Abstract

47 Loss of hand function after stroke is a major cause of long-term disability. Hand function
48 can be partitioned into strength and independent control of fingers (individuation). Here
49 we developed a novel paradigm, which independently quantifies these two aspects of
50 hand function, to track hand recovery in 54 patients with hemiparesis over the first year
51 after their stroke. Most recovery of both strength and individuation occurred in the first
52 three months after stroke. Improvement in strength and individuation were tightly
53 correlated up to a strength level of approximately 60% of the unaffected side. Beyond
54 this threshold, further gains in strength were not accompanied by improvements in
55 individuation. Any observed improvements in individuation beyond the 60% threshold
56 were attributable instead to a second independent stable factor. Lesion analysis revealed
57 that damage to the hand area in motor cortex and the corticospinal tract (CST) correlated
58 more with individuation than with strength. CST involvement correlated with
59 individuation even after factoring out the strength-individuation correlation. The most
60 parsimonious explanation for these behavioral and lesion-based findings is that most
61 strength recovery, along with some individuation, can be attributed to descending
62 systems other than the CST, whereas further recovery of individuation is CST dependent.

67

Introduction

68 Human hand function comprises at least two complementary aspects: strength as
69 manifest in a power grip, and control of individual finger movements as in piano playing.
70 The most common observation after stroke is that both are impaired (Kamper and Rymer,
71 2001; Lang and Schieber, 2003). Weakness presents as difficulties in voluntarily opening
72 of the hand, extending the wrist and fingers against resistance, and producing a strong
73 grip (Colebatch and Gandevia, 1989; Kamper *et al.*, 2003). Loss of finger control
74 manifests as inability to either move a single finger while keeping the others immobile, or
75 to make complex hand gestures, both of which impair the ability to perform tasks such as
76 typing or buttoning a shirt (Kamper and Rymer, 2001; Li *et al.*, 2003; Lang and Schieber,
77 2004). When strength does recover after stroke, control often remains impaired, causing
78 lasting disability (Heller *et al.*, 1987; Sunderland *et al.*, 1989). However, the relationship
79 between strength and control after stroke remains poorly understood. Separating the
80 effect of stroke on finger strength versus control is a challenge given that most current
81 clinical measurements conflate weakness with deficits in control. In the current study we
82 therefore sought to develop a new paradigm that could measure these two aspects of hand
83 function separately, and to investigate the relationship between strength and control over
84 the time course of hand recovery after stroke. We were specifically interested to test
85 whether these two components recover in a lawful relationship with each other, or
86 whether they recover independently.

87 Existing behavioral tasks used to assess hand function after stroke, such as the
88 Fugl-Meyer Assessment (FMA) (Fugl-Meyer *et al.*, 1975), the Nine-Hole Peg Task
89 (9NPT) (Sharpless, 1982), and the Action Reach Arm Test (ARAT) (Lyden and Lau,

90 1991), are not designed to separate deficits in strength and control. To isolate these two
91 aspects of hand function it is necessary to remove any obligatory relationship between
92 them (Reinkensmeyer *et al.*, 1992), i.e. derive a control measure that is independent of
93 strength. Intuitively, a rock climber may have stronger fingers than a pianist, but not
94 necessarily superior control of individual fingers.

95 Schieber (1991) devised an individuation task that requires participants to move
96 individual fingers while keeping the non-moving ones stationary. Movements of the
97 passive fingers were used as a measure of loss of control. This paradigm however does
98 not directly track the force relationship between active and passive fingers. In the
99 paradigm used here, we first measured the maximum voluntary contraction force (MVF)
100 that a participant could produce with each finger. We then asked participants to produce
101 isometric forces over four sub-maximal levels with each finger, while keeping the passive
102 fingers immobile. Even controls show involuntary force production (enslaving) on the
103 passive fingers, which increases with the required active force level (Li *et al.*, 1998;
104 Zatsiorsky *et al.*, 2000). The slope of the function of passive finger enslaving on active
105 force thus provides a measure of individuation that is independent of strength.

106 Using this paradigm we tracked the recovery of hand strength and finger
107 individuation in patients over a one-year period after stroke. One possibility is that
108 strength and control recover independently. For example, a patient may remain quite
109 weak but have good recovery of individuation, or a patient may recover a significant
110 amount of grip strength but fail to individuate the digits. Alternatively, recovery may be
111 such that when strength recovers so does individuation, because either they share a
112 common neural substrate or repair processes are proceeding in parallel in separate neural

113 substrates. Finally, lesion analysis allowed us to investigate whether there is any
114 identifiable anatomical basis for any observed dissociation between strength and control
115 deficits.

