Dankers (2009). First the daily discharge time-series is smoothed
143 applying a seven day moving average in order to remove the day-to-day variations and then for the
144 magnitudes of low flows ($Q_{lowRP10}$ and $Q_{lowRP100}$), the lowest smoothed discharge event is selected,
145 every year. For the duration of low flows a threshold approach is used with the 20th flow percentile of
146 the smoothed flow duration curve as threshold. After computing the 20th percentile (for each pixel,
147 projection and hydrological model) we select all the days that have a smoothed discharge value below
148 this 20th percentile and then we compute the duration of each event below that threshold and select the
149 maximum drought duration for each year. Finally, for both drought magnitude and duration, the rest of
150 the methodology is equal to section 2.3.1 (fitting a GEV distribution on each set of 30 values in order to
151 compute $Q_{lowRP10}$ and $Q_{lowRP100}$ magnitude and duration; we also set as missing values pixel that do
152 not pass the Wilcoxon or Anderson-Darling test)

153

154 3. Results and discussion

155

156 3.1 Hydrological model validation and selection for ensemble projections

157 A broad and detailed validation of the hydrological models focusing on average conditions is
158 presented in Greuell et al. (2015). The aim of the validation presented here is to assess the models' skill
159 to simulate specific indicators used in this study. For each hydrological model we therefore assess if the
160 median QRP100 (Q_{low}RP100) computed based on the 11 bias corrected climate runs is close to the
161 QRP100 (Q_{low}RP100) computed with observed discharge data. Results are shown in Figure S1 (see
162 supplementary material) for floods and Figure S2 for low flows. The skills of the three hydrological
163 models are generally better for high than low flows. Lisflood performs slightly better than the other
164 models, according to the Nash-Sutcliffe Efficiency coefficient (NSE = 0.82) and the Root Mean Squared
165 Error (RMSE = 961 m³/s). However, when focusing on the NSE of the logarithmic modeled and observed
166 values (NSE(log), used for extreme values, see Krause et al., (2005)), E-Hype is slightly better than
167 Lisflood. For low flows, Lisflood somewhat overestimates Q_{low}RP100 while the other two models
168 underestimate it. E-Hype has the best performance for low flows (NSE = 0.72, NSE(log)=0.68, RMSE = 75
169 m³/s) compared to Lisflood (NSE=0.54, NSE(log)=0.51, RMSE=95 m³/s) and VIC (NSE=0.38,
170 NSE(log)=0.38, RMSE=112 m³/s).

171 A likely explanation for these differences in performance could be the way these models are
172 tuned to observation data. The Lisflood model is calibrated in individual catchments using a high-
173 resolution (5 km) interpolated observation data set (EFAS-meteo, see Ntegeka et al. (2013)) and default
174 parameters in ungauged catchments. The VIC model uses a general set of parameters applicable
175 anywhere in the model domain, but linked to soil-type and landuse. This parameter tuning was done
176 using a specific forcing dataset described in Nijssen et al. (2001) .The E-HYPE model also uses a general
177 set of parameters, linked to soil-type and landuse. For E-HYPE, these parameters were originally
178 calibrated to a small set of representative gauged basins for each soil and land use using a corrected
179 ERA-INTERIM forcing data set (see Donnelly et al. (2015)), but for this study an evapotranspiration
180 parameter was slightly adjusted to better balance the model performance with the E-OBS data set. This

181 was deemed important by the E-HYPE modeling team as the climate scenarios were bias-corrected to
182 the E- OBS data set and recent studies have shown that bias-correction and climate impact results can
183 vary between reference observation data sets (e.g. Gutmann et al. (2014)). It is therefore not surprising
184 that overall E-HYPE performs well when forced with data bias-corrected to E-OBS, at least regarding
185 mean discharge. Lisflood is likely to perform better in regions where the E-OBS forcing is not significantly
186 different to the EFAS-meteo data as the other models compromise performance in individual
187 catchments for relatively good performance in multiple catchments using the same parameters. For
188 hydrological extremes, again Lisflood can be expected to perform well in calibration catchments. E-HYPE
189 may outperform VIC for extremes because the representative gauged basins used to calibrate E-HYPE
190 are generally smaller catchments (1000 to 5000 km²) where runoff generating processes dominate over
191 routing and lake processes.

