**Transmission of cytosolic  $[Ca^{2+}]_c$  ([ $Ca^{2+}$ ]<sub>c</sub>) oscillations into the mitochondrial matrix is thought to be supported by local calcium control between IP<sub>3</sub> receptor  $Ca^{2+}$  channels (IP3R) and mitochondria, but study of the coupling mechanisms has been difficult. We established a permeabilized cell model in which the  $Ca^{2+}$  coupling between endoplasmic reticulum (ER) and mitochondria is retained, and mitochondrial  $[Ca^{2+}]_m$  ([ $Ca^{2+}$ ]<sub>m</sub>) can be monitored by fluorescence imaging. We demonstrate that maximal activation of mitochondrial  $Ca^{2+}$  uptake is evoked by IP<sub>3</sub>-induced perimitochondrial  $[Ca^{2+}]_c$  elevations, which appear to reach values >20-fold higher than the global increases of  $[Ca^{2+}]_c$ . Incremental doses of IP<sub>3</sub> elicited  $[Ca^{2+}]_m$  elevations that followed the quantal pattern of  $Ca^{2+}$  mobilization, even at the level of individual mitochondria. In contrast, gradual increases of IP<sub>3</sub> evoked relatively small  $[Ca^{2+}]_m$  responses despite eliciting similar  $[Ca^{2+}]_c$  increases. We conclude that each mitochondrial  $Ca^{2+}$  uptake site faces multiple IP3R, a concurrent activation of which is required for optimal activation of mitochondrial  $Ca^{2+}$  uptake. This architecture explains why calcium oscillations evoked by synchronized periodic activation of IP3R are particularly effective in establishing dynamic control over mitochondrial metabolism. Furthermore, our data reveal fundamental functional similarities between ER–mitochondrial  $Ca^{2+}$  coupling and synaptic transmission.**

## Introduction

Signal transmission between cells of multicellular organisms is often facilitated by privileged communications (e.g. synaptic transmission, paracrine control), which enhance the fidelity of signal recognition by target cells and decrease undesired effects on other cells. The same arrangements are emerging for intracellular signaling, particularly in the case of multifunctional second messengers such as  $Ca^{2+}$  or cAMP (reviewed in Berridge 1997; Houslay and Milligan, 1997; Pawson and Scott, 1997). Cytosolic  $[Ca^{2+}]_c$  ([ $Ca^{2+}$ ]<sub>c</sub>) and cAMP increases mediate the effects of many extracellular stimuli on a diverse range of cell functions, including motility, secretion, metabolism,

gene expression and proliferation. Targeting of the effects of cAMP can be established by localization of cAMP-dependent protein kinase to specific subcellular sites through the interaction of regulatory subunits with A-kinase anchoring proteins (reviewed in Lester and Scott, 1997). Compelling evidence has been presented recently that local spatial and temporal patterns of calcium signals are important in encoding the specificity of cellular responses (Tse *et al.*, 1993; Hanson *et al.*, 1994; Hajnóczky *et al.*, 1995; Dolmetsch *et al.*, 1997; De Koninck and Schulman, 1998; reviewed in Putney, 1998). In many cases, strategic localization of  $Ca^{2+}$  entry/release sites at the subcellular level may account for selective activation of specific processes.

Some calcium signals rely on stimulation of plasma membrane  $Ca^{2+}$  entry channels. In these cases, much larger increases of  $[Ca^{2+}]_c$  can occur in the vicinity of the plasma membrane than the global increases of  $[Ca^{2+}]_c$ , and some  $Ca^{2+}$ -activated responses (e.g. secretion) may depend on the generation of such large localized calcium increases (Silver *et al.*, 1990; Llinás *et al.*, 1992; Marsault *et al.*, 1997; contrary finding in Kim *et al.*, 1997). Other forms of calcium signal rely on mobilization of  $Ca^{2+}$  from intracellular stores to fuel the  $[Ca^{2+}]_c$  increases. Many hormones, neurotransmitters and growth factors stimulate IP<sub>3</sub> formation, which in turn activates  $Ca^{2+}$  release channels located predominantly in the ER. Calcium signals driven by IP<sub>3</sub> receptors were described first as global increases of  $[Ca^{2+}]_c$ , which were often manifested in the form of frequency-modulated  $Ca^{2+}$  oscillations propagating throughout the cell as calcium waves (reviewed in Cobbold and Cuthbertson, 1990; Berridge, 1993; Petersen *et al.*, 1994; Clapham, 1995; Thomas *et al.*, 1996). Such global  $[Ca^{2+}]_c$  signals have been suggested to result from spatially and temporally coordinated recruitment of subcellular release units (Parker *et al.*, 1996; Bootman *et al.*, 1997). It is important to note that the cytoplasm is a relatively poor passive conductor for  $Ca^{2+}$  increases due to the large amount of  $Ca^{2+}$  buffering proteins, and conduction of IP<sub>3</sub>-induced  $Ca^{2+}$  signals is an active, self-propagating process. Recently, elementary events of IP3R-driven  $[Ca^{2+}]_c$  signals have been resolved as  $Ca^{2+}$  ‘sparks’, ‘puffs’ and ‘blips’. These are believed to represent  $Ca^{2+}$  responses associated with activation of one or a few IP3Rs (Yao *et al.*, 1995; Bootman and Berridge, 1996; Parker and Yao, 1996; Reber and Schindelholtz, 1996; Horne and Meyer, 1997). During the brief periods of channel opening at the sites of the elementary  $Ca^{2+}$  release events, the local concentration rises to high levels before it dissipates into the surrounding cytoplasm. Within the microdomain of the elementary event, the high levels of  $Ca^{2+}$  may yield rapid and spatially limited changes in the activity of  $Ca^{2+}$ -regulated processes, which are less sensitive to  $Ca^{2+}$  than the processes controlled by the global  $Ca^{2+}$  signals.

Calcium is a well-known activator of mitochondrial dehydrogenases (for review see McCormack *et al.*, 1990) and so  $\text{Ca}^{2+}$  could be an ideal signal to synchronize cell function and mitochondrial metabolism during stimulation by  $\text{Ca}^{2+}$ -mobilizing stimuli. Mitochondrial matrix  $[\text{Ca}^{2+}]_m$  ( $[\text{Ca}^{2+}]_m$ ) is regulated by specific  $\text{Ca}^{2+}$  transport pathways. The uptake of  $\text{Ca}^{2+}$  is driven by the membrane potential and is mediated by an electrogenic uniport. The egress of mitochondrial  $\text{Ca}^{2+}$  occurs via distinct  $\text{Na}^+$ -independent and -dependent carriers (reviewed in Gunter *et al.*, 1994; Pozzan *et al.*, 1994). Considering that the rise of global  $[\text{Ca}^{2+}]_c$  to between 500 nM and 1  $\mu\text{M}$  during  $\text{IP}_3$ -activated  $[\text{Ca}^{2+}]_c$  signals is probably not sufficient to activate the low-affinity mitochondrial  $\text{Ca}^{2+}$  uptake mechanisms, mitochondria were believed to be relatively insensitive to physiological  $[\text{Ca}^{2+}]_c$  increases. A major breakthrough was achieved using aequorin targeted to the mitochondrial matrix. Rizzuto, Pozzan and co-workers demonstrated that mitochondria undergo a large increase of  $[\text{Ca}^{2+}]_m$  in response to stimulation with  $\text{IP}_3$ -linked stimuli in a wide variety of cells (Rizzuto *et al.*, 1992, 1993, 1994). Furthermore, using fluorescent  $\text{Ca}^{2+}$ -tracers compartmentalized into the mitochondria, we achieved resolution of  $[\text{Ca}^{2+}]_m$  at the single-cell level and demonstrated that the pulsatile release of  $\text{Ca}^{2+}$  underlying  $[\text{Ca}^{2+}]_c$  oscillations driven by the  $\text{IP}_3$ R is delivered efficiently into the mitochondrial matrix, giving rise to coupled oscillations of  $[\text{Ca}^{2+}]_m$  (Hajnóczky *et al.*, 1995). Through this process, a large activation of  $\text{Ca}^{2+}$ -sensitive steps of mitochondrial metabolism is achieved by  $\text{IP}_3$ -induced increases of  $[\text{Ca}^{2+}]_m$  (Pralong *et al.*, 1994; Hajnóczky *et al.*, 1995), demonstrating a physiological role for mitochondrial  $\text{Ca}^{2+}$  signaling. It is also becoming apparent that mitochondria modulate cytosolic  $\text{Ca}^{2+}$  signaling (Jouaville *et al.*, 1995; Budd and Nicholls, 1996; Babcock *et al.*, 1997; Hoth *et al.*, 1997; Ichas *et al.*, 1997; Simpson *et al.*, 1997). Taken together, these observations show that the release of  $\text{Ca}^{2+}$  from the ER in response to  $\text{IP}_3$  is closely coupled with mitochondrial  $\text{Ca}^{2+}$  uptake in the cells, suggesting a privileged transfer of  $\text{Ca}^{2+}$  between ER and mitochondria. It has been proposed that mitochondria are exposed to microdomains of high  $[\text{Ca}^{2+}]$  due to a close spatial coupling between  $\text{IP}_3$ -induced  $\text{Ca}^{2+}$  release sites and mitochondrial  $\text{Ca}^{2+}$  uptake sites (Rizzuto *et al.*, 1993, 1994, 1998).