116

117 **Materials and Methods**

118 *Participants*

119 Fifty-four patients with first-time ischemic stroke and hemiparesis (34 male, 20
120 female; mean age 57.4 ± 14.9 years) were recruited from three centers: The Johns Hopkins
121 Hospital and Affiliates, Columbia University Medical Center, and The University
122 Hospital of Zurich and Cereneo Center for Neurology and Rehabilitation. According to
123 the Edinburgh Handedness Inventory (Oldfield, 1971), Forty-four patients were right-
124 and 10 were left-handed. All patients met the following inclusion criteria: 1) First-ever
125 clinical ischemic stroke with a positive DWI lesion within the previous 2 weeks; 2) One-
126 sided upper extremity weakness (MRC < 5); 3) Ability to give informed consent and
127 understand the tasks involved. We excluded patients with one or more of the following
128 criteria: initial UE FMA > 63/66, age under 21 years, hemorrhagic stroke, space-
129 occupying hemorrhagic transformation, bihemispheric stroke, traumatic brain injury,
130 encephalopathy due to major non-stroke medical illness, global inattention, large visual
131 field cut (greater than a quadrantanopia), receptive aphasia (inability to follow 3-step
132 commands), inability to give informed consent, major neurological or psychiatric illness
133 that could confound performance/recovery, or a physical or other neurological condition
134 that would interfere with arm, wrist, or hand function recovery. Due to the exclusion of
135 aphasic patients, the sample had a bias towards right-sided infarcts (17 left-sided, 37

136 right-sided; for detailed patient characteristics, see Table 1). The lesion distribution is
137 shown in Fig. 5A.

138 We also recruited 14 age-matched healthy control participants (10 male, 4
139 female; mean age 64 ± 8.2 years; all right-handed) at the three centers. There was no age
140 difference between the patient and control samples (two-samples t-test $t(65) = 1.60$, $p =$
141 0.11), nor did the ratio of gender and handedness in the two groups differ (Fisher's exact
142 test yielded results of $p = 0.11$ and 0.75 , respectively). The healthy controls did not have
143 any neurological disorder or physical deficit involving the upper limbs. All participants
144 signed a written consent, and all procedures were approved by Institutional Research
145 Board at each study center.

146

147 *Assessment of finger maximum voluntary contraction and of individuation*

148 To achieve good characterization of hand function recovery, the study design
149 required patient testing at the following five time points post-stroke: within the first 2
150 weeks (W1, 10 ± 4 days), at 4-6 weeks (W4, 37 ± 8 days), 12-14 weeks (W12, 95 ± 10 days),
151 24-26 weeks (W24, 187 ± 12 days), and 52-54 weeks (W52, 370 ± 9 days). Healthy controls
152 were tested at comparable intervals.

153 At each of the five visits, hand function was tested using an ergonomic device that
154 measures isometric forces produced by each finger (Fig. 1A). The hand-shaped keyboard
155 was comprised of ten keys. Force transducers (FSG-15N1A, Honeywell®; dynamic range
156 0-50 N) measured the force exerted by each finger with a sampling rate of 200 Hz. The
157 data were digitized using National Instrument USB-621x devices interfacing with
158 MATLAB (The MathWorks, Inc., Natick, MA) Data Acquisition Toolbox. Visual stimuli

159 of the task were presented on the computer monitor, run by custom-written software
160 using the Psychophysics Toolbox (Psychtoolbox) in MATLAB environment (Brainard,
161 1997).

162 Participants were seated in a comfortable chair, facing the computer monitor.
163 During the entire procedure, participants rested their two hands on the keyboards with
164 each finger on top of a key, their wrists were strapped and fixed on a wrist-rest, and their
165 forearms extended and supported by foam arm rests. Throughout the experiment, ten
166 vertical gray bars representing the ten digits appeared on top of the screen, and another
167 ten vertical bars below them instructed the amount of force to be exerted; the required
168 force level for each finger in each trial was indicated by the height of green filling the
169 vertical gray bar (Fig. 1B). Participants could monitor the force exerted by all ten digits
170 in real time by the heights of ten small white horizontal lines moving along the vertical
171 force bars.

172 Two separate aspects of finger function were tested: maximal voluntary
173 contraction force (MVF) and individuation. During each MVF trial, participants were
174 asked to depress one finger at a time with its maximum strength, and maintain the force
175 level for two seconds. The participants could press with the other fingers as much as they
176 wanted as long as maximal force on the instructed finger was achieved. To signal the
177 start, one force bar corresponding to the instructed finger turned to green. MVF was
178 measured twice per digit.

179 In the individuation task, participants had to press each individual finger at a sub-
180 MVF level of force, while at the same time keeping their other fingers immobile on the
181 keys. Four target force levels were tested for each digit: 20%, 40%, 60%, and 80% of

182 MVF, and each level was repeated 4 times. On each trial, a section of a force bar
183 corresponding to the finger to be depressed turned to green, with the height of the middle
184 black line representing the target force level and the green region around the middle line
185 representing the 25% upper and lower bounds around the target force level (Fig. 1B). The
186 participants were asked to bring the corresponding white line up to the force target line,
187 and maintain the force level for 0.5 sec. If no response passing the force threshold of 2.5
188 N was detected within two seconds, the trial was terminated.