192 Given the variability in model performance for extremes, and perhaps inability of some models
193 to successfully represent these extremes, we suggest to remove for the initial selection the hydrological
194 models that have a NSE and a NSE(log) below 0.5 for the index studied, i.e. QRP100 and QlowRP100.
195 Based on the NSE threshold, an ensemble consisting of results from E-HYPE, Lisflood, and VIC will be
196 used for floods, and Lisflood and E-HYPE for low flows.

197 3.2 Summary of projected changes in meteorological variables pertaining to floods and droughts

198 We first aim at studying here the future evolution of some of the drivers of low and high flow
199 changes. We therefore plot in Figure 1 the projected change in maximum annual snowpack (outputs
200 from the 3 hydrological models) and intense daily rainfall (return period is 10 years, computed using a
201 GEV distribution using the aforementioned methodology for discharge) at +2°C warming. Results show
202 that there is generally a clear decrease in maximum snowpack, reflecting the future warming over
203 Europe. The regions that are less affected like southern Spain or southern Italy are those with currently

204 marginal snowfall. The snowpack decrease is particularly important in Fenno-Scandinavia and the Alps.
205 Intense rainfall events are projected to increase significantly over the whole continent, with no
206 particular spatial pattern, which is consistent with previous studies (Madsen et al. (2014); Rajczak et al.
207 (2013)).

208

209 3.3 Floods (QRP10 and QRP100)

210 For changes in flood magnitude there is a clear North to South gradient, with a strong increase
211 with a strong increase in flood magnitudes south the 60°N line, except for some regions in Bulgaria,
212 Czech Republic, Poland, the western Balkans, the Baltic countries, and southern Spain where no
213 significant changes can be detected (Figure 2). Almost everywhere the increase in 100 year floods
214 (QRP100) is stronger than the 10 year floods (QPR10). Floods are even increasing in areas such as
215 southern Mediterranean where the average discharge is projected to decrease (Greuell et al., 2015).
216 However flood changes are consistent with the extreme rainfall changes south of 60°N (Figure 1). Above
217 the 60°N line, the situation is more heterogeneous with a relatively strong decrease in flood magnitude
218 in parts of Finland, NW Russia and North of Sweden with the exception of southern Sweden and some
219 coastal areas in Norway where increases in floods are projected. Projections of decreasing flood
220 magnitudes are mainly due to the decreases in snowpack in areas where most of the floods are caused
221 by spring snowmelt in combination with rainfall. Increases in flood magnitude in Scandinavia are mainly
222 seen in coastal areas where the rain-fed floods will increase (similar results were found by Vormoor et
223 al. (2015)). Note also that the date of occurrence of annual maximum discharge is expected to be earlier
224 in spring for these areas (Figure S8) while for the rest of Europe, changes are quite limited.

225 Following this reduction in snow-melt floods in Fenno-Scandinavia and according to the
226 decreasing snow pattern shown in Figure 1, it is expected a similar decrease in floods would be expected

227 for the Alps. However, our results shown an increase in floods which is also reported in several other
228 studies (Rojas et al. (2012), Gobiet et al. (2014) or Köplin et al. (2014)). For Switzerland, Köplin et al.
229 (2014) showed that there are large contrasts in the flood regime in the Alps, and snowmelt-floods only
230 occur in a limited part of country. Thus, at a $0.5^{\circ} \times 0.5^{\circ}$ resolution, we are not able to capture some local
231 decreases of QRP10 and QRP100 due to earlier snowmelt. This hypothesis is confirmed by the same
232 analysis performed only for Lisflood at 5×5 km grid that shows for some areas a decrease of QRP100.
233 Secondly, we think that at the $0.5^{\circ} \times 0.5^{\circ}$ resolution over the Alps, there is for most of the pixels a change
234 of flood regime (from snowmelt to rain-fed or mixed snowmelt-rain-fed) rather than only an earlier
235 occurrence of snowmelt floods, leading to a different situation compared to Fenno-Scandinavia. This
236 hypothesis, is supported by Figure S8 which shows (i) a clear reduced number of high flows in June
237 (southern Alps) and July (rest of the Alps) but (ii) no strong increase in earlier spring. A deeper analysis,
238 at a finer scale, is needed to fully understand all the changes in the Alps but beyond the scope of the
239 present paper.