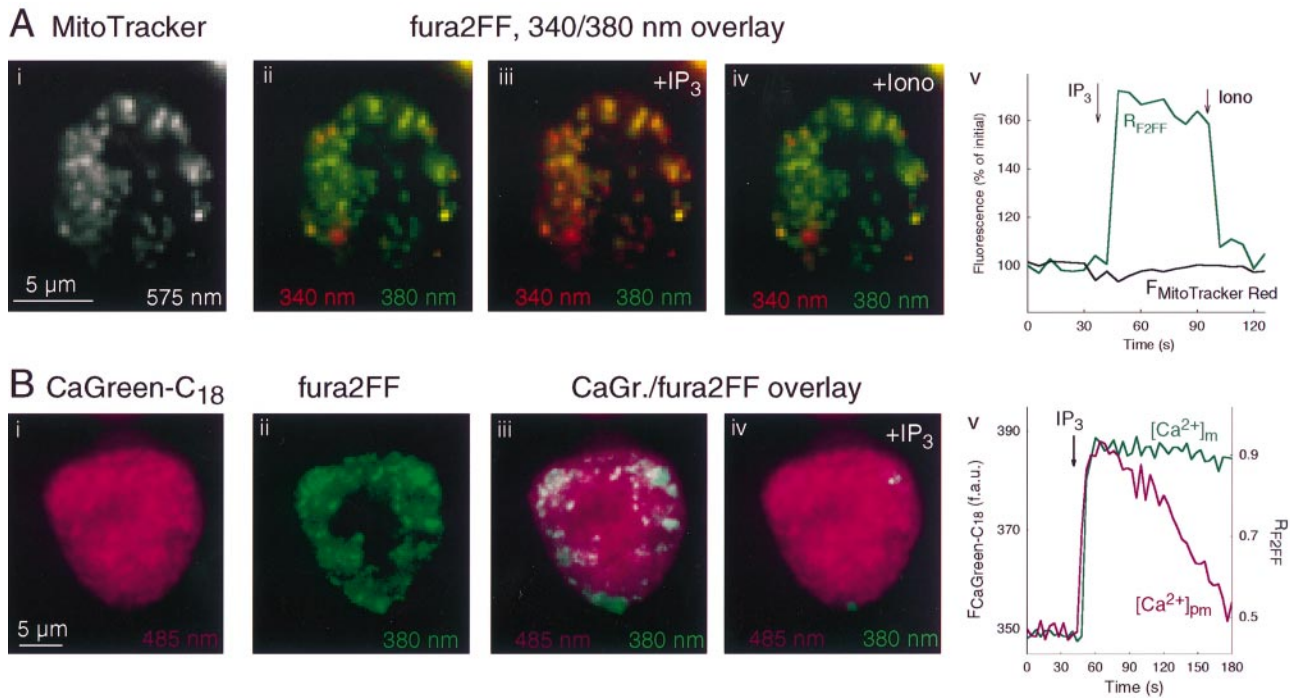

The major aim of this study was to determine the functional organization of  $\text{Ca}^{2+}$  transfer between  $\text{IP}_3$ R and mitochondria. We established an experimental model that allowed us to monitor  $[\text{Ca}^{2+}]_m$  responses evoked by  $\text{IP}_3$  down to the level of single mitochondria. Using this model, we show that synchronous activation of  $\text{IP}_3$ R results in a localized  $[\text{Ca}^{2+}]$  increase at the ER–mitochondrial junction, which is sufficient to evoke maximal activation of mitochondrial  $\text{Ca}^{2+}$  uptake sites. Calibration of mitochondrial  $\text{Ca}^{2+}$  uptake by varying the extra-mitochondrial  $[\text{Ca}^{2+}]$  showed that  $\text{IP}_3$ -induced  $\text{Ca}^{2+}$  elevation in the vicinity of the mitochondria can reach values >20-fold higher than the global increases of  $[\text{Ca}^{2+}]_c$ . We show that the quantal pattern of  $\text{Ca}^{2+}$  release evoked by submaximal  $\text{IP}_3$  is associated with quantal elevations of  $[\text{Ca}^{2+}]_m$ , though low doses or gradual increases of  $\text{IP}_3$  evoked relatively small  $[\text{Ca}^{2+}]_m$  responses. We propose that  $\text{Ca}^{2+}$  release through multiple  $\text{IP}_3$ R is integrated at each mitochondrial  $\text{Ca}^{2+}$  uptake site, so that

optimal signal transmission is achieved during synchronous activation of multiple  $\text{IP}_3$ R. Thus, the  $\text{IP}_3$ R-mediated elementary  $\text{Ca}^{2+}$  release signals which represent the building blocks of cytosolic  $\text{Ca}^{2+}$  signaling may stimulate mitochondrial  $\text{Ca}^{2+}$  uptake on an individual basis, but recruitment of multiple elementary events leads to disproportionately larger mitochondrial  $[\text{Ca}^{2+}]$  responses.

## Results and discussion

### Fluorescence imaging of $[\text{Ca}^{2+}]_m$ responses evoked by $\text{IP}_3$

In order to dissect the mechanisms underlying local  $\text{Ca}^{2+}$  regulation between  $\text{IP}_3$ R and mitochondria, our first aim was to establish a permeabilized cell model in which mitochondrial  $[\text{Ca}^{2+}]$  could be monitored fluorometrically and where the  $\text{Ca}^{2+}$  coupling between ER and mitochondria was preserved. We recognized that loading of mast cells (RBL-2H3 cells) with the acetoxymethyl ester form of fura2FF or rhod2 yielded compartmentalization of these dyes into mitochondria. Figure 1A shows fluorescence images of the distribution of the compartmentalized fura2FF in permeabilized mast cells. The spatial pattern of the mitochondria was visualized using fluorescence imaging of the vital mitochondrial dye MitoTracker Red in the same cells. Typically, oval-shaped mitochondrial cross-sections were detected (Figure 1A), although elongated mitochondria were also observed, particularly at the base of the cells. Using green fluorescent protein targeted to the mitochondria (mitoGFP), the same pattern of mitochondria was evident (Figure 2). It is also shown that the permeabilized preparation retained much of the mitochondrial morphology of the intact cells (Figure 2). Identical structures were found to be labeled with compartmentalized fura2FF and MitoTracker Red, suggesting that fura2FF was trapped in the mitochondria (Figure 1A, i and ii). Fura2FF fluorescence was relatively high using excitation of the  $\text{Ca}^{2+}$  free form (380 nm, green), whereas little fluorescence was obtained with excitation of the  $\text{Ca}^{2+}$ -bound form (340 nm, red), yielding a mainly green color when the two color images were overlaid (Figure 1Aii). Addition of  $\text{IP}_3$  led to a rapid elevation of  $[\text{Ca}^{2+}]$  measured by the fluorescence response of compartmentalized fura2FF (increase of the red component and decrease of the green component in Figure 1A, iii versus ii), whereas the  $\text{Ca}^{2+}$ -insensitive fluorescence signal of the MitoTracker Red was unchanged (Figure 1Av). The increase of  $[\text{Ca}^{2+}]$  evoked by  $\text{IP}_3$  was reversed after addition of a  $\text{Ca}^{2+}$  ionophore, ionomycin, demonstrating that the  $\text{IP}_3$ -induced elevation of  $[\text{Ca}^{2+}]$  occurred in a non-acidic vesicular pool (Figure 1A, iv versus iii). Preincubation with mitochondrial uncouplers prevented the  $\text{IP}_3$ -induced changes of  $[\text{Ca}^{2+}]_{\text{fura2FF}}$  (not shown). Fura2FF has been shown to become compartmentalized in the ER of hepatocytes (Hajnóczky and Thomas, 1997) and partly in the ER of astrocytes (Golovina and Blaustein, 1997), as judged by  $\text{IP}_3$ -induced decrease of  $[\text{Ca}^{2+}]_{\text{fura2FF}}$ , but addition of  $\text{IP}_3$  was not found to exert such an effect in RBL-2H3 cells (Figures 1 and 3). Taken together, these data show the predominant mitochondrial localization of compartmentalized fura2FF and suggest that mitochondria respond to  $\text{IP}_3$ -induced  $\text{Ca}^{2+}$  release in permeabilized RBL-2H3 cells.

**Fig. 1.** Fluorescence imaging of  $[Ca^{2+}]_m$  with compartmentalized fura2FF in single permeabilized RBL-2H3 cells. (A) The gray image (i) shows the distribution of mitochondria visualized by MitoTracker<sup>TM</sup> Red. The green (380 nm excitation)/red (340 nm excitation) overlay images (ii–iv) show the distribution of the compartmentalized fura2FF and the fluorescence changes upon addition of saturating IP<sub>3</sub> (ii–iii) and ionomycin (iii–iv), respectively. Time-courses of the fluorescence changes are plotted in panel v. (B) Fluorescence distribution of the lipophilic perimembrane Ca<sup>2+</sup> indicator dye CaGreen-C<sub>18</sub> (i and iii–iv, marked in purple) and of the compartmentalized fura2FF measured at 380nm excitation (ii–iv, marked in green) are shown. IP<sub>3</sub>-induced fluorescence changes are shown in the overlay images (iii–iv). In (v), time-courses of the fluorescence changes are shown.

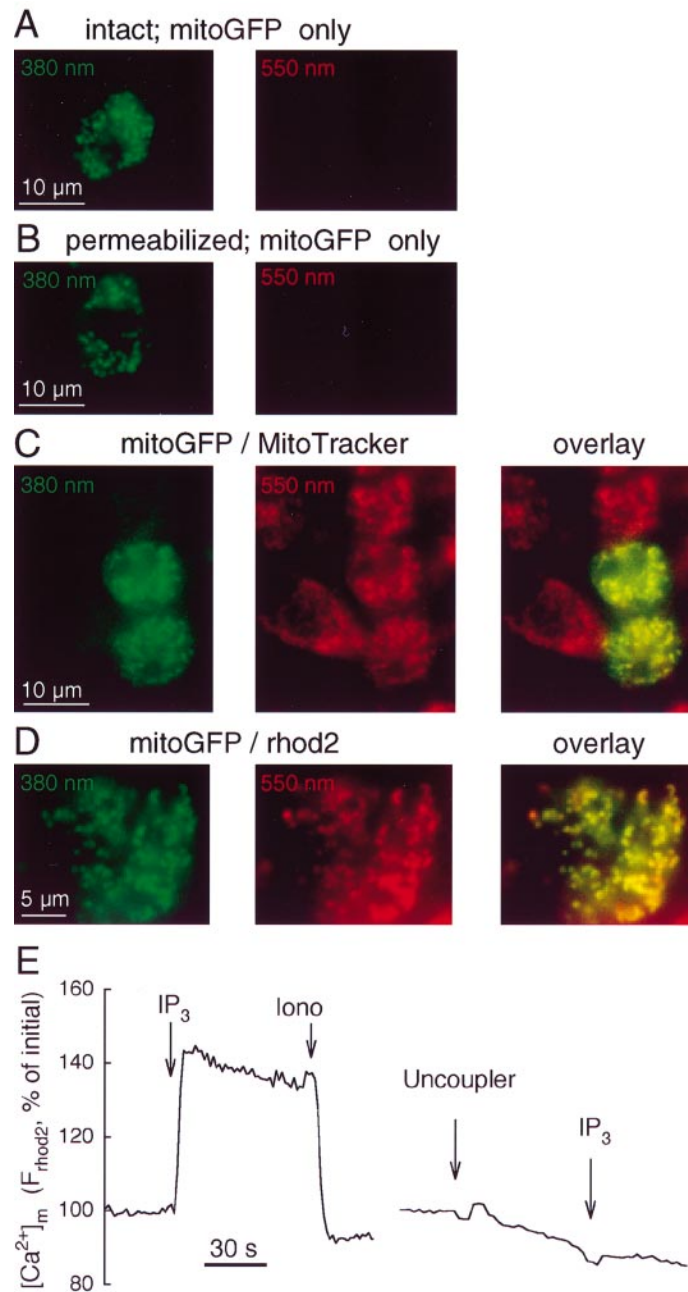

Compartmentalized rhod2 was also found to occur in the organelles labeled with MitoTracker Green or mitoGFP (Figure 2D) and was found to measure mitochondrial uncoupler-sensitive  $[Ca^{2+}]_m$  increases in response to IP<sub>3</sub> as well (Figure 2E). Nevertheless, fura2FF was used to monitor  $[Ca^{2+}]_m$  in most experiments in the present study, because this dye can be used for ratiometric  $[Ca^{2+}]_m$  measurements, and the lower affinity of fura2FF towards Ca<sup>2+</sup> ( $K_d \sim 35 \mu M$  for fura2FF versus  $1 \mu M$  for rhod2) is favorable in order to avoid saturation during large increases of  $[Ca^{2+}]_m$ . Indeed, the basal  $[Ca^{2+}]_m$  was found to be in the discriminatory range of rhod2 (100–500 nM), but IP<sub>3</sub>-induced increases of  $[Ca^{2+}]_m$  led to saturation of rhod2 in many cells (not shown). Using fura2FF, IP<sub>3</sub>-induced elevations of  $[Ca^{2+}]_m$  did not cause saturation of the dye, and calibration of the fluorescence signals yielded values of 10–20  $\mu M$  for the peak of  $[Ca^{2+}]_m$ , which are in good agreement with the  $[Ca^{2+}]_m$  of  $\sim 15 \mu M$  reported in intact single cells stimulated with IP<sub>3</sub>-linked agonists (Rutter *et al.*, 1996).