191 -----

192

193 ***Data analysis***

194 *Strength Index.* The 95th percentile of the force traces produced across all the
195 sampled force data points during the finger depressing period in each trial was calculated,
196 and then averaged across the two MVF trials to obtain a measure of MVF for each digit.
197 If the force achieved on one of the two trials was below 60% of the force produced on the
198 other trial, only the larger force was taken as MVF measure (6.5% of the trials were
199 excluded). The overall strength of the hand was then calculated by averaging across all
200 five digits. To account for the large inter-subject variability in pre-morbid strength, all
201 MVF values were normalized by MVF of the non-paretic hand at W52; estimated using a
202 mixed-effects model (see below). This normalization provided a Strength Index, with a
203 value close to 1 implying full recovery. For control participants, one of the hands was
204 randomly assigned to take the role as the “non-paretic” hand for normalization purposes.

205 To account for possible laterality effects, the assignment followed the ratio of dominant
206 to non-dominant hands found in the patients (~10:4).

207 *Individuation Index.* If individuation was perfect, a participant should be able to
208 press the instructed finger without any force being exerted by the passive fingers. For
209 each time bin t (5ms) in a single trial, we calculated the enslaved deviation of the force of
210 each passive finger ($F_{t,j}$) from baseline force (BF_j), which was assessed at the beginning
211 of the trial when a go cue was presented. This deviation was averaged over all bins (T) in
212 the force trace from the go cue to the end of the trial:

$$213 \quad \text{meanDevP} = \frac{1}{T} \sum_{t=0}^T \sqrt{\sum_{j=\text{passive}} (F_{t,j} - BF_j)^2} \quad (1)$$

214 where the index j denotes the j th passive finger. A higher *mean deviation* indicates more
215 enslaving of the passive finger.

216 For a measure of individuation ability, it is necessary to account for the
217 relationship between the force deviations of the passive fingers to the force produced by
218 the active finger. Consistent with previous reports (Li *et al.*, 1998), we observed that
219 enslaving of passive fingers increases with higher active force (Fig. 1E). The relationship
220 between the two variables was close to linear. Thus a good measure of individuation is
221 how much the mean deviation in passive fingers increases for each N of force produced
222 by the active finger. The ratio of these two variables can be reliably estimated by fitting a
223 regression line without an intercept. To reduce the influence of outliers, we used robust
224 regression (Holland and Welsch, 1977). The *slope* of the regression line reflects
225 individuation ability: The smaller the slope, the better the individuation ability, with the
226 best case being 0, which means keeping the passive fingers perfectly immobile at any
227 active force level. Because the regression slope is bounded by zero (as mean deviation is

228 positive), its distribution is positively skewed. To allow for the use of parametric
229 statistics the slope was log-transformed. The sign of this value was inverted, so that
230 higher values would correspond to better function. The negative log slope was calculated
231 separately for each active finger and then averaged across fingers, giving the
232 Individuation Index for the hand. As was done for the Strength Index, the Individuation
233 Index was normalized by each participant's "non-paretic" (randomly assigned for healthy
234 controls) hand's W52 value as estimated by mixed-effect model to provide the final
235 Individuation Index for each hand.

236 *Reliability measures for Strength and Individuation.* To determine the reliability
237 of the Strength and Individuation Indices, split-half reliabilities for both measures were
238 calculated. For the Strength Index, we used one MVF trial per digit in each split. We then
239 calculated the (normalized) Strength Index on each half of the data independently in the
240 same way as for the full data set. The correlation between the two halves across all
241 available sessions and patients was then used as a measure of split-half reliability.

242 For the Individuation Index, data from each finger was split such that two trials
243 per force level were assigned to each split. The slope of the regression line and
244 Individuation Index was then calculated separately for each split, and normalized in the
245 same way as MVF. We repeated the split multiple times, each time assigning trials at
246 random and then averaging the split-half correlations from all splits for more reliable
247 results.

248 Split-half correlation will underestimate reliability because the variability in each
249 half will be higher than the variability when using all the data (Guttman, 1945). The
250 estimate was therefore corrected using the formula

251
$$r_{full} = \frac{2r_p}{r_p + 1} \quad (1)$$

252 where r_p is the correlation between the two splits.

