Real-time three-dimensional object reconstruction by use of a phase-encoded digital hologram

Osamu Matoba, Thomas J. Naughton, Yann Frauel, Nicolas Bertaux, and Bahram Javidi

A three-dimensional (3D) object reconstruction technique that uses only phase information of a phase-shifting digital hologram and a phase-only spatial-light modulator is proposed. It is well known that a digital hologram can store both amplitude and phase information of an optical electric field and can reconstruct the original 3D object in a computer. We demonstrate that it is possible to reconstruct optically 3D objects using only phase information of the optical field calculated from phase-shifting digital holograms. The use of phase-only information enables us to reduce the amount of data in the digital hologram and reconstruct optically the 3D objects using a liquid-crystal spatial light modulator without optical power loss. Numerical evaluation of the reconstructed 3D object is presented. © 2002 Optical Society of America

1. Introduction

Three-dimensional (3D) imaging, display, and processing have been investigated frequently.[1–5] Holography is one popular technique that can record and reconstruct 3D objects. Recently, digital holography[6] has become viable with the ongoing development of megapixel CCD sensors that have sufficient dynamic range in each pixel. It has been shown with numerical propagation that the fully complex field calculated from the digital holograms in the Fresnel domain can be used to reconstruct 3D objects successfully.[6–9] Storage of the hologram in a computer enables us to reduce the noise through image-processing techniques and numerically reconstruct the object with arbitrary views. The digital hologram is also in a convenient form for data transmission and object recognition.[10,11] With digital reconstruction, however, it takes a long time to calculate the Fresnel diffraction pattern. This makes it difficult to develop a real-time 3D display device.

In this paper, we propose a real-time 3D object reconstruction system that uses phase-only information of the complex field from the digital holograms and a phase-only spatial light modulator. It is well known that the phase distribution, that is a wave front, contains 3D position information of point sources. Phase-only hologram or information is used in kinoform[12,13] and diffractive optical elements for interconnection,[14,15] imaging or optical elements such as lenses and prisms. The proposed method is suitable for real-time optical reconstruction of the 3D object because phase-only reconstruction allows us to use commercially available display devices, such as liquid-crystal spatial light modulator(s) (SLM)(s).[16,17] These devices can only be operated in either phase or amplitude modulation mode. Using only this phase information, we can reduce by half the storage requirements of the digital hologram. We also take advantage of minimal optical power loss in the reconstruction process. Reconstructed 3D objects with phase-only information are evaluated numerically. An experimental demonstration with a liquid-crystal spatial light modulator is also presented.

2. Reconstruction with Phase-Only Information

An illustration of the proposed 3D object recording and reconstruction system is presented in Fig. 1. The proposed system consists of two subsystems: One is a recording system for digital holograms of 3D objects and the other is an optical reconstruction system by use of phase-only data of a digital hologram.

For the recording system, we use a Mach–Zehnder interferometer architecture as a phase-shifting interferometer. A laser beam is divided into two beams by beamsplitter BS1. A 3D object is illuminated by a collimated laser beam and diffracts this beam. Because 3D objects used in experiments are small enough compared with the CCD size and the object is located far enough from the CCD, we consider the paraxial region where the scalar diffraction theory is valid. The diffraction pattern propagates to a CCD camera that is located at a distance z along the optical axis and is described by using the Fresnel approximation as

$$\tilde{U}(x', y') = A(x', y')\exp\{j\phi(x', y')\}$$

$$= \frac{1}{j\lambda} \iiint U(x, y, z) \frac{1}{z} \exp\{jkz\}$$

$$\times \exp\left\{\frac{jk}{2z}\{(x' - x)^2 + (y' - y)^2\}\right\} \mathrm{d}x\mathrm{d}y\mathrm{d}z, \quad (1)$$

where λ and k are the wavelength and the wavenumber of the illumination, respectively. In Eq. (1), $A(x', y')$ and $\phi(x', y')$ are, respectively, the amplitude and the phase of the complex optical electric field at

the CCD plane. The diffracted beam interferes in line with a reflected plane wave (reference beam) by use of beamsplitter BS2. To reconstruct the complex field of the 3D object as described in Eq. (1) from the digital holograms, we employ a phase-shifting digital holography technique.[7] This technique is effective to remove the conjugate reconstruction even when an in-line hologram is used. To implement phase-shifting digital holography, the reference beam passes through both a half-wave plate and a quarter-wave plate as shown in Fig. 1(a). Phase retardations in the reference beam of 0, $\pi/2$, π, and $3\pi/2$ can be achieved by controlling the positions of the fast and slow axes of the two plates. By use of the resulting four digital interferograms, the complex field of the 3D object in Eq. (1) can be calculated as described in Refs. 7 and 8.