In order to investigate further the role of Ca<sup>2+</sup> release induced by IP<sub>3</sub> in the activation of mitochondrial Ca<sup>2+</sup> uptake, fura2FF-loaded permeabilized RBL cells were exposed to Calcium Green-C18. The lipophilic alkyl chain anchors the Ca<sup>2+</sup> indicator Calcium Green to the lipid membranes, allowing measurements of  $[Ca^{2+}]_m$  immediately adjacent to cellular membranes (Tanimura and Turner, 1996). Calcium Green-C18 labeled cellular membranes throughout the cell, whereas the compartmentalized fura2FF showed a distribution that correlated with the mitochondria in the same cells (Figure 1B, i and ii). Addition of IP<sub>3</sub> caused an increase of perimembrane

$[Ca^{2+}]_m$  ( $[Ca^{2+}]_{pm}$ ) (increase of the purple component on Figure 1B, iv versus iii) and an increase of  $[Ca^{2+}]_m$  (decrease of the green component on Figure 1B, iv versus iii). The increase of  $[Ca^{2+}]_{pm}$  preceded the elevation of  $[Ca^{2+}]_m$  and was transient (Figure 1B, v). The fall of  $[Ca^{2+}]_{pm}$  could be due to Ca<sup>2+</sup> uptake into other compartments or to dilution of released Ca<sup>2+</sup> in the large bath volume. The latter explanation is supported by our finding that addition of uncoupler, or addition of an inhibitor of the sarco-endoplasmic reticulum Ca<sup>2+</sup> pump, thapsigargin (Tg), to prevent re-uptake of Ca<sup>2+</sup> released by IP<sub>3</sub>, did not change the shape of  $[Ca^{2+}]_{pm}$  transients markedly (not shown). Unexpectedly, the  $[Ca^{2+}]_m$  signal induced by IP<sub>3</sub> showed prolonged elevation despite the decay of the  $[Ca^{2+}]_{pm}$  rise (Figure 1B, v) suggesting a low activity of mitochondrial Ca<sup>2+</sup> efflux. This could be explained by the loss of some regulatory factors during cell permeabilization, though cell-type specific differences in activation of mitochondrial Ca<sup>2+</sup> efflux should also be considered, since  $[Ca^{2+}]_m$  signals were more sustained in RBL-2H3 cells than that in permeabilized hepatic cells or cardiac myoblasts under comparable conditions (unpublished observation).

### Transmission of $[Ca^{2+}]_c$ increases to the mitochondrial matrix

As a further approach to characterize the mechanism underlying propagation of IP<sub>3</sub>-induced  $[Ca^{2+}]_m$  increases into the mitochondria,  $[Ca^{2+}]_c$  and  $[Ca^{2+}]_m$  responses to exogenous Ca<sup>2+</sup> and IP<sub>3</sub> were compared in suspensions of fura2FF-loaded permeabilized RBL cells. Cytosolic  $[Ca^{2+}]_c$  and  $[Ca^{2+}]_m$  were measured simultaneously using

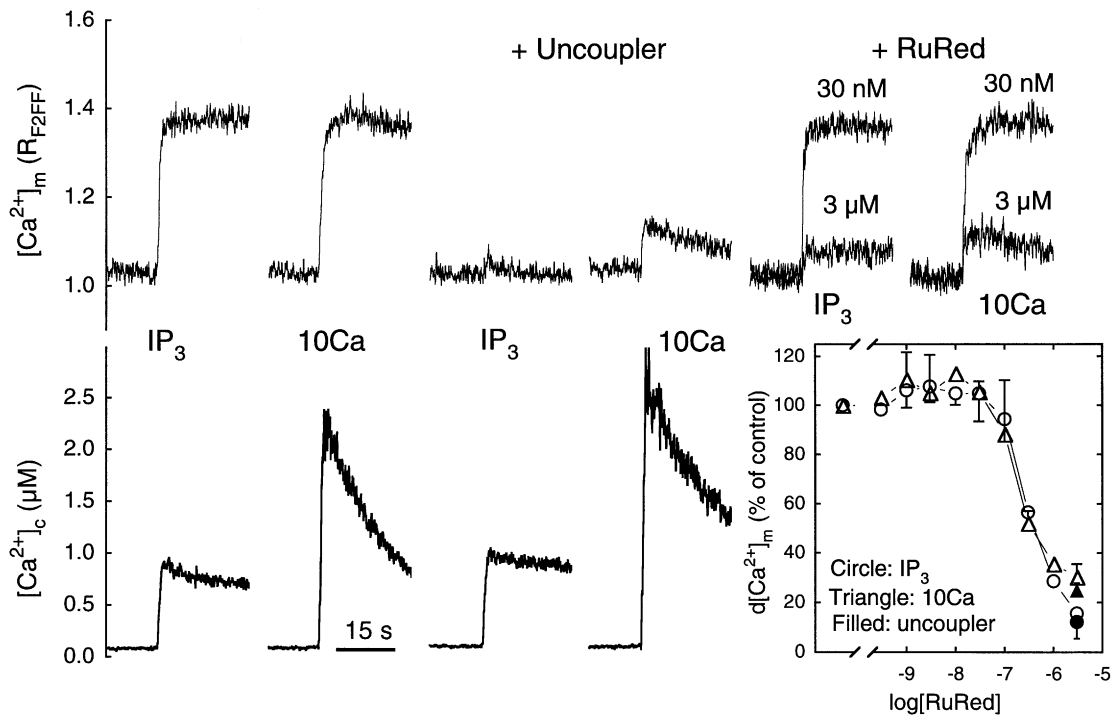

**Fig. 2.** Visualization of mitochondria by mitoGFP. Fluorescence images of (A) intact and (B–D) permeabilized mast cells transfected with mitoGFP. Cells were also loaded with MitoTracker Red (C) or rhod2/AM (D). The green images (380 nm excitation, left panels) show the distribution of mitoGFP, the red images (550 nm excitation, middle panels) show the distribution of MitoTracker Red (C) or compartmentalized rhod2 (D). These images are overlaid in the right panels to show the coincidence of the labeled organelles (overlay). (E) IP<sub>3</sub> (12.5  $\mu$ M)-induced [Ca<sup>2+</sup>]<sub>m</sub> responses recorded in the absence and presence of uncoupler (FCCP/Oligomycin, 5  $\mu$ g/ml of each) using compartmentalized rhod2 in single permeabilized cells.

rhod2 added into the medium and compartmentalized fura2FF, respectively. In contrast to the imaging studies, intracellular Ca<sup>2+</sup> stores were able to control global medium [Ca<sup>2+</sup>] (the cytosolic phase; [Ca<sup>2+</sup>]<sub>c</sub>) in the cell suspension studies, since the ratio of cell mass to bath volume was >20 times larger than that in the imaging experiments. Figure 3 shows that IP<sub>3</sub>-induced Ca<sup>2+</sup> release appeared as an increase of [Ca<sup>2+</sup>]<sub>m</sub> and a subsequent increase of [Ca<sup>2+</sup>]<sub>c</sub>. Pretreatment with mitochondrial uncoupler abolished the IP<sub>3</sub>-induced increase of [Ca<sup>2+</sup>]<sub>m</sub>, whereas the IP<sub>3</sub>-induced [Ca<sup>2+</sup>]<sub>c</sub> increase was slightly enhanced, presumably due to the absence of mitochondrial

Ca<sup>2+</sup> uptake (Figure 3). The IP<sub>3</sub>-induced mitochondrial Ca<sup>2+</sup> elevation was also inhibited by an inhibitor of the mitochondrial Ca<sup>2+</sup> uniporter, ruthenium red (3  $\mu$ M, Figure 3). Thus, IP<sub>3</sub>-induced [Ca<sup>2+</sup>]<sub>m</sub> increases are established in two steps: (i) IP<sub>3</sub>R-mediated Ca<sup>2+</sup> release from ER into cytosol; and (ii) Ca<sup>2+</sup>-uniporter-mediated membrane potential-dependent Ca<sup>2+</sup> uptake from cytosol into the mitochondrial matrix.

In order to reproduce the magnitude of IP<sub>3</sub>-induced increases of [Ca<sup>2+</sup>]<sub>m</sub> by direct addition of Ca<sup>2+</sup> to the medium, it was necessary to add 10–15  $\mu$ M CaCl<sub>2</sub> (Figure 3, upper row). Strikingly, these concentrations of CaCl<sub>2</sub>

**Fig. 3.** Simultaneous measurements of  $[Ca^{2+}]_c$  and  $[Ca^{2+}]_m$  responses evoked by  $IP_3$  and  $CaCl_2$  additions in suspensions of fura2FF-loaded permeabilized RBL-2H3 cells. Cytosolic  $[Ca^{2+}]_c$  was followed with rhod2/FA added to the medium (lower panel), and  $[Ca^{2+}]_m$  was measured using compartmentalized fura2FF (upper panel).  $IP_3$ - (12.5  $\mu M$ ) and  $CaCl_2$ - (10  $\mu M$ , '10Ca') induced  $[Ca^{2+}]_c$  and  $[Ca^{2+}]_m$  responses were recorded in the presence or absence of uncoupler (FCCP/Oligomycin, 5  $\mu g/ml$  of each, middle panels) or ruthenium red (RuRed, 30 nM or 3  $\mu M$ , right panel). Inset: dose-dependent inhibition of  $IP_3$ - and  $CaCl_2$ -induced  $[Ca^{2+}]_m$  elevation by Ruthenium Red is shown (means  $\pm$  SE,  $n = 4-5$ ). The effect of uncoupler (FCCP/Oligomycin, 5  $\mu g/ml$  of each) measured in the same experiments is shown with filled symbols.

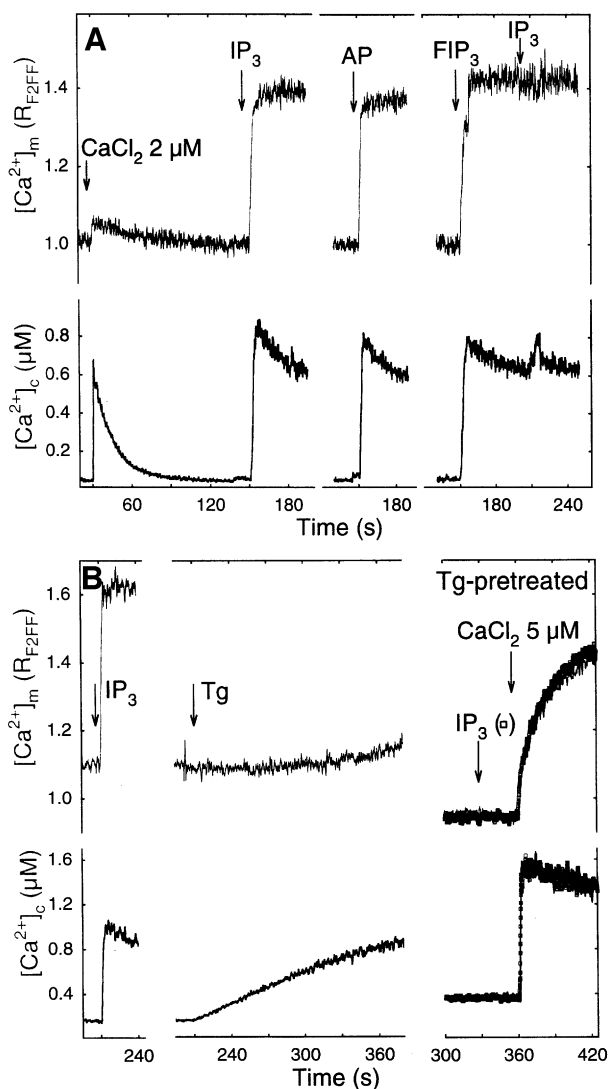

caused much larger increases of  $[Ca^{2+}]_c$  than did  $IP_3$  (Figure 3, lower row). These findings show that  $Ca^{2+}$  release induced by  $IP_3$  is utilized extremely efficiently to raise  $[Ca^{2+}]_m$ . This supports the suggestion that  $IP_3$ Rs may be strategically positioned, allowing mitochondria to sense microdomains of high  $[Ca^{2+}]$  generated in the vicinity of activated  $IP_3$ R (Rizzuto *et al.*, 1993, 1994; Hajnoczky *et al.*, 1995). Interestingly, Sparagna *et al.* (1995) have described a rapid mode of mitochondrial  $Ca^{2+}$  uptake that is activated by relatively small but fast elevations of extramitochondrial  $[Ca^{2+}]$  and inhibited by high concentrations of ruthenium red. Since submaximal concentrations of ruthenium red were reported to exert different effects on the standard mode and on the rapid mode of mitochondrial  $Ca^{2+}$  uptake (Sparagna *et al.*, 1995), we examined the dose response to ruthenium red to test whether the rapid mode was used primarily during uptake of  $Ca^{2+}$  released by  $IP_3$ . Figure 3 (inset) shows that each concentration of ruthenium red exerted identical effects on  $[Ca^{2+}]_m$  responses induced by  $IP_3$  or  $Ca^{2+}$  addition, respectively. Since  $IP_3$ -induced and  $Ca^{2+}$ -induced  $[Ca^{2+}]_m$  responses were modulated by ruthenium red in the same manner, it is unlikely that the highly efficient transmission of  $IP_3$ -induced  $Ca^{2+}$  release into the mitochondria is achieved by utilizing selectively the rapid  $Ca^{2+}$  uptake mode.