253 *Stability analysis.* To assess whether the relative deficits in strength and
254 individuation remained stable across different testing time points, or whether there was
255 meaningful biological change, we calculated the correlation of each measure across
256 neighboring testing time points. One caution when interpreting these correlations is that
257 the correlation between two repeated measures will always be smaller than 1 even if the
258 underlying factor did not change. This is because both measures contain some
259 measurement noise. To account for this effect, we used the reliability (r_{full}) of the measure
260 at each time point to compute a noise ceiling, which indicates how much two repeated
261 noisy measurements should correlate with each other if the underlying variable were
262 perfectly stable:

263
$$r_{noise\ ceiling} = \sqrt{r_{full}^1 * r_{full}^2} \quad (2)$$

264 *Statistical analysis and handling of missing data.* Data analysis was performed
265 using custom-written MATLAB and R (R Core Team, 2012) routines. The analysis
266 focused on the Strength and Individuation Indices, but was also performed on standard
267 clinical assessments, FMA, ARAT, and Dynamometry strength measures.

268 The requirement for 5 post-stroke time-points was ambitious, with the
269 consequence of some missing sessions. A total of 21 patients completed all five time-
270 points; on average each patient completed 3.6 sessions; thus a total of 75% of the possible
271 sessions were acquired. To optimally use all the measured data, we employed linear
272 mixed-effect models. The model specifies joint distributions for observed and missing

273 observations – then the parameters of those distributions can be estimated by maximizing
274 the likelihood of the data under the model. There are several advantages to this approach.
275 First, all the available data can be used and there is no need to exclude any data.
276 Secondly, it avoids the statistical pitfalls inherent in “filling in” missing observations
277 with point estimates. Linear mixed-effect models implemented in the *lme4* package in R
278 (Bates *et al.*, 2014) were used to test the changes in these measures over time. Participant
279 was taken as a random factor. Time Point (five time points from W1-W52) and Hand
280 Condition (paretic, non-paretic, and control) were considered fixed factor. The model was
281 applied to control and patient data separately. Mixed-effect model estimation for group
282 summary statistics was implemented in MATLAB using the restricted maximum
283 likelihood method (Laird and Ware, 1982).

284 *Modeling the time-invariant function.* To test the hypothesis that there is time-
285 invariant relationship between strength and individuation, a two-segment piecewise linear
286 function was fitted. This function had four free parameters: the intercept, the location of
287 the inflection point, and the slope on each side of the inflection point. Let x be the
288 predictor with two segments separated by a constant breakpoint c , $x_1 \leq c$ and $x_2 \geq c$. The
289 linear functions for each segment are

$$\begin{aligned} y_{1i} &= b_{10} + b_{11}x_{1i} + e_{1i} \\ y_{2i} &= b_{20} + b_{21}x_{2i} + e_{2i} \end{aligned} \quad (3)$$

291 The two pieces can be joined at the breakpoint constant c by setting $y_{1i} = y_{2i}$, yielding

$$\begin{aligned} b_{20} &= b_{10} + (b_{11} - b_{21})c \\ y_{2i} &= b_{10} + (b_{11} - b_{21})c + b_{21}x_{2i} + e_{2i} \end{aligned} \quad (4)$$

293 Putting the two pieces together, we have the full model

294
$$y_i = a + b_1 x_i \cdot I(x_i \leq c) + [(b_1 - b_2)c + b_2 x_i] \cdot I(x_i \geq c) + e_i \quad (5)$$

295

296 where $I(\cdot)$ is an indicator variable, coded as 1's or 0's to indicate the condition satisfied.

297 The maximum-likelihood (or least-squares) estimates of these parameters were
298 obtained by using the non-linear optimization routine `fminsearch` in Matlab. Leave-one-
299 out cross-validation (Picard and Cook, 1984) was used to evaluate whether this function
300 changed systematically over time, or whether it was time-invariant. The time-invariant
301 model with fixed parameters across all time points was compared with a more complex
302 model that allowed free parameters for each time point. Cross validation provides an
303 unbiased estimate of a model's ability to predict new data and automatically penalizes
304 models that are too complex.

305

306 ***Lesion Imaging and Quantification***

307 *Imaging acquisition and lesion distribution.* Images were acquired using 3T MRI
308 Phillips scanner and consisted of two DTI datasets (TR/TE=6600/70ms, EPI, 32 gradient
309 directions, $b=700$ s/mm²), and an MPRAGE T1-WI (TR/TE=8/3.8ms) sequence. FOV,
310 matrix, number of slices, and slice thickness were 212×212 mm, 96×96 (zero-filled to
311 256x256), 60, 2.2mm, respectively, for DTI; and 256×256mm, 256×256, 170, 1.2mm,
312 respectively, for T1-WI. The DTI were processed using DtiStudio (www.MRISStudio.org)
313 and the mean diffusion-weighted image (DWI) was calculated.