It has already been shown that with computer reconstruction the fully complex field of the 3D object calculated from the digital holograms can be successfully reconstructed. Using the complex field of the hologram, we can reconstruct numerically the 3D object by the Fresnel–Kirchhoff integral, written by

$$R(x, y; z) = -\frac{1}{j\lambda} \iint \tilde{U}(x', y') \frac{1}{z} \exp\{-jkz\}$$
$$\times \exp\left\{-\frac{jk}{2z}\{(x-x')^2\right.$$
$$\left. + (y-y')^2\}\right\} dx' dy'. \quad (2)$$

In the proposed method that uses phase-only information, a reconstructed object is described as

$$P(x, y; z) = -\frac{a}{j\lambda} \iint \exp\{j\phi(x', y')\} \frac{1}{z} \exp\{-jkz\}$$
$$\times \exp\left\{-\frac{jk}{2z}\{(x-x')^2\right.$$
$$\left. + (y-y')^2\}\right\} dx' dy', \quad (3)$$

where

$$a = \left[\frac{\iint |R(x, y; z)|^2 \, dxdy}{\iint |P(x, y; z)|^2 \, dxdy}\right]^{1/2}. \quad (4)$$

Note that the total powers of Eqs. (2) and (3) have been made equivalent by choosing a as indicated in Eq. (4). In the next section we evaluate the quality of the reconstructed 3D object using phase-only information.

Fig. 2. Numerically reconstructed 3D objects of die from (a) a fully complex field, (b) phase-only information, (c) low-pass filtered 3D objects with a mean filter of 11×11 pixels, (d) 21×21 pixels after reconstruction with phase-only information.

3. Numerical Evaluation

To evaluate the error in the reconstructed 3D object, we calculate a normalized root mean square (NRMS) criterion as follows:

NRMS
$$= \frac{\left[\iint \{|R(x, y; z)|^2 - |P(x, y; z)|^2\}^2 \, dxdy\right]^{1/2}}{\left[\iint \{|R(x, y; z)|^2\}^2 \, dxdy\right]^{1/2}}. \quad (5)$$

Note that the total powers in Eqs. (2) and (3) can be made equivalent by adjusting a in Eq. (4).

Digital holograms of the 3D object are recorded optically as shown in Fig. 1(a). Numerically reconstructed 3D objects are evaluated. An argon ion laser operated at a wavelength of 514.5 nm is used as a recording beam. The CCD array consists of 2028×2044 pixels. Each pixel is 9 μm $\times$ 9 μm and has 1024 gray levels (10 bits). We use two 3D objects in the experiments: One is a die with dimensions 5 mm $\times$ 5 mm $\times$ 5 mm, and the other is a screw of similar size. The die and the screw are located at distances of 322 mm and 390 mm from the CCD, respectively.

Figures 2(a) and 2(b) show the numerically reconstructed 3D die object by use of complex information and phase-only information, respectively. Figures 3(a) and 3(b) show the numerically reconstructed 3D screw object by use of complex information and phase-only information, respectively. These figures show that the phase-only information can reconstruct the 3D object successfully. We can also see that speckle noise is an influence on both 3D

reconstructed images. The speckle is a key in this method. It is important to mention that the speckle on the hologram is necessary if we want to reconstruct the object with the phase-only information. The effect of the speckle is to spread the intensity histogram of the hologram, so that the equalization error of the amplitude is reduced.