Another mechanism to underlie the large effect of  $IP_3$  on  $[Ca^{2+}]_m$  could be that  $IP_3$  or a metabolite of  $IP_3$  facilitates mitochondrial  $Ca^{2+}$  uptake independent of the  $Ca^{2+}$  release. This issue was addressed by two experimental approaches. First,  $[Ca^{2+}]_m$  increases induced by

$IP_3$  or a slowly metabolized  $IP_3$  analog, 3-deoxy-3-fluoro- $IP_3$  (FIP<sub>3</sub>), or a chemically unrelated activator of  $IP_3$ R, adenophostin (Takahashi *et al.*, 1994), were compared. The same  $Ca^{2+}$  release responses and identical rapid increases of  $[Ca^{2+}]_m$  were observed in each condition (Figure 4A), suggesting that the metabolism of  $IP_3$  does not play a role in stimulation of mitochondrial  $Ca^{2+}$  uptake. Secondly, endoplasmic reticulum  $Ca^{2+}$  stores were discharged with Tg pretreatment in order to prevent  $IP_3$ -induced  $Ca^{2+}$  release (Hajnoczky and Thomas 1994, 1997), and, subsequently, the effect of  $IP_3$  on  $Ca^{2+}$ -induced mitochondrial  $Ca^{2+}$  uptake was studied (Figure 4B). In agreement with previous data obtained with intact cells (Rizzuto *et al.*, 1994; Hajnoczky *et al.*, 1995), Tg caused a slow and large increase of  $[Ca^{2+}]_c$  that was not associated with concurrent elevation of  $[Ca^{2+}]_m$ .  $IP_3$  did not cause  $Ca^{2+}$  release from Tg-pretreated cells and failed to exert any effect on  $[Ca^{2+}]_m$  increases induced by subsequent addition of  $Ca^{2+}$  (Figure 4B). These observations suggest that an  $IP_3$ -dependent conformational change of the uniporter does not account for the large stimulation of mitochondrial  $Ca^{2+}$  uptake that is associated with  $IP_3$ -induced  $Ca^{2+}$  release. Taken together, these data support the idea that  $IP_3$  leads to activation of mitochondrial  $Ca^{2+}$  uptake via generation of a localized large increase in  $[Ca^{2+}]_c$  in the vicinity of the mitochondria.

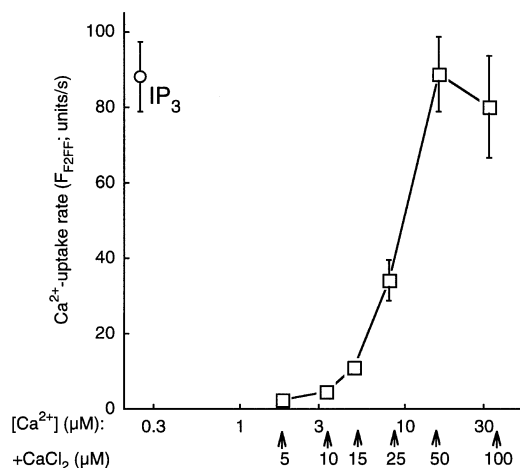

#### **Maximal activation of mitochondrial $Ca^{2+}$ uptake during $IP_3$ -induced $Ca^{2+}$ release**

In order to estimate the magnitude of the local  $[Ca^{2+}]_c$  increases evoked by  $IP_3$ , rates of mitochondrial  $Ca^{2+}$

**Fig. 4.** Effect of IP<sub>3</sub> and IP<sub>3</sub>R-activation on mitochondrial Ca<sup>2+</sup> uptake. (A) [Ca<sup>2+</sup>]<sub>c</sub> and [Ca<sup>2+</sup>]<sub>m</sub> responses were elicited by different activators of the IP<sub>3</sub>R. Supramaximal concentrations of IP<sub>3</sub> (12.5 μM), adenophostin (AP, 2.5 μM) or 3F-IP<sub>3</sub> (FIP<sub>3</sub>, 5 μM) were added. In order to optimize Ca<sup>2+</sup> loading of the ER, CaCl<sub>2</sub> (2 μM) was added at the beginning of each run. (B) [Ca<sup>2+</sup>]<sub>m</sub> and [Ca<sup>2+</sup>]<sub>c</sub> responses elicited by IP<sub>3</sub> (12.5 μM)-induced Ca<sup>2+</sup> release (left), by Tg (2 μM)-evoked Ca<sup>2+</sup> leakage from ER (middle) or by CaCl<sub>2</sub> (5 μM) added to Tg-pretreated cells in the presence or absence of IP<sub>3</sub> (right).

uptake were measured with varying extramitochondrial [Ca<sup>2+</sup>], and the rate of Ca<sup>2+</sup> uptake obtained during IP<sub>3</sub> induced Ca<sup>2+</sup> release was translated into an effective [Ca<sup>2+</sup>]. This experiment was performed using adherent single cells, since intracellular structures can be preserved better in attached cells than in suspensions of cells during permeabilization (Renard-Rooney *et al.*, 1993; Hajnóczky *et al.*, 1994). The activity of the Ca<sup>2+</sup> uniporter is manifested in the rate of mitochondrial Ca<sup>2+</sup> uptake. Figure 5 shows that addition of Ca<sup>2+</sup> led to dose-dependent increases in mitochondrial Ca<sup>2+</sup> uptake rates. Half-maximal stimulation was attained at a [Ca<sup>2+</sup>]<sub>c</sub> of ~10 μM, which is in agreement with data obtained using other methods (reviewed in Gunter *et al.*, 1994; Pozzan *et al.*, 1994). Maximal activation was obtained at >16 μM [Ca<sup>2+</sup>]<sub>c</sub>, which is similar to the data obtained for permeabil-

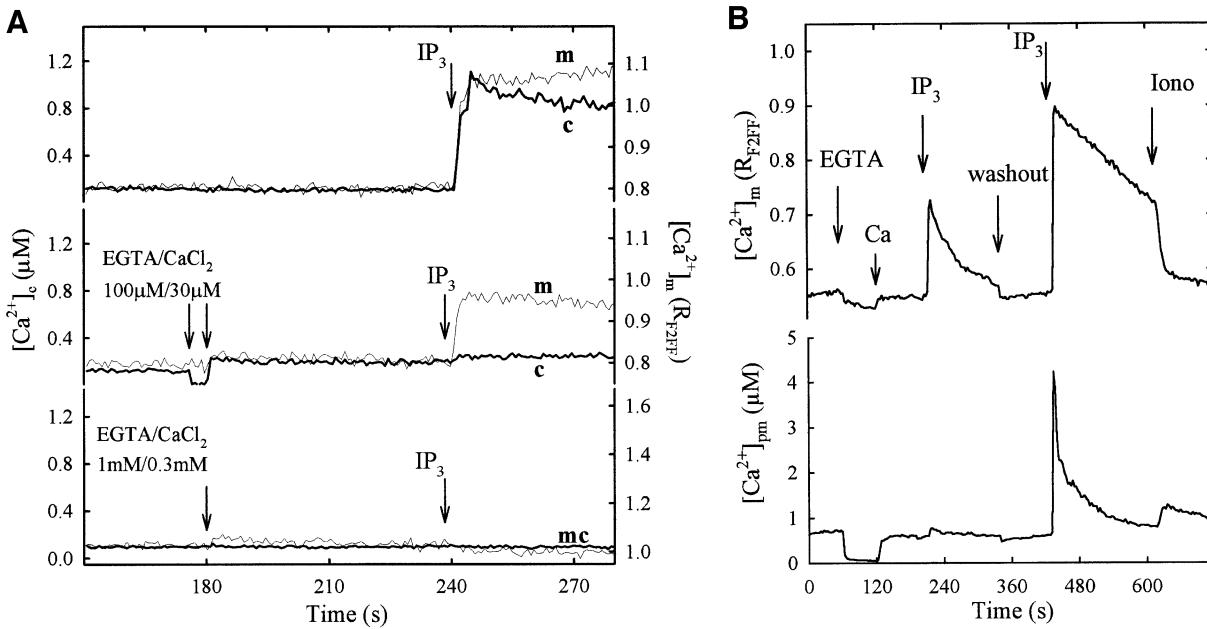

**Fig. 5.** Maximal activation of mitochondrial Ca<sup>2+</sup> uptake during IP<sub>3</sub>-induced Ca<sup>2+</sup> release. The rate of mitochondrial Ca<sup>2+</sup> uptake was measured at varying [Ca<sup>2+</sup>]<sub>c</sub> obtained by addition of CaCl<sub>2</sub> in adherent fura2FF-loaded permeabilized cells. Cytosolic [Ca<sup>2+</sup>]<sub>c</sub> was calculated using constants obtained from Bers *et al.* (1994). The added CaCl<sub>2</sub> concentration values are indicated with arrows below the x axis. Data are the average of three separate experiments (mean ± SE).

ized HeLa cells (Rizzuto *et al.*, 1994) but smaller than the extramitochondrial [Ca<sup>2+</sup>]<sub>c</sub> required to attain maximal activation of Ca<sup>2+</sup> uptake by isolated mitochondria. This difference may be due to differences in the allosteric regulation of the uniporter between permeabilized cells and subcellular fractions. It is also noteworthy that measurements of [Ca<sup>2+</sup>]<sub>m</sub> were used to determine the rate of mitochondrial Ca<sup>2+</sup> uptake in the studies with permeabilized cells, whereas extraluminal [Ca<sup>2+</sup>]<sub>c</sub> responses were used to calculate Ca<sup>2+</sup> uptake rates in suspensions of isolated mitochondria.