314 To define the boundary(s) of the acute stroke lesion(s) for each participant, a
315 threshold of >30% intensity increase from the unaffected area in the first-time-point
316 diffusion-weighted image (DWI) extracted from DTI images was applied. A

317 neuroradiologist (AVF), blind to the patients' clinical information, manually modified the
318 boundary to avoid false-positive and false-negative areas on RoiEditor
319 (www.MRIstudio.org). The definitions were double checked by a second rater (MB). The
320 averaged lesion distribution map across all patients in the current study is shown in Fig.
321 5A. For the seven patients who had no DTI in the acute phase, lesion definition was
322 performed on the clinical DWI, which has lower resolution (1x1mm in plane, 4-6mm
323 thickness). Analysis of white matter ROIs, including the CST, was not performed in
324 patients.

325 *Region of interest definition and lesion quantification.* The focus was on two
326 ROIs: 1) The cortical gray matter of the hand area in the motor cortex; 2) The entire CST
327 superior to pyramids, identified by probabilistic maps derived from tract tracing methods
328 (see below). The percentage volume affected in these regions was correlated with our
329 main outcome measures, the Strength and Individuation Indices.

330 To defined the CST, each image and respective lesion were mapped to a single
331 subject adult template, the JHU-MNI atlas (Mori *et al.*, 2008; Oishi *et al.*, 2008, 2009,
332 2010), using affine transformation followed by dual channel (both b0 and FA maps) large
333 deformation diffeomorphic metric mapping (LDDMM) (Ceritoglu *et al.*, 2009). This
334 template has already been segmented into more than 200 regions of interest (ROIs), and
335 contains probabilistic maps of multiple tracts, including the CST (Zhang *et al.*, 2010). To
336 ensure accurate mapping, we first used "artificial" images, in which the stroke area was
337 masked out and substituted by the normal images from the contralateral hemisphere. This
338 helped to minimize inaccuracies caused by the focal changes in intensity due to the
339 stroke. The white matter beneath the cortex was identified with a FA-threshold of 0.25.

340 The segmentation defined in the template, as well as a probabilistic map of the CST, were
341 then “back-warped” by each subject's deformation field to generate individualized
342 parcellations.

343 A different approach was used to define an ROI that would encompass the hand
344 area of the primary motor cortex. The hand ROI was defined on the average
345 reconstruction of the cortical surface available in the Freesurfer software (Dale *et al.*,
346 1999), selecting Brodmann area (BA) 4 based on cytoarchitectonic maps (Fischl *et al.*,
347 2008). To restrict the ROI to the area of motor cortex involved in the control of the upper
348 limb, we only included the area 2.5 cm dorsal and ventral of the hand knob (Yousry *et*
349 *al.*, 1997). The defined ROI was then morphed into MNI space using the surfaces of the
350 age-matched controls. These ROIs were then brought to the JHU-MNI atlas (in which
351 each subject and respective stroke area were already mapped, as mentioned above) using
352 T1-based LDDMM to construct a probabilistic map of the hand area. The probabilistic
353 map was threshold of 70% to calculate percent-volume affected.

354

355 ***Clinical assessments***

356 At each visit, all participants were also assessed with several clinical outcome
357 measures. Here we report data for FMA and ARAT. Grip strength was assessed with a
358 Jamar hydraulic hand dynamometer (Sammons Preston, Rolyan, Bolingbrook, IL, USA).
359 Strength in the first dorsal interosseous (FDI) and the flexor carpi radialis (FCR) muscles
360 was assessed using a hand-held dynamometer (Hoggan MiroFET2 Muscle Tester, Model
361 7477, Pro Med Products, Atlanta, GA, USA).

362

363

Results

364 A total of 54 patients with acute stroke and 14 healthy controls underwent five
365 testing sessions over a one-year period. Data in the final analysis comprised a total of 251
366 sessions tested in 53 patients (one patient only completed two blocks of the task, and was
367 thus removed from further analysis) and 14 controls. Forty-one patients and twelve
368 controls completed ≥ 3 sessions. The data were 75% complete, with 25% of the sessions
369 were missing or unusable. Non-tested sessions were treated as data missing at random
370 and all available data were used in the statistical analysis (see Materials and Methods).

371

The Strength and Individuation Indices were reliable.

372
373 Finger strength was assessed by measuring the maximum voluntary force (MVF)
374 for each finger separately and then averaged across all fingers for each hand. MVF for
375 healthy controls had an average value of 20.35 N (SD = 8.56) for the dominant hand, and
376 22.76 N (SD = 6.89) for the non-dominant hand. The normalized Strength Index for the
377 controls' dominant hand was 1.00 (SD = 0.19), and non-dominant hand was 1.17 (SD =
378 0.25). For patients, the mean for the non-paretic hand was 0.93 (SD = 0.20), and for the
379 paretic hand it was 0.59 (SD = 0.38). For the paretic hand, Strength Indices did not
380 correlate with age ($r = 0.04$, $p = 0.75$), nor were they affected by gender ($t(51) = 0.98$, $p =$
381 0.33) or handedness ($t(51) = 0.10$, $p = 0.92$).