240 Finally, we also provide model-by-model details of these results in the Appendix. Generally, all
241 three hydrological models show the same pattern. However, in Western Europe and the Mediterranean
242 area, Lisflood projects a stronger flood increase than the other models.

243 Even if it is difficult to compare with studies that do not focus on exactly the same set of
244 parameters (climate models, resolution, time period), these results are mainly in line with the recent
245 literature as reviewed by Madsen et al. (2014) (table 3 in their paper). Out of 22 studies dealing with
246 future flood projections in Europe, 4 of them are not directly comparable (they differentiate winter and
247 spring floods), 14 have a global agreement with our findings and 4 give different results. Those four
248 studies include (i) the UK, where Reynard et al. (2010) find few catchments with changes in flood
249 frequency above +20% and Kay et al. (2006), with a limited ensemble of driving climate runs, depict a

250 decrease in flood magnitude in south and east England; (ii) France (Seine and Somme rivers) where
251 Ducharne et al. (2010) cannot conclude on any robust change while we find a significant increase of
252 flood events and (iii) eastern Germany, Poland and southern Sweden where Rojas et al. (2012) find
253 decreases in flood magnitude (this latter study which covers the whole continent agrees however with
254 our results for the rest of Europe). Finally, Dankers et al. (2014) find more contrasted changes for 1 in 30
255 year flood change in Europe using several GCMs and hydrological models: according to these results,
256 floods would decrease in large parts of Europe including Greece, Italy and eastern Europe.

257

258 3.4 Low flows: magnitude and duration

259 Low floods ($Q_{lowRP10}$) are expected to decrease for many countries mainly located in the
260 southern part of Europe: Spain, France, Italy, Greece, the Balkans and also south of the UK and Ireland.
261 This is mainly due to less rainfall (Rajczak et al., 2013) and also higher potential evapotranspiration in
262 some regions like Italy (see Figure S4 and Van Vliet et al., 2015). The duration of these droughts is also
263 increasing (Figure 3, top), especially in Spain. For the rest of Europe, the projections show generally a
264 decrease of drought magnitude and duration. Moreover, changes are not significant in some areas like
265 western Germany or southern Sweden: areas with in-significant changes are larger for low flows than
266 for floods. This reduction of low flow duration and magnitude is mainly caused (i) by less snowfall and
267 more precipitation for areas with low flows in winter and (ii) by a general increase of rainfall for areas
268 with low flows in summer (Vautard et al., 2014). Both hydrological models depict generally the same
269 pattern (see Figure S5 for magnitude). However, for southern Sweden, E-HYPE predicts a small decrease
270 in low-flow magnitudes and Lisflood an increase. Lisflood also tends to predict a significant increase of
271 $Q_{lowRP10}$ across Eastern Europe while for E-HYPE this change is also positive, but not significant (white

272 pixels). The same spatial pattern is found for the 100 year return period (see Figure S6) but the results
273 are generally less significant, see for example southern France.

274 Our results on drought magnitude change are similar to those presented by Forzieri et al. (2014).
275 Focusing on the Q_{lowRP20} they also find for the 2080s a decrease for the Mediterranean and the UK but
276 their findings for Sweden and Norway show an almost uniform increase of low flows although we
277 observed a North/South difference that may reflect the different set of climate models used.
278 Prudhomme et al. (2014), using several climate and hydrological models find a general increase of
279 hydrological droughts over Europe, but they focus on less extreme droughts, and they use RCP 8.5, at
280 the end of the century. At a more local scale, other studies agree with our results. For example, in
281 France, Chauveau et al. (2013) also predict a decrease in low flow magnitude; in Germany Huang et al.
282 (2014) find a decrease of Q_{lowRP50} in 2080 for some areas like the Rhine basin and uncertainty
283 elsewhere.