Remarkably, when IP<sub>3</sub>-induced mitochondrial Ca<sup>2+</sup> uptake was studied under the same conditions in permeabilized cells, the Ca<sup>2+</sup> uptake rate was as large as it was with maximally effective concentrations of [Ca<sup>2+</sup>]<sub>c</sub> (Figure 5). Hence, our results show that mitochondrial Ca<sup>2+</sup> uptake sites were fully activated during Ca<sup>2+</sup> release induced by maximally effective IP<sub>3</sub>. Since maximal rates of mitochondrial Ca<sup>2+</sup> uptake in response to addition of exogenous Ca<sup>2+</sup> were obtained at >16 μM [Ca<sup>2+</sup>]<sub>c</sub>, we conclude that the localized increase of [Ca<sup>2+</sup>]<sub>c</sub> caused by IP<sub>3</sub> is >16 μM. Considering that the IP<sub>3</sub>-induced global elevations of [Ca<sup>2+</sup>]<sub>c</sub> peak at 400–700 nM in mast cells (Oancea and Meyer, 1996), IP<sub>3</sub>-induced Ca<sup>2+</sup> elevation in the vicinity of the mitochondria can reach values >20-fold higher than the global increases of [Ca<sup>2+</sup>]<sub>c</sub>. This appears to involve all mitochondrial uptake sites that participated in uptake of Ca<sup>2+</sup> during IP<sub>3</sub>-induced Ca<sup>2+</sup> release in permeabilized mast cells.

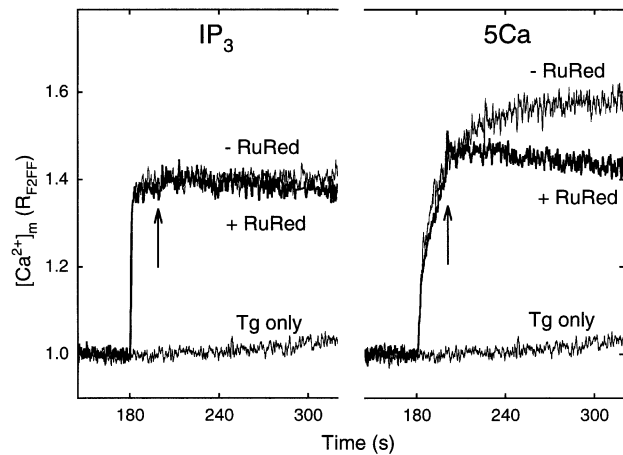

Although IP<sub>3</sub>-linked stimuli exert large effects on [Ca<sup>2+</sup>]<sub>m</sub> and subsequently on mitochondrial metabolism in intact individual cells (Hajnóczky *et al.*, 1995; Rutter *et al.*, 1996), it is not clear whether all or only subsets of mitochondria contribute to the activation of Ca<sup>2+</sup> accumulation in different cell types. Using mitochondrially targeted aequorin, 30% of the total cellular mitochondrial pool was calculated to be highly responsive to IP<sub>3</sub>-linked stimuli in populations of MH75 cells (Rizzuto *et al.*, 1994), whereas in individual CHO cells an essentially

**Fig. 6.** Effect of  $\text{Ca}^{2+}$ -EGTA buffer on  $[\text{Ca}^{2+}]_m$  responses evoked by  $\text{IP}_3$ . **(A)** Cytosolic  $[\text{Ca}^{2+}]_c$  was followed with rhod2/FA added to the medium (hairline) and  $[\text{Ca}^{2+}]_m$  was measured using compartmentalized fura2FF (thick line) in suspensions of permeabilized RBL-2H3 cells.  $\text{IP}_3$ - (12.5  $\mu\text{M}$ ) induced  $[\text{Ca}^{2+}]_c$  and  $[\text{Ca}^{2+}]_m$  responses were recorded in the presence or absence of EGTA titrated with  $\text{CaCl}_2$  to maintain the preaddition level of  $[\text{Ca}^{2+}]_c$  (EGTA: 0, upper panel; 100  $\mu\text{M}$ , middle panel; 1 mM, lower panel). **(B)**  $[\text{Ca}^{2+}]_m$  and  $[\text{Ca}^{2+}]_{pm}$  responses evoked by  $\text{IP}_3$  (12.5  $\mu\text{M}$ ) in the presence and absence of  $\text{Ca}^{2+}$ -EGTA buffer (EGTA 200  $\mu\text{M}$ ,  $\text{CaCl}_2$  120  $\mu\text{M}$ ) were recorded sequentially in an individual fura2FF-loaded permeabilized RBL cell.  $[\text{Ca}^{2+}]_{pm}$  was monitored using CaGreen- $\text{C}_{18}$ . Since CaGreen- $\text{C}_{18}$  is associated with all cellular membranes,  $[\text{Ca}^{2+}]$  in the close vicinity of  $\text{IP}_3\text{Rs}$  is detected by only a small fraction of the dye. After the first stimulation with  $\text{IP}_3$  (12.5  $\mu\text{M}$ ),  $\text{Ca}^{2+}$ -EGTA and  $\text{IP}_3$  were washed out (three changes of medium). In order to facilitate comparison of the  $[\text{Ca}^{2+}]_m$  responses obtained in the presence and absence of EGTA, a cell with complete reversal of the first  $[\text{Ca}^{2+}]_m$  response prior to the second addition of  $\text{IP}_3$  is shown. In most of the cells, decay of the first  $[\text{Ca}^{2+}]_m$  response was slower and so the second rise was superimposed on the falling phase of the first elevation.

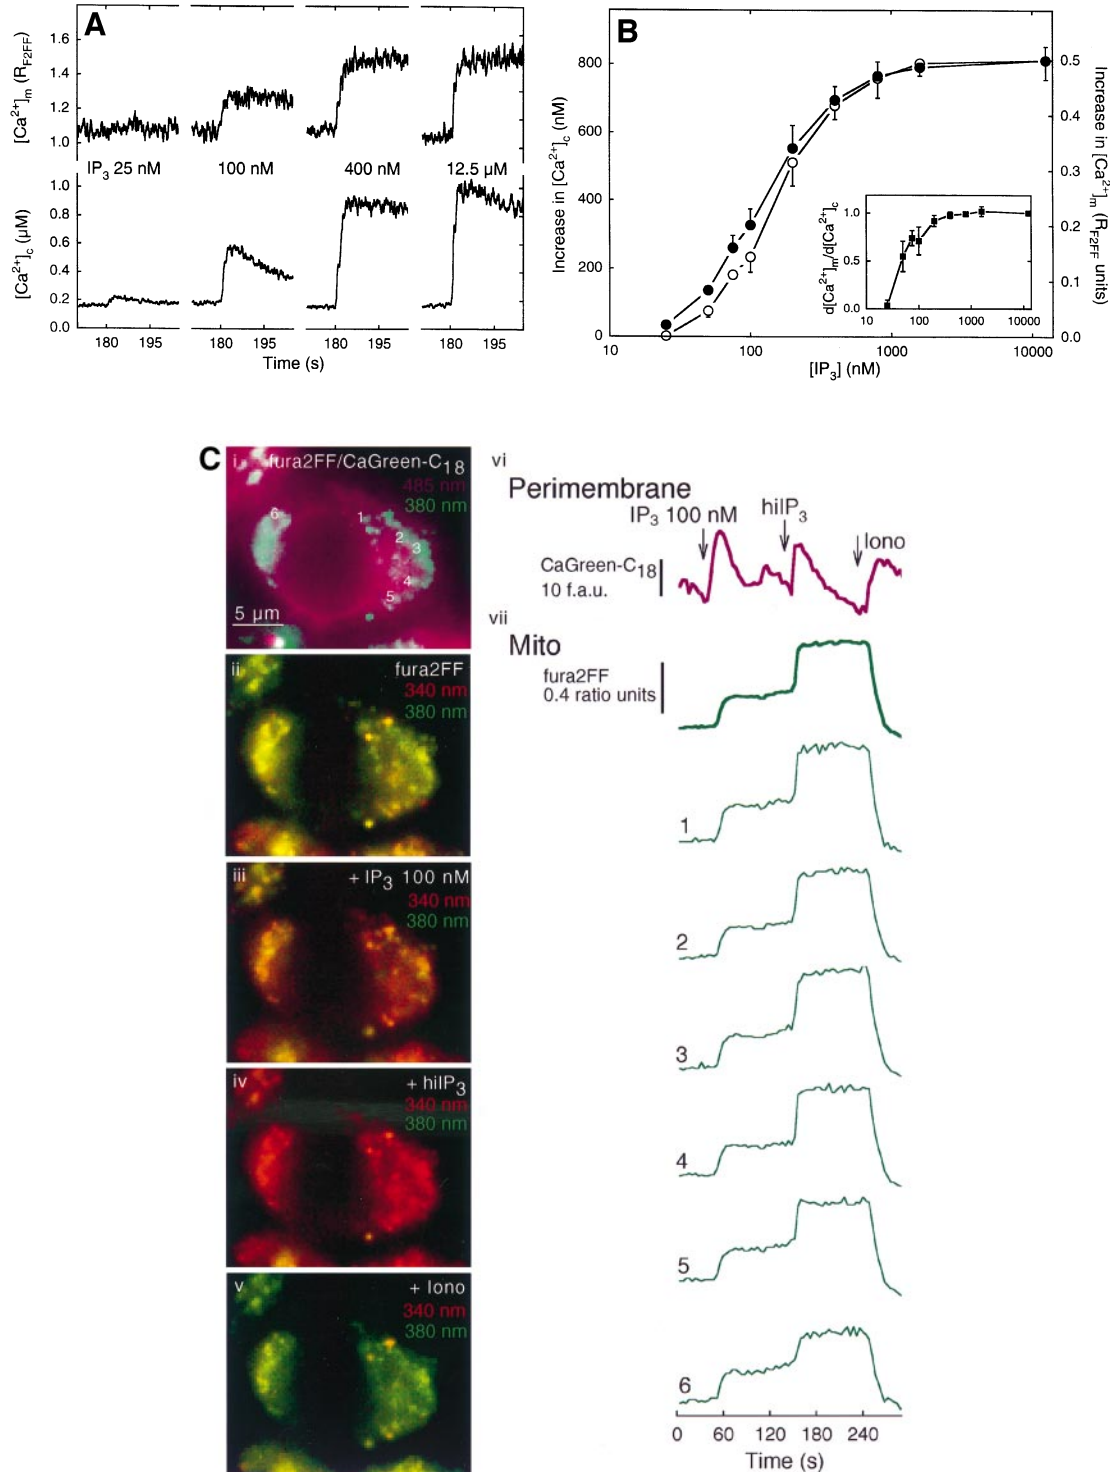

homogenous increase in  $[\text{Ca}^{2+}]_m$  was observed across the cells (Rutter *et al.*, 1996). Recent studies using aequorin targeted to the intermembrane space indicate that only a small fraction of the mitochondrial inner membrane is exposed to high  $[\text{Ca}^{2+}]$  microdomains in HeLa cells (Rizzuto *et al.*, 1998). Different distributions and densities of  $\text{IP}_3\text{Rs}$  in various cells or differences in the spatiotemporal pattern of  $\text{IP}_3\text{R}$  activation during stimulation with  $\text{IP}_3$ -linked stimuli may account for cell-specific mitochondrial responses. Nevertheless, the ability of the  $\text{IP}_3$  receptors to evoke maximal activation of all or subsets of mitochondrial  $\text{Ca}^{2+}$  uptake sites is an extremely significant feature of mitochondrial  $\text{Ca}^{2+}$  signaling, since the time window for mitochondrial  $\text{Ca}^{2+}$  uptake is limited during  $[\text{Ca}^{2+}]_c$  transients evoked by  $\text{IP}_3$ -linked hormones in intact cells (Hajnoczky *et al.*, 1995).