382 To assess individuation, we measured the amount of involuntary force changes
383 (enslaving) on the passive fingers for different levels of force production with the active
384 fingers. The amount of enslaving systematically increased at higher force levels (Fig.
385 1E). Loss of control at increasing force levels has been shown for the angular position of

386 the fingers (Li *et al.*, 1998) and the reaching radius of the arm after stroke (Sukal *et al.*,
387 2007; Ellis *et al.*, 2009). To control for this relationship, we characterized the
388 Individuation Index as the slope of the function between active force and passive
389 enslaving. Lower values of Individuation Index indicate more impaired individuation.
390 Healthy, age-matched controls showed, on average, a normalized Individuation Index of
391 1.00 (SD = 0.18). This refers to a slope of 0.087 (SD = 0.046), meaning that for a finger
392 press of 10N the mean deviation of the passive fingers was 0.69N. As was the case for
393 Strength, Individuation Indices in the paretic hand were not correlated with age ($r = 0.16$,
394 $p = 0.26$), nor affected by gender ($t(51) = 0.17$, $p = 0.86$) or handedness ($t(51) = 0.34$, $p =$
395 0.74).

396 When introducing a new instrument, it is important to first establish its reliability,
397 i.e., the accuracy with which true differences between subjects and changes within
398 subject can be determined. We therefore split the data for each session in half, calculated
399 Strength and Individuation Indices on these two independent data sets, and correlated the
400 resultant scores across patients and sessions (see methods). The adjusted split-half
401 reliability across all patients and weeks for the Strength Index was $r_{full} = 0.99$ and 0.94
402 for the paretic and non-paretic hands respectively, and $r_{full} = 0.89$ for controls, which
403 indicates good reliability. The adjusted split-half reliability of the Individuation Index of
404 all patients was $r_{full} = 0.99$ and 0.93 for the paretic and non-paretic hands respectively,
405 and for controls was $r_{full} = 0.97$.

406 Consistent with our effort to construct an individuation measure that is
407 independent of strength, the overall correlation between Individuation and Strength in

408 controls was very low for both controls ($r = -0.19, p = 0.51$), and for patients' non-paretic
409 hand ($r = 0.17, p = 0.21$).

410

411 ***The Strength and Individuation indices correlated with standard clinical measures.***

412 The Strength and Individuation Indices were compared with existing clinical measures:
413 the Fugl-Meyer (a measure of impairment) and ARAT (a measure of activity) Table 2
414 shows the correlations for all four measures obtained from the paretic hand across all
415 time points. Overall, all correlations were very high ($\max p = 1.21 \times 10^{-26}$), indicating that
416 all the measures could detect severity of the hand function deficit. The correlation in the
417 patients between the two clinical measures was 0.91, whereas the correlation between the
418 Strength and Individuation Indices was 0.73, a significant difference ($z = 5.62, p =$
419 2.0×10^{-8} , using z-test with $N = 180$ (Fisher, 1921)). Given comparable reliabilities for all
420 measures, this difference unlikely results from measurement noise – rather it suggests
421 that our Strength and Individuation Indices measure two different aspects of the hand
422 function, whereas the clinical scales tend to capture a mixture of strength and control.
423

424 ***Recovery of strength and individuation occurred mainly in the first three months after***
425 ***stroke.***

426 We first examined the time courses of recovery for strength and individuation in
427 the paretic hand. If the two observed variables change in parallel, their recovery may or
428 may not be mediated by the same underlying process. A difference in the time courses,
429 however, would provide a strong hint of separate recovery processes for strength and
430 individuation.

431 For both measures, most of the recovery appeared to occur within the first 12
432 weeks after stroke (Fig. 2A-B). A model with a fixed effect of Week and a random effect
433 of Subject was built to evaluate this statistically. An effect of Week was tested with a
434 likelihood ratio test against the null model with the random effect only. Results indicate
435 that both the Strength and Individuation Indices significantly improved over time
436 (Strength: $\chi^2 = 47.65$, $p = 5.10 \times 10^{-12}$; Individuation: $\chi^2 = 18.58$, $p = 1.63 \times 10^{-5}$). Paired *t*-
437 tests between adjacent time points showed significant improvement (after Bonferroni
438 correction) of the Strength Index up to week 12; whereas the Individuation Index only
439 showed a significant improvement between weeks 4-12 (see detailed statistics in Fig. 2A-
440 B). A similar recovery curve was found for the standard clinical measures of motor
441 function (detailed statistics in Fig. 3).