284 3.5 Uncertainties and summary of the results

285 We analyzed the spread in future change of hydrological extremes using three different
286 parameters (QRP10, Q_{lowRP10} and Q_{lowRP10} duration) and focusing on the 1st and 3rd quartiles of
287 relative changes distribution (Figure 4 and Figure S7). The spread among results is the largest for
288 Q_{lowRP10} duration, depicted in Figure 4 by the inter-quartile range. Despite this spread, the sign of
289 Q_{lowRP10} duration change (positive or negative) is the same for the first and third quartiles for areas
290 with a very large spread (e.g. eastern Europe), i.e. the ensemble of projections somewhat agree on the
291 direction of change, but uncertainty is high. Second, for Q_{lowRP10} magnitude the spread between both
292 quartiles is generally smaller especially in areas like France, the UK, Italy, Portugal and Greece where it is
293 generally below 20%. However, both quartiles do not have the same sign in all these areas (e.g. the UK
294 and Italy) thus depicting projections less robust than for Portugal, south of France or south of Spain.

295 Third, for floods (QRP10) the quartiles agreement is slightly better than for QlowRP10 magnitude except
296 in southern Fenno-scandinavia This general larger uncertainty for low flows is mainly due to (i)
297 differences between the two models in soil moisture and evapotranspiration calculation which are
298 directly related to low flows (Greuell et al., 2015) and (ii) the number of selected models is different for
299 floods (VIC, E-HYPE, Lisflood) and droughts (E-HYPE, Lisflood). Figure S1 and Figure S2 show clearly that
300 the three hydrological models perform similar for floods while for droughts, Lisflood tends to
301 overestimate QlowRP10 and E-HYPE to underestimate it, thus resulting in a larger spread. Moreover,
302 with this kind of assessment using quartiles, the areas with robust results are generally the same than
303 the ones using the Wilcox test, except for some areas like southern Spain where this latter test gives
304 significant changes.

305 In order to detect hotspot regions that will be subject to negative changes in several extreme
306 flow indicators, we combined the floods, drought magnitude and drought duration changes in a single
307 analysis (Figure 5). In most parts of France, Spain, Portugal, Ireland, Greece and Albania, the projected
308 changes under +2°C are generally more extreme. We mean by “more extreme” regions where there is a
309 consistent worsening (of at least 5%) in all the extreme indicators considered for a 10-years return
310 period: more intense floods (QRP10 >+5%), more intense hydrological droughts (QlowRP10<-5%) and
311 longer droughts (QlowRP10 duration > +5%). In parts of Norway, Sweden, Finland and western Russia
312 future warming will see a reduction in both streamflow floods and droughts.

313

314 4. Conclusion

315 Our aim is to make a robust assessment of the impact that a +2°C global warming would have on
316 hydrological extremes (floods, droughts magnitude and duration) in Europe by using an ensemble of
317 eleven high-resolution RCM outputs and three pan-European hydrological models. Results show that

318 such a warming could increase flood magnitudes (10 years and 100 years return period) significantly in
319 most parts of Europe (e.g. about +20% close to London; and Warsaw for QRP10), even for areas where
320 the annual rainfall is expected to decrease in the future, e.g. Spain (about +10% QRP10 close to Sevilla).
321 However, in Fenno-Scandinavia the situation is more contrasted with (i) a large area that is expected to
322 have less intense snowmelt floods, occurring earlier in spring except and (ii) the southern and coastal
323 areas of Fenno-Scandinavia where we predict an increase of rain-fed flood magnitude. In the Alps, even
324 though snowpack is also projected to reduce, floods are expected to increase generally due to a change
325 of flood regime from snowmelt to rain-fed and possibly because the spatial resolution of this study
326 (0.5°*0.5°) potentially hides local decreases of intense snowmelt floods. Moreover, despite some
327 significant differences among the hydrological models' structure and calibration, the results are quite
328 similar from one model to another and consistent with other studies.

329 Future changes in hydrological drought magnitude and duration show contrasting patterns across
330 Europe. Our projections show that for large areas of Italy, France, Spain, Greece, the Balkans, Ireland
331 and the UK, droughts will become more intense and longer mainly due to less rainfall and higher
332 evapotranspiration, in some areas. The sign of these changes is particularly robust in southern France,
333 parts of Spain, Portugal and Greece. For the rest of Europe changes in droughts are not significant or
334 there is a reduction of droughts length and magnitude, especially in northern Fenno-Scandinavia and
335 Western Russia where the sign of the changes is also very robust.

336 Our results show that for a significant part of Europe there will be a clear intensification of the
337 hydrological cycle resulting in both increases in droughts and floods. Extreme flows will be particularly
338 harmful in Spain, Greece, France, Ireland and Albania: it is thus urgent to integrate these future changes
339 for policy making in water resources management and flood protection design.