Since  $\text{IP}_3$  addition led to saturation of the available mitochondrial  $\text{Ca}^{2+}$  uptake, these experiments provided information only on the lower limit of  $\text{IP}_3$ -induced elevations of perimitochondrial  $[\text{Ca}^{2+}]$ . Peak  $[\text{Ca}^{2+}]_c$  could potentially reach 100  $\mu\text{M}$  or more in the close vicinity of an activated  $\text{IP}_3\text{R}$ , as has been calculated for an activated voltage-operated  $\text{Ca}^{2+}$  channel (reviewed in Neher, 1998). Cytosolic  $[\text{Ca}^{2+}]$  is estimated to rise to  $\sim 100$   $\mu\text{M}$  at close proximity to an activated  $\text{Ca}^{2+}$  channel ( $< 20$  nm distance), whereas it peaks at 10–20  $\mu\text{M}$  at 100 nm distance. Slow  $\text{Ca}^{2+}$  buffers like EGTA are efficient at suppressing global  $[\text{Ca}^{2+}]_c$  responses and  $[\text{Ca}^{2+}]_c$  increases at a distance of 100 nm, but fail to attenuate the extremely rapid large  $[\text{Ca}^{2+}]_c$  responses in the 20 nm area. In order to estimate the upper limit of  $\text{IP}_3$ -induced perimitochondrial  $[\text{Ca}^{2+}]$

**Fig. 7.** Transient activation of mitochondrial  $\text{Ca}^{2+}$  uptake during  $\text{IP}_3$ -induced  $\text{Ca}^{2+}$  release. Mitochondrial  $[\text{Ca}^{2+}]$  responses were recorded in suspensions of fura2FF-loaded permeabilized cells. Ruthenium red (RuRed, 1  $\mu\text{M}$ ) was added 20 s after the addition of  $\text{IP}_3$  (12.5  $\mu\text{M}$ , left panel) or  $\text{CaCl}_2$  (5Ca, 5  $\mu\text{M}$ , right panel). In both cases,  $\text{Ca}^{2+}$  uptake into the ER was blocked by Tg (2  $\mu\text{M}$ ) added 5 s before  $\text{IP}_3$  or  $\text{CaCl}_2$ .

increases and the average distance between  $\text{IP}_3\text{R}$  and mitochondrial  $\text{Ca}^{2+}$  uptake sites, the effect of EGTA/ $\text{Ca}^{2+}$  buffer on  $\text{IP}_3$ -induced  $[\text{Ca}^{2+}]_c$  and  $[\text{Ca}^{2+}]_m$  increases was investigated (Figure 6). EGTA was titrated with  $\text{CaCl}_2$  to maintain the preaddition level of  $[\text{Ca}^{2+}]_c$ , and hence to avoid depletion of  $\text{Ca}^{2+}$  stores. When EGTA was present at a concentration of 100  $\mu\text{M}$ , the  $\text{IP}_3$ -induced  $[\text{Ca}^{2+}]_c$  increase was eliminated ( $96.5 \pm 0.5\%$  inhibition,  $n = 4$ ), but the  $[\text{Ca}^{2+}]_m$  increase was still observed ( $58.3 \pm 6.3\%$

**Fig. 8.** Quantal properties of IP<sub>3</sub>-induced  $[Ca^{2+}]_c$  and  $[Ca^{2+}]_m$  responses. **(A)** Time courses of  $[Ca^{2+}]_c$  and  $[Ca^{2+}]_m$  responses elicited by addition of submaximal (25, 100 and 400 nM) and supramaximal (12.5  $\mu$ M) doses of IP<sub>3</sub> in suspensions of fura2FF-loaded permeabilized cells. **(B)** Dose-response curves of IP<sub>3</sub>-induced  $[Ca^{2+}]_c$  and  $[Ca^{2+}]_m$  responses in suspensions of fura2FF-loaded permeabilized cells are shown with filled and hollow circles, respectively. Data were normalized to the maximum response. Mean  $\pm$  SE ( $n = 3-4$ ) are shown. Inset: ratios of the IP<sub>3</sub>-induced  $[Ca^{2+}]_m$  and  $[Ca^{2+}]_c$  responses induced by 25 and 50 nM IP<sub>3</sub> were different at the  $P < 0.05$  level. **(C)**  $[Ca^{2+}]_m$  and  $[Ca^{2+}]_pm$  responses evoked by consecutive additions of submaximal (100 nM) and supramaximal (12.5  $\mu$ M) doses of IP<sub>3</sub> in an individual fura2FF-loaded permeabilized RBL cell are shown. The overlaid images on the left (i-v) show the distribution of the membrane-bound CaGreen-C18 (image i, purple) and the mitochondrially compartmentalized fura2FF (image i, green), and the changes in the fura2FF fluorescence (images ii-v, 380 nm green/340 nm red) upon addition of 100 nM IP<sub>3</sub> (ii versus iii), 12.5  $\mu$ M IP<sub>3</sub> (iii versus iv) and ionomycin (iv versus v). Right: time courses of the global  $[Ca^{2+}]_pm$  response (vi) and the average  $[Ca^{2+}]_m$  response (vii, thick line), and the  $[Ca^{2+}]_m$  responses of the marked (1-6 on image i) individual mitochondria (vii, thin lines) are shown.

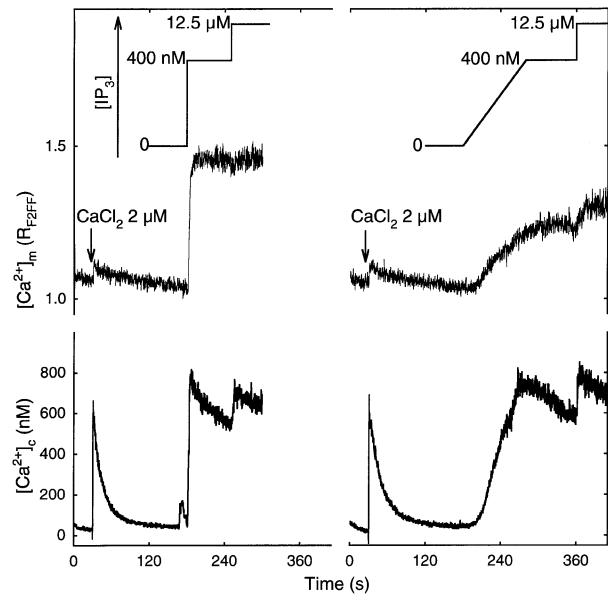

inhibition,  $n = 4$ ). When EGTA was added in millimolar concentrations (1–10 mM), the IP<sub>3</sub>-induced [Ca<sup>2+</sup>]<sub>m</sub> increases were also abolished ( $100 \pm 0\%$  inhibition,  $n = 4$ ). In agreement with the data obtained in permeabilized cell suspensions, the IP<sub>3</sub>-induced rise of [Ca<sup>2+</sup>]<sub>pm</sub> was essentially abolished, whereas the corresponding [Ca<sup>2+</sup>]<sub>m</sub> response was only partially inhibited by 100–200 μM EGTA in adherent single cells (Figure 6B). Complete inhibition of both responses required 1–10 mM EGTA. It is also shown on Figure 6B that the inhibition exerted by the Ca<sup>2+</sup> buffer was reversed upon washout of EGTA. These results suggest that the high Ca<sup>2+</sup> microdomain sensed by the mitochondria is outside of the EGTA-insensitive (100 μM) zone of [Ca<sup>2+</sup>]<sub>c</sub> elevations. Thus, the spatial separation between IP<sub>3</sub>R and mitochondrial Ca<sup>2+</sup> uptake sites is probably >10–20 nm and the free Ca<sup>2+</sup> sensed by the mitochondria is likely to be below 100 μM. By analogy to the voltage-operated Ca<sup>2+</sup> channel (Neher, 1998), the lower limit of IP<sub>3</sub>-induced perimitochondrial [Ca<sup>2+</sup>]<sub>m</sub> elevations which was calculated to be ~16 μM predicts an average distance of ~100 nm.

#### Temporal constraints of IP<sub>3</sub>-induced mitochondrial Ca<sup>2+</sup> uptake

IP<sub>3</sub>-induced increases of [Ca<sup>2+</sup>]<sub>m</sub> occurred in the form of a rapid rise and a subsequent plateau in the present experiments (Figures 1–4), suggesting that maximal activation of the mitochondrial Ca<sup>2+</sup> uptake sites lasted at most for a few seconds, despite the sustained rise of [Ca<sup>2+</sup>]<sub>c</sub>. It is unlikely that rapid saturation of the mitochondrial fura2FF with Ca<sup>2+</sup> prevented us from detecting a continuous rise of [Ca<sup>2+</sup>]<sub>m</sub>, because omission of the Ca<sup>2+</sup> prepulse that was applied in most experiments prior to IP<sub>3</sub> addition (shown in Figures 4A and 9) resulted in smaller IP<sub>3</sub>-induced Ca<sup>2+</sup> release and mitochondrial Ca<sup>2+</sup> uptake responses, with no change in the time-course of [Ca<sup>2+</sup>]<sub>m</sub> (not shown).

Alternatively, a large activation of mitochondrial Ca<sup>2+</sup> efflux could balance an enhanced mitochondrial Ca<sup>2+</sup> uptake activity during the plateau phase. In order to determine the activity of the Ca<sup>2+</sup> uptake component, the effect of ruthenium red added after the rapid upstroke of [Ca<sup>2+</sup>]<sub>m</sub> was studied on IP<sub>3</sub>-induced [Ca<sup>2+</sup>]<sub>m</sub> elevations (Figure 7). Since pretreatment with ruthenium red abolished mitochondrial Ca<sup>2+</sup> accumulations elicited by IP<sub>3</sub> (Figure 3), ruthenium red was expected to cause a fall of [Ca<sup>2+</sup>]<sub>m</sub> if the plateau phase of the IP<sub>3</sub>-induced [Ca<sup>2+</sup>]<sub>m</sub> increase was caused by a steady-state between stimulated Ca<sup>2+</sup> uptake and release. In these experiments, thapsigargin was also added prior to IP<sub>3</sub> so that Ca<sup>2+</sup> re-uptake into the ER could not attenuate activation of mitochondrial Ca<sup>2+</sup> accumulation by released Ca<sup>2+</sup>. Figure 7 shows that only a very slow decrease of the IP<sub>3</sub>-dependent [Ca<sup>2+</sup>]<sub>m</sub> response was elicited by ruthenium red applied after the rapid rise of [Ca<sup>2+</sup>]<sub>m</sub>, whereas the continuous rise of [Ca<sup>2+</sup>]<sub>m</sub> evoked by addition of exogenous Ca<sup>2+</sup> was promptly halted by ruthenium red. These results provide evidence that mitochondrial Ca<sup>2+</sup> uptake falls rapidly following the initial activation during IP<sub>3</sub>-induced Ca<sup>2+</sup> mobilization. The apparent anomaly that sustained [Ca<sup>2+</sup>]<sub>c</sub> increases induced by maximal doses of IP<sub>3</sub>-linked hormones were associated with only a single transient increase

**Fig. 9.** Control of mitochondrial [Ca<sup>2+</sup>]<sub>m</sub> uptake by the temporal pattern of IP<sub>3</sub>R-activation. Time courses of [Ca<sup>2+</sup>]<sub>m</sub> and [Ca<sup>2+</sup>]<sub>c</sub> responses to IP<sub>3</sub> 400 nM added as a bolus (left) or gradually over 120 s (right) were measured in suspensions of fura2FF-loaded permeabilized cells. The plots above the traces show the time-course profiles of IP<sub>3</sub> addition. In order to optimize Ca<sup>2+</sup> loading of the ER, CaCl<sub>2</sub> (2 μM) was added at the beginning of each run.

of [Ca<sup>2+</sup>]<sub>m</sub> in intact cells (Hajnoczky *et al.*, 1995) can also be explained by this result.