442 To directly compare the time courses of between the two indices at the early stage
443 of recovery, we *z*-normalized scores of the two variables and then investigated the change
444 in the scores for the time intervals W1-4 vs. W4-12 (Fig. 2C). This analysis suggests that
445 strength may recover mostly in the first four weeks, while individuation recovery may
446 occur equally in both time periods. Repeated-measures ANOVA over *z*-scores for
447 Strength and Individuation Indices during the two time intervals yielded a significant
448 interaction ($F(1,25) = 6.82$, $p = 0.015$, Fig. 2C). Thus, despite overall similarity, there
449 was a significant difference in the time courses of recovery of strength and individuation,
450 with strength showing faster early recovery.

451 That most improvement in both strength and individuation occurred over the first
452 12 weeks is also apparent in the correlations between adjacent testing time points for each
453 variable across individuals (Fig. 2D). The correlation between weeks 1 and 4 for the

454 Individuation Index was significantly lower than it was for subsequent time points (W1-4
455 vs. W24-52: $z = -4.23$, $p = 0.000023$), and this difference for Strength Index was
456 marginally significant ($z = -1.83$, $p = 0.067$), using z -test with $N = 28$ and 33 (Fisher,
457 1921). Thus, the position of the patients on the mean recovery curve changed more
458 during the first 4 weeks than in the last 6 months. This correlation difference cannot be
459 attributed to measurement noise, as both measures had stable reliabilities at all time
460 points (dashed line). Instead, the lack of stability of these measures during early recovery
461 is indicative of meaningful biological change.

462

463

Insert Figure 2

464

465 Consistent with previous findings (Noskin *et al.*, 2008), the non-paretic hand also
466 showed mild impairment in the first month after stroke. A likelihood ratio test of the
467 mixed-effect model showed a significant effect of Week for Strength ($\chi^2 = 7.86$, $p =$
468 0.0051), and a more subtle effect for Individuation ($\chi^2 = 4.12$, $p = 0.042$) (Fig. 2A-B).
469 This increase in performance is unlikely to be related to a general practice effect, because
470 the Strength Index in healthy controls decreased slightly over time ($\chi^2 = 4.54$, $p = 0.033$),
471 perhaps due to reduced effort, whereas the Individuation Index for healthy controls was
472 maintained at a similar level over the whole year ($\chi^2 = 0.33$, $p = 0.56$).

473

474

Insert Figure 3

475

476 In summary, most recovery of both strength and individuation occurred in the first
477 three months after stroke, with stabilization of recovery around 3-6 months. The data also
478 suggest a slight difference in the time course, with strength recovering faster than
479 individuation in the first month.

480

481 ***Evidence for a time-invariant relationship between strength and control.***

482 The time course analysis only provides weak evidence for partial independence of
483 the recovery processes for strength and individuation. Therefore we undertook a closer
484 examination of the relationship between the two variables at each testing time-point (Fig.
485 4A). Although patients tended to move from the lower left corner to the upper right
486 corner of this space over the time course of recovery, the overall shape of the strength-
487 individuation impairment relationship seemed to be remarkably preserved across weeks.
488 At lower strength levels, there was a clear correlation between strength and individuation;
489 whereas once above ~60% of normal strength level, the two variables were unrelated,
490 producing a distinct curvilinear shape for the overall function (Fig. 4B).

491 To formally test the time invariance suggested by visual inspection, we first found
492 a function to describe the strength-individuation relationship. We used data from all time
493 points and evaluated the goodness of fit of a piecewise function with two linear segments
494 connected at an inflection point, using leave-one-out cross-validation (see Materials and
495 Methods). Cross-validation automatically penalizes models that are too complex. This
496 functional form gave us a good fit to the data (cross-validated $R^2 = 0.53$, Fig. 4B). We
497 also explored first- to fourth- order polynomial functions. All four models resulted in a
498 worse fit (cross-validated $R^2 < 0.49$) than the piece-wise linear function.

499 We then tested for “time-invariance” of this strength-control relationship, that is,
500 whether the function shape changed across weeks. Again, using leave-one-out cross-
501 validation, the time-invariant model with fixed parameters across all weeks was
502 compared with a model that allowed the parameters to change for each week (time-
503 varying model). The cross-validated R^2 for the time-varying two-segment piecewise
504 linear function was 0.45, a worse fit than the time-invariant model.

505 These results suggest that there is a time-invariant recovery relationship between
506 strength and individuation after stroke, which consists of two parts: up to a certain level
507 of strength (60.7% of non-paretic hand), the Strength and Individuation Indices are
508 strongly correlated ($r = 0.74$, $p = 6.61 \times 10^{-18}$); after strength exceeds this threshold, the
509 two variables are no longer correlated ($r = -0.17$, $p = 0.11$; Fig 4B). This lack of
510 correlation cannot be attributed to a ceiling effect for the Individuation Index, because for
511 both patients and controls there was still a considerable variability, and the reliability of
512 Individuation Index was very high. This indicates that our measure has enough dynamic
513 range and sensitivity to detect inter-individual differences even in the healthy population.