We evaluate the reconstructed 3D object. The reconstructed 3D objects are low-pass filtered by the mean filter to reduce the speckle noise in the reconstructed image. The low-pass filtered images are presented in Figs. 2(c), 2(d), 3(c), and 3(d). The sizes of the mean filter in Figs. 2(c) and 3(c) are 11×11 pixels, and in Figs. 2(d) and 3(d) are 21×21 pixels. The intensity levels are scaled to enhance the contrast. We can see that speckle noise is removed to a large extent by low-pass filtering. The intensities of the die and the screw reconstructed from the phase-only holograms are compared with the intensities of the objects reconstructed from fully complex holograms, for different mean filtering neighborhoods. Figure 4 shows a NRMS difference as a function of the side length of the mean filter. We can see that the NRMS difference is reduced as the size of the mean filter increases for both 3D objects. In the die 3D object, the error is reduced from 40% to 15%.

Here we discuss the effect of the mean filter and the remaining error in Fig. 4. The mean filter is used to remove the multiplicative speckle noise. Ideally the filter would give the mean of the original object multiplied by the mean of the noise, which is a constant all over the image. Unfortunately, the size of the mean filter that is $N \times N$ is finite. When N is finite we can only obtain an estimate of the mean of the noise. This estimate has a standard deviation that decreases when N increases. This standard devia-

tion is a noise that limits the accuracy that we can expect when we compare two reconstructed images from the phase-only hologram and the fully complex hologram. For a small value of N, this accuracy is low, which is responsible most of the RMS error. When N increases, the RMS error decreases until it is only due to the actual difference between the images. The remaining error is due to the loss of amplitude information of the hologram. We expect that these errors can be decreased by manipulating the phase distribution by use of any error reduction technique, such as simulated annealing or genetic algorithm.[18]

In practical systems, there is a limit on the number of phase levels that can be displayed in phase-only spatial light modulators. Die and screw reconstructions from phase-only information are compared with intensity images reconstructed from fully complex information, for different numbers of quantization levels. For these calculations, we use a mean filter with 11×11 pixels. Figures 5 and 6 show the reconstructed 3D objects without quantization reduction, and with quantization reductions to 4 bits and 1 bit. We can discern the 3D objects even when the phase level of the phase-only spatial light modulators is binary. Figure 7 shows NRMS as a function of the number of phase levels of phase-only information. As few as 16 levels (4 bits) are sufficient to reconstruct the 3D objects without significant loss of detail.

4. Optical Reconstruction

The optical setup to reconstruct 3D objects is shown in Fig. 1(b). A He–Ne laser operated at a wavelength of 632.8 nm is used. After the collimation and the beam-width expansion of the He–Ne laser beam, the beam illuminates a liquid-crystal SLM with 1024×768 pixels. The size of each pixel is approximately 18 μm × 18 μm. This SLM does not have enough pixels to display the complete 2044×2028 pixel phase-only hologram, and so a 1024×768 pixel window is presented. By measuring phase retardation of the SLM in a Mach–Zehnder interferometer, the maximum amount of phase retardation possible with our SLM is 0.6π. The phase retardation is almost linearly proportional to the signal level from the computer. Figures 8 and 9 show the reconstructed 3D die and screw objects. Figures 8(a), 8(b), and 8(c) contain reconstructions with the CCD located at distances of 113 mm, 123 mm, and 133 mm from the SLM, respectively. Figures 9(a), 9(b) and 9(c) show reconstructions at distances of 135 mm, 155 mm, and 165 mm from the SLM, respectively. Figures 8(b) and 9(b) are the most in focus. From these figures, we can see that the die and the screw are reconstructed at different planes. The calculated positions of the in-focus reconstructions are 104 mm and 126 mm, respectively. These errors are caused by a small amount of phase retardation of the SLM, our use of a different readout wavelength, different pixel size, and a readout wavefront not exactly the same as a plane wave.

5. Conclusions

We have proposed a method to reconstruct 3D objects that uses only the phase information of the complex field from digital holograms. Experimental demonstration shows that optical reconstruction of views of 3D objects can be successfully implemented. Numerical evaluation shows that NRMS errors of from 10% to 40% appear due to speckle noise. These errors were caused by the loss of amplitude information

of the hologram. The error could be decreased by manipulation of the hologram's phase distribution. We think that the proposed method is a promising way for a real-time 3D display because the phase-only reconstruction allows us to use commercially available display devices such as liquid-crystal SLMs.