340

341 **Acknowledgments**

342 The authors would like to thank the FP7 project IMPACT2C and all the contributing members for funding
343 this study and providing climate data. Moreover, we thank Goncalo Gomes from JRC for his help with
344 observed discharges and Alessandra Bianchi for GIS support. We finally thank three anonymous
345 reviewers for their helpful comments.

525 **A1. Summary of models**

526 • **E-HYPE**

527 The E-HYPE model (Donnelly et al., 2015) is a pan-European application of the Hydrological
528 Predictions for the Environment (HYPE, Lindström et al. (2010)) which simulates hydrological variables in
529 more than 35000 sub-basins (median size 200 km²) across Europe. A modified Hargreaves-Samani
530 equation using daily minimum and maximum temperature and a time constant radiation that is
531 assumed to vary with latitude is used to compute evapotranspiration. Snow melt is calculated using a
532 degree day method. In HYPE evapotranspiration, snow and runoff generation calculations are made for
533 hydrological response units (HRUs) representing unique land use and soil type combinations and
534 consisting of up to three soil layers down to 2.5 m. Each sub-basin may consist of any number of HRUs.
535 The model is forced by daily precipitation and temperature and then calculates flow paths in the soil
536 based on snow melt, evapotranspiration, surface runoff, infiltration, percolation, macropore flow, tile
537 drainage, and lateral outflow to the stream from soil layers with water content above field capacity.
538 HRUs are connected directly to the stream and act in parallel. The groundwater level in each HRU is
539 fluctuating, may saturate the soil layers and water may percolate between sub-basins. Routing of the
540 runoff is made along local and main rivers within each sub-basin and includes delay and dampening
541 processes. Lakes, where they exist, cause delay of flow using the weir equation and may be local (off the
542 main river) or main (on the main river).

543

544

545 • **LISFLOOD**

546 LISFLOOD is a GIS-based spatially-distributed hydrological rainfall-runoff model, which includes a
547 one-dimensional hydrodynamic channel routing mode. Driven by meteorological forcing data
548 (precipitation, temperature, potential evapotranspiration, and evaporation rates for open water and
549 bare soil surfaces), LISFLOOD calculates a complete water balance at every daily time step and every grid
550 cell defined in the modelled domain (current resolution is 5*5km). Basically, the model is made up of
551 the following components: (i) a 2-layer soil water balance sub-model, (ii) sub-models for the simulation
552 of groundwater and subsurface flow (using 2 parallel interconnected linear reservoirs), (iii) a sub-model
553 for the routing of surface runoff to the nearest river channel, (iv) a sub-model for the routing of channel
554 flow. The processes that are simulated by the model include snow melt, infiltration, interception of
555 rainfall, leaf drainage, evaporation and water uptake by vegetation, surface runoff, preferential flow
556 (bypass of soil layer), exchange of soil moisture between the two soil layers and drainage to the
557 groundwater, sub-surface and groundwater flow, and flow through river channels. Runoff produced for
558 every grid cell is routed through the river network using a kinematic wave approach.

559

560 • **VIC**

561 The Variable Infiltration Capacity model (VIC) performed calculations on a regular 0.5x0.5
562 degrees lat-lon grid. In VIC each grid cell is subdivided into an arbitrary number of tiles, each covered by
563 a particular vegetation type. Evapotranspiration is computed for each tile, whereas the soil is uniform
564 within each grid cell. The soil consists of 3 layers with a total depth of ~3 m for most cells. The energy
565 balance approach of Penman-Monteith (Shuttleworth, 1993) is used to compute evapotranspiration,
566 requiring a forcing consisting of atmospheric temperature and humidity, wind speed and incoming
567 radiation. Penman-Monteith is also employed to simulate snow melt. VIC owes its name to the

568 treatment of surface runoff, which is generated from net precipitation under the assumption that the
569 infiltration capacity varies within each grid cell according to a one-parameter distribution function
570 (Wood et al., 1992). Routing of the runoff is taken into account with the model described in Lohmann et
571 al. (1996). This model first transports the runoff generated in a grid cell to the main river leaving the grid
572 cell with a unit hydrograph and then routes the water through the river network connecting the cells.