#### Quantal calcium responses in the mitochondria

An intriguing and intensively investigated feature of IP<sub>3</sub>-induced Ca<sup>2+</sup> release is the ability of IP<sub>3</sub> dose to control the incremental magnitude of Ca<sup>2+</sup> release, resulting in the phenomenon of quantal Ca<sup>2+</sup> mobilization (Muallem *et al.*, 1989; Taylor and Potter, 1990). Figure 8A shows the effects of suboptimal doses of IP<sub>3</sub> on [Ca<sup>2+</sup>]<sub>c</sub> and [Ca<sup>2+</sup>]<sub>m</sub> measured simultaneously in permeabilized cell suspensions. The quantal pattern of IP<sub>3</sub>-induced Ca<sup>2+</sup> release was paralleled by a similar phenomenon of quantal mitochondrial Ca<sup>2+</sup> uptake (Figure 8A). Importantly, the results shown in Figure 8A represent average responses of cell populations and so the incremental [Ca<sup>2+</sup>]<sub>m</sub> response may reflect cell-to-cell or mitochondrion-to-mitochondrion differences in IP<sub>3</sub> sensitivity, rather than quantal or incremental behavior at the subcellular level. In order to determine whether the incremental [Ca<sup>2+</sup>]<sub>m</sub> response occurs at the level of individual mitochondria, high-spatial-resolution [Ca<sup>2+</sup>]<sub>m</sub> imaging was used to monitor the effect of incremental IP<sub>3</sub> doses. Figure 8C shows global [Ca<sup>2+</sup>]<sub>pm</sub> and [Ca<sup>2+</sup>]<sub>m</sub> responses recorded over a single cell, together with the [Ca<sup>2+</sup>]<sub>m</sub> responses of individual mitochondria. Addition of a suboptimal and, subsequently, a maximal dose of IP<sub>3</sub> evoked transient rises of global [Ca<sup>2+</sup>]<sub>pm</sub>, which were associated with incremental elevations of global [Ca<sup>2+</sup>]<sub>m</sub> (Figure 8C, vi–vii). Although subcellular heterogeneities of the prestimulation fluorescence distribution were observed, elevations of [Ca<sup>2+</sup>]<sub>m</sub> in response to IP<sub>3</sub> increments appeared to be fundamentally homogeneous over the cell, and individual mitochondria largely reflected the incremental Ca<sup>2+</sup> responses of the whole cell (Figure 8C, ii–vii). In context of the suggestion

**Table I.** Functional similarities between calcium signal transmission from ER to mitochondria and synaptic transmission

	Calcium signal transmission between ER and mitochondria	Synaptic transmission between cells
Activator	IP <sub>3</sub>	action potential
Messenger	Ca <sup>2+</sup>	neurotransmitter
Source	ER through IP3R	synaptic vesicle
Target	Ca <sup>2+</sup> -uniporter	neurotransmitter receptor
Spatiotemporal organization	Microdomains of high messenger concentration which rapidly dissipate	
	Maximal activation of the targets	
	Quantal pattern of transmission	
	Multiple source units communicate with each target	
	Constitutive/non-vesicular release of the messenger is poorly detected	

that activation of subsets of IP<sub>3</sub>R with different sensitivities to IP<sub>3</sub> can account for the incremental Ca<sup>2+</sup> release responses, our data showing the incremental pattern of the corresponding mitochondrial Ca<sup>2+</sup> uptake suggest that each mitochondrion is functionally linked to multiple subsets of IP<sub>3</sub>R that are activated at each IP<sub>3</sub> concentration.

The connection between IP<sub>3</sub>R and a mitochondrion may be established by two fundamentally different architectures at the level of coupling between individual IP<sub>3</sub>R and mitochondrial Ca<sup>2+</sup> uptake sites. Mitochondrial Ca<sup>2+</sup> uptake sites could be activated independently of each other by the Ca<sup>2+</sup> release through a single IP<sub>3</sub>R, analogous to the recruitment of Ca<sup>2+</sup> release through ryanodine receptors by Ca<sup>2+</sup> entry through single L-type Ca<sup>2+</sup> channels in the heart (Lopez-Lopez *et al.*, 1995). Alternatively, populations of mitochondrial Ca<sup>2+</sup> uptake sites could communicate with populations of IP<sub>3</sub>R similarly to the transmission in synapses. Since fluorescence microscopy does not have the resolution to decide whether the Ca<sup>2+</sup> signal originates from a single channel or from a channel cluster, we designed alternative approaches to this question. If IP<sub>3</sub>R and mitochondrial Ca<sup>2+</sup> uptake sites are coupled on a one-to-one basis as the first model predicts, cooperation between IP<sub>3</sub>R in activation of mitochondrial Ca<sup>2+</sup> uptake would not be expected. In contrast, in a quasi-synaptic organization, integration of Ca<sup>2+</sup> release via multiple IP<sub>3</sub>R at each mitochondrial uptake site could result in cooperative activation. In order to test this possibility, the dose–response curves for IP<sub>3</sub>-induced [Ca<sup>2+</sup>]<sub>c</sub> release and for IP<sub>3</sub>-induced mitochondrial Ca<sup>2+</sup> uptake were compared. Cooperation between Ca<sup>2+</sup> release events supporting mitochondrial Ca<sup>2+</sup> uptake was expected to appear in a rightward shift and a larger slope of the curve describing the mitochondrial Ca<sup>2+</sup> response. Figure 8B shows that the curves describing the IP<sub>3</sub> sensitivity of Ca<sup>2+</sup> release and mitochondrial Ca<sup>2+</sup> uptake responses are close to each other, but, consistent with the cooperative model, low doses of IP<sub>3</sub> appeared to be less effective at evoking rises of [Ca<sup>2+</sup>]<sub>m</sub> than of [Ca<sup>2+</sup>]<sub>c</sub>. This difference is underscored by plotting the ratio of [Ca<sup>2+</sup>]<sub>m</sub> and [Ca<sup>2+</sup>]<sub>c</sub> responses against the concentration of IP<sub>3</sub> (Figure 8B, inset).

It might be argued that we failed to detect [Ca<sup>2+</sup>]<sub>m</sub> responses at the lowest IP<sub>3</sub> concentrations because fura2FF has a low affinity towards Ca<sup>2+</sup> and so small increases of [Ca<sup>2+</sup>]<sub>m</sub> do not cause measurable fluorescence responses. However, we were also able to show [Ca<sup>2+</sup>]<sub>c</sub> increases at low [IP<sub>3</sub>] without a measurable [Ca<sup>2+</sup>]<sub>m</sub> increase, using the higher-affinity rhod2 to measure [Ca<sup>2+</sup>]<sub>m</sub> (not shown). Considering the steep dependence of activation of mitochondrial Ca<sup>2+</sup> uptake on [Ca<sup>2+</sup>]<sub>c</sub> (Figure 5), it is also possible that increases of IP<sub>3</sub> concentration gradually enhance Ca<sup>2+</sup> efflux via single IP<sub>3</sub>R and that cooperativity is involved at the level of Ca<sup>2+</sup> activation of the Ca<sup>2+</sup> uniporter. This explanation is not likely, however, since by utilizing the positive feedback effect exerted by released Ca<sup>2+</sup> (reviewed in Berridge, 1993), each IP<sub>3</sub>R is expected to demonstrate an essentially all-or-none activation during IP<sub>3</sub>-induced Ca<sup>2+</sup> release. Assuming that the concentration of IP<sub>3</sub> controls the number of activated IP<sub>3</sub>R contributing to the Ca<sup>2+</sup> release, it is most likely that mitochondrial Ca<sup>2+</sup> uptake is facilitated by cooperation between these Ca<sup>2+</sup> release sites.

If mitochondrial Ca<sup>2+</sup> uptake is supported by a positive interaction between IP<sub>3</sub>R Ca<sup>2+</sup> release units and the local Ca<sup>2+</sup> increases generated by IP<sub>3</sub> dissipate rapidly, the temporal pattern of IP<sub>3</sub>R activation may also play a fundamental role in shaping mitochondrial Ca<sup>2+</sup> responses. To investigate this issue, bolus addition and gradual infusion of the same dose of IP<sub>3</sub> were applied in suspensions of permeabilized cells, while [Ca<sup>2+</sup>]<sub>c</sub> and [Ca<sup>2+</sup>]<sub>m</sub> were monitored simultaneously (Figure 9). Addition of a 400 nM bolus of IP<sub>3</sub> led to an almost maximal Ca<sup>2+</sup> release and mitochondrial Ca<sup>2+</sup> uptake (left traces). When the same dose of IP<sub>3</sub> was injected slowly (the addition was completed in 120 s) the rise of [Ca<sup>2+</sup>]<sub>c</sub> was slow, but the final magnitude was the same as with the bolus addition (right traces). Elevation of [Ca<sup>2+</sup>]<sub>m</sub> was also slow under these conditions, and it is clear that the total response was only 50–60% of the response observed during bolus addition of IP<sub>3</sub> (Figure 9, right traces). This is not a consequence of IP<sub>3</sub> metabolism, since the metabolism-resistant analog of IP<sub>3</sub>, FIP<sub>3</sub>, also caused smaller [Ca<sup>2+</sup>]<sub>m</sub> responses in continuous infusion than in bolus additions. These results demonstrate that the Ca<sup>2+</sup> stored in the ER

can be released to a similar extent by either gradual or simultaneous activation of IP3Rs, but simultaneous activation of IP3Rs is required for optimal activation of mitochondrial  $\text{Ca}^{2+}$  uptake. Taken together, these data show that  $\text{Ca}^{2+}$  release through multiple IP3Rs is integrated at the level of individual mitochondrial  $\text{Ca}^{2+}$  uptake sites. This conclusion is also supported by the fact that the average distance between IP3R and mitochondrial  $\text{Ca}^{2+}$  uptake sites is not in the  $<20$  nm range but may be in the 100 nm range (see above). Microdomains of this size can result from the superposition of the  $\text{Ca}^{2+}$  contributions of several nearby channels (Dunlap *et al.*, 1995; Borst and Sakmann, 1996; Cooper *et al.*, 1996).

Remarkably, several features of the IP3R–mitochondrial  $\text{Ca}^{2+}$  signaling system demonstrated in our study indicate that the functional organization underlying ER–mitochondrial  $\text{Ca}^{2+}$  coupling is similar to that of synaptic transmission. The corresponding elements of subcellular  $\text{Ca}^{2+}$  signal transmission and synaptic transmission and their common functional features are listed in Table I. The molecular microstructure underlying  $\text{Ca}^{2+}$  signal transmission between ER and mitochondria has not been explored, but the close apposition of ER and mitochondrial membranes is well known and there are reports demonstrating clusters of IP3Rs in ER membranes facing mitochondria (Shore and Tata, 1977; Maeda *et al.*, 1989; Mignery *et al.*, 1989; Satoh *et al.*, 1990; Rizzuto *et al.*, 1998). Assuming that the matching regions of the mitochondria are rich in  $\text{Ca}^{2+}$  uniporters, these areas may provide the surface for  $\text{Ca}^{2+}$  signal transmission from IP3Rs to mitochondrial  $\text{Ca}^{2+}$  uptake sites. Release of  $\text{Ca}^{2+}$  from the ER occurs in a quantal manner in response to  $\text{IP}_3$ , similar to neurotransmitter release in response to  $\text{Ca}^{2+}$  entry through voltage-operated  $\text{Ca}^{2+}$  channels (del Castillo and Katz, 1954; Katz, 1969). Microdomains of high  $[\text{Ca}^{2+}]$  with a short lifetime are built up at the ER–mitochondrial junctions, analogous to the large transients of neurotransmitter concentration in the synaptic cleft. Diffusion and re-uptake of the messenger are involved in the rapid clearance in both cases. Several lines of evidences suggest that each mitochondrial  $\text{Ca}^{2+}$  uptake site is supported by  $\text{Ca}^{2+}$  release occurring through more than one IP3R, which is compatible with the fact that each postsynaptic receptor can be activated by neurotransmitter release from more than one synaptic vesicle. This coupling pattern is different from the  $\text{Ca}^{2+}$  coupling between the dihydropyridine  $\text{Ca}^{2+}$  channel and the ryanodine receptor, where single  $\text{Ca}^{2+}$  channels activate ryanodine receptors independently of one other. Furthermore, the IP3R–mitochondrial  $\text{Ca}^{2+}$  uptake site coupling shows maximal efficiency in activation of the  $\text{Ca}^{2+}$  uniporter, just as maximal activation of the neurotransmitter receptors can be obtained during neurotransmitter release in the synapses. Our study shows that synchronized activation of IP3Rs is required for optimal activation of mitochondrial  $\text{Ca}^{2+}$  uptake sites, whereas saturation of postsynaptic receptors may require a single quantum of neurotransmitter or more (reviewed in Frerking and Wilson, 1996). Constitutive release of the messenger at the ER–mitochondrial junction triggered by thapsigargin is poorly detected by the mitochondrial  $\text{Ca}^{2+}$  uptake sites, just as non-vesicular release of the neurotransmitter is detected with low efficiency at the synapses. Taken together, our data show that  $\text{Ca}^{2+}$  signal transmis-

sion between intracellular organelles can utilize a closely related functional architecture to that used for synaptic signal propagation between cells.

## Conclusions

This work describes fundamental features of the local  $\text{Ca}^{2+}$  regulation that supports communication between endoplasmic reticulum and mitochondria. We show that  $\text{Ca}^{2+}$  release through IP3Rs leads to maximal but short-lasting activation of mitochondrial  $\text{Ca}^{2+}$  uptake and that this response is explained by the generation of large perimitochondrial  $[\text{Ca}^{2+}]$  spikes. Localized increases of  $[\text{Ca}^{2+}]_c$  peak over 15  $\mu\text{M}$  and these responses are at least 20-fold larger than the global  $[\text{Ca}^{2+}]_c$  elevations. Furthermore, we show that quantal  $\text{Ca}^{2+}$  release via IP3Rs yields quantal mitochondrial  $\text{Ca}^{2+}$  uptake, even at the level of individual mitochondria. Although this suggests that single IP3Rs are effective at raising  $[\text{Ca}^{2+}]_m$ , optimal activation of mitochondrial  $\text{Ca}^{2+}$  uptake is obtained by synchronous activation of IP3Rs. Thus, the IP3R-mediated elementary  $\text{Ca}^{2+}$  release signals which represent the building blocks of cytosolic  $\text{Ca}^{2+}$  signaling may stimulate mitochondrial  $\text{Ca}^{2+}$  uptake on an individual basis, but recruitment of multiple elementary events leads to disproportionately larger mitochondrial  $[\text{Ca}^{2+}]$  responses. Since calcium signaling involves temporal and spatial coordination of the elementary  $\text{Ca}^{2+}$  release events, calcium spikes and oscillations evoked by synchronized and periodic activation of IP3Rs become particularly effective in establishing dynamic control over mitochondrial  $[\text{Ca}^{2+}]$ , and in turn, cellular energy metabolism.

## Materials and methods

### Cells

RBL-2H3 mucosal mast cells (kindly provided by Clare Fewtrell) were cultured in Eagle's minimum essential medium supplemented with 20% (v/v) fetal bovine serum, 4 mM glutamine, 100 U/ml penicillin and 100  $\mu\text{g}/\text{ml}$  streptomycin in 5%  $\text{CO}_2$  and 95% air at 37°C (Taugro *et al.*, 1979). For imaging measurements, cells were plated onto poly-D-lysine-coated coverslips and cultured for 4–5 days prior to experiments. For cell suspension studies, cells were cultured for 6 days in 75  $\text{cm}^2$  flasks.

### Transfection of cells for fluorescence imaging

Cells plated onto poly-D-lysine-coated coverslips were transfected with plasmid DNA (1  $\mu\text{g}/\text{ml}$  of pCMV/*myc*/mito/GFP for 7 h, Invitrogen) using Lipofectamine (10  $\mu\text{g}/\text{ml}$ ) and OPTI-MEM medium (Life Technologies). Cells were observed 24 h after transfection.

### Fluorescence imaging measurements in permeabilized RBL-2H3 cells

Prior to use, the cells were preincubated for 30 min in extracellular medium (ECM) composed of 121 mM NaCl, 5 mM  $\text{NaHCO}_3$ , 10 mM Na–HEPES, 4.7 mM KCl, 1.2 mM  $\text{KH}_2\text{PO}_4$ , 1.2 mM  $\text{MgSO}_4$ , 2 mM  $\text{CaCl}_2$ , 10 mM glucose and 2% bovine serum albumin (BSA) pH 7.4 at 37°C. For measurements of  $[\text{Ca}^{2+}]_m$ , the cells were loaded with 5  $\mu\text{M}$  fura2FF/AM or 2  $\mu\text{M}$  rhod2/AM in the presence of 0.003% (w/v) pluronic acid for 50–70 min. In order to label mitochondria, the cells were loaded with the vital dye MitoTracker Red (50 nM) for 30–45 min. Dye-loaded cells were washed with  $\text{Ca}^{2+}$ -free extracellular buffer composed of 120 mM NaCl, 20 mM Na–HEPES, 5 mM KCl, 1 mM  $\text{KH}_2\text{PO}_4$ , 100  $\mu\text{M}$  EGTA/Tris pH 7.4 and then permeabilized by incubation for 5 min with 15  $\mu\text{g}/\text{ml}$  digitonin in intracellular medium (ICM) composed of 120 mM KCl, 10 mM NaCl, 1 mM  $\text{KH}_2\text{PO}_4$ , 20 mM Tris–HEPES pH 7.2 with 2 mM MgATP, 2 mM succinate and 1  $\mu\text{g}/\text{ml}$  each of antipain, leupeptin and pepstatin. ICM was passed through a Chelex column prior to addition of ATP and protease inhibitors to lower the ambient  $[\text{Ca}^{2+}]$ . The medium free  $[\text{Ca}^{2+}]$  was  $<100$  nM

after Chelex treatment and did not exceed 300–400 nM after addition of ATP, succinate and protease inhibitors. In most of the experiments, 20  $\mu\text{M}$  EGTA/Tris was also present during permeabilization in order to decrease  $[\text{Ca}^{2+}]_i$  (<50 nM). For measurements of  $[\text{Ca}^{2+}]_{\text{pm}}$ , labeling of cells with CaGreen-C18 or fura-C18 (1.5–5  $\mu\text{M}$ ) was carried out during permeabilization. After permeabilization, the cells were washed into fresh buffer without digitonin and incubated in the imaging chamber, at 35°C.

Fluorescence images were acquired using an Olympus IX70 inverted microscope fitted with either 40 $\times$  (UAp0, NA 0.65–1.35) or 100 $\times$  (UPlanApo, NA 0.5–1.35) oil immersion objective and a cooled CCD camera (PXL, Photometrics) under computer control. The computer also controlled a filter wheel or a scanning monochromator (DeltaRam, PTI) to select the excitation wavelength. Excitation at 340 and 380 nm was used for fura2FF and for fura-C18, respectively; 380 nm was used for mitoGFP, 490 nm for CaGreen-C18, 545 nm for rhod2 and 570 nm for MitoTracker Red, with multiwavelength beamsplitter/emission filter combinations that allowed simultaneous measurement of fura2FF and CaGreen-C18 fluorescence, or fura-C18 and rhod2 fluorescence, or mitoGFP and MitoTracker Red fluorescence, or fura2FF and rhod2 fluorescence, or fura2FF, CaGreen-C18 and MitoTracker Red fluorescence (Chroma Technology Corp.).  $[\text{Ca}^{2+}]_m$  in fura2FF-loaded individual permeabilized cells was calculated from the fluorescence ratio derived from image pairs obtained with 340 and 380 nm excitation using a  $K_d$  for  $\text{Ca}^{2+}$  of 35  $\mu\text{M}$  (A.Minta, Teflabs).

Experiments were carried out with at least four different cell preparations, and 20–60 cells were monitored in each experiment. Traces represent single-cell or single-mitochondrion responses unless indicated otherwise.

#### Fluorometric measurements of $[\text{Ca}^{2+}]_c$ and $[\text{Ca}^{2+}]_m$ in suspensions of permeabilized RBL-2H3 cells

Measurements of  $[\text{Ca}^{2+}]_m$  were carried out by first loading the intact cells for 60 min with 5  $\mu\text{M}$  Fura2FF/AM in ECM supplemented with 0.003% of pluronic acid at 37°C. Fura2FF-loaded cells were detached using Trypsin-Versene (BioWhittaker), washed in  $\text{Ca}^{2+}$ -free extracellular buffer (125 g for 4 min) and stored on ice. The cells (~2.4 mg protein/1.8 ml) were permeabilized using 25  $\mu\text{g}/\text{ml}$  digitonin for 6 min in ICM at 35°C, followed by washout of the released cytosolic fura2FF (125 g for 4 min). Permeabilized cells were resuspended in ICM supplemented with 0.25  $\mu\text{M}$  rhod2/FA and maintained in a stirred thermostated cuvette at 35°C. In most experiments, 2  $\mu\text{M}$   $\text{CaCl}_2$  was added after permeabilization (shown in Figures 3A and 8) to facilitate loading of the ER  $\text{Ca}^{2+}$  store. Fluorescence was monitored in a multiwavelength-excitation dual-wavelength-emission fluorimeter (DeltaRAM, PTI) using 340 and 380 nm excitation, and 500 nm emission for fura2FF, and 540 nm excitation and 580 nm emission for rhod2.

Calibration of the rhod2 signal was carried out at the end of each measurement, adding 1.5 mM  $\text{CaCl}_2$ , and subsequently EGTA/Tris 10 mM pH 8.5.  $[\text{Ca}^{2+}]_c$  was calculated by using a  $K_d$  of 1  $\mu\text{M}$  (A.Minta, Teflabs).

Calcium release induced by  $\text{IP}_3$  was found to be utilized extremely efficiently to raise  $[\text{Ca}^{2+}]_m$  in suspensions of permeabilized cells, though even stronger coupling between  $\text{Ca}^{2+}$  release and mitochondrial  $\text{Ca}^{2+}$  uptake was observed in adherent permeabilized cells (mitochondrial  $\text{Ca}^{2+}$  uptake rates are translated into an effective perimitochondrial  $[\text{Ca}^{2+}]_i$  of 3–5  $\mu\text{M}$  and >16  $\mu\text{M}$ , respectively). This difference is probably due to a better preservation of intracellular structures, particularly the connections between ER and mitochondria in adherent permeabilized cells (Renard-Rooney *et al.*, 1993; Hajnóczky *et al.*, 1994). Hence, the technically less-difficult suspension experiments were used for pharmacological tests, whereas imaging of adherent permeabilized cells was used to estimate the maximal efficiency of  $\text{Ca}^{2+}$  signal transmission between ER and mitochondria and to visualize  $[\text{Ca}^{2+}]_m$  signals at subcellular resolution.

Experiments were carried out with 3–4 different cell preparations.

#### Acknowledgements

We would like to thank Drs Tamás Balla, Sandor Györke, Jan Hoek and Bob Silver for helpful discussions. We are greatly indebted to Drs Clare Fewtrell and M.Takahashi for providing us with RBL-2H3 cells and adenophostin, respectively. This work was supported by National Institutes of Health grant DK51526 and by the Burroughs Wellcome Fund Career Award in the Biomedical Sciences #272 to G.H.