514 -----

515 Insert Figure 4

516 -----

517 Overall, our results suggest that recovery can be captured as traversal along a
518 time-invariant function relating strength and individuation. Differences in recovery arise
519 because patients vary substantially in the distance they move along this function: some
520 patients with initial severe impairment made a good recovery, moving past the inflection
521 point of 60.7% strength (exemplified by the yellow dot in Fig. 4A). Other severely

522 impaired patients failed to reach the inflection point (red dot in Fig. 4A). Finally, some
523 mildly impaired patients started off beyond the inflection point and showed a good range
524 of individuation capacity.

525

526 *A second process contributed additional recovery of finger individuation.*

527 The fact that recovery of both strength and individuation could be captured by a
528 single time-invariant function that relates them is compatible with the hypothesis of a
529 single underlying process that drives recovery of both aspects of hand function. It is
530 possible, however, that an additional process injects further recovery, which determines a
531 patient's position relative to the mean recovery function in strength-individuation space.
532 If such a process exists, a given patient should occupy a consistent position above or
533 below the mean recovery function across time points.

534 To test this hypothesis we investigated the residuals of the Individuation Index for
535 each patient at each time point after subtracting out the mean two-segment piecewise-
536 linear recovery function. If the variability around this mean function were purely due to
537 noise, we should observe no consistent week-by-week correlation between residuals for
538 each patient. Alternatively, if the residuals were to be correlated across weeks, it would
539 indicate that some patients were consistently better at individuation than that predicted
540 from the function, and others were consistently worse, suggesting an additional factor
541 mediating individuation recovery (black arrows in Fig. 6).

542 Correlations of residuals from adjacent time points across patients were initially quite
543 low. However, from week 4 onwards, most patients' distances from the mean function
544 remained stable (Fig. 4C-D). This consistent structure in residuals provides evidence for

545 an extra factor contributing to recovery of individuation. The consistent pattern of
546 residuals at later time points could not be attributed to pre-morbid inter-individual
547 differences, because both the Strength and Individuation Indices were normalized to the
548 non-paretic hand. The low week-by-week correlations between early time points argues
549 that the later correlations do not simply reflect sparing of a particular neural system after
550 the stroke. If this had been true, the correlation between the Individuation residuals
551 should have remained constant across all time points. Furthermore, the lower early
552 correlation cannot be attributed to measurement noise, as reliabilities for the early
553 measurement points were high (Fig. 4D). Rather, the initially low but then increasing
554 correlation indicates an additional recovery process operating above the lower bound of
555 the strength-individuation function (Fig. 6). This process is mostly active in the first three
556 months after stroke and determines how well individuation recovers above that expected
557 from the time-invariant recovery function.

558

559 ***Lesions involving motor cortex and the corticospinal tract correlated more with***
560 ***individuation than strength.***

561 To investigate the underlying neural substrates of recovery processes, we
562 correlated the location and size of the lesion with the Strength and Individuation Indices.
563 We were especially interested in the particular role of the corticospinal tract (CST).

564 While both corticospinal and corticoreticular projections originate in part from the
565 precentral gyrus and are intermingled to some degree, cortical projections to the reticular
566 formation have a more widespread bilateral origin from other pre-motor areas (Keizer
567 and Kuypers, 1989), whereas direct corticospinal projections to ventral horn neurons

568 primarily arise from the anterior bank of the precentral gyrus/central sulcus, i.e. “new
569 M1” (Rathelot and Strick, 2009; Witham *et al.*, 2016). We therefore predicted that extent
570 of the damage to the hand area of the primary motor cortex, and to the white matter ROI
571 that characterizes the most likely course of the CST (see Materials and Methods) would
572 correlate more with Individuation, and less with Strength. Furthermore, lesions in these
573 areas should correlate with individuation recovery over and above the level expected
574 from the mean recovery function.

575 As hypothesized, the extent of involvement by the lesion of the cortical hand area
576 correlated significantly with the Individuation Index at all time points. For the CST, all
577 correlations were significant after week 1 (Fig. 5B-D). While both lesion measures also
578 correlated with the Strength Index, these correlations were weaker (repeated-measures
579 ANOVA showed a significant main effect for behavioral measure ($F(1,3) = 146, p =$
580 0.001). This difference was not due to measurement noise, as the Strength and
581 Individuation Indices had comparable reliabilities. Furthermore, percent lesion
582 involvement also significantly correlated with the Individuation Index, after accounting
583 for the average Strength-Individuation relationship ($p < 0.05$ for correlations after week
584 24 for cortical hand area, and after week 12 for CST). Indeed, at W52, the correlations
585 with the residuals were as high as with the Individuation Indices themselves ($r = 0.61$ vs.
586 $r = 0.57$ for the cortical hand area, $r = 0.51$ vs. $r = 0.54$ for the CST). Together these
587 results suggest that Individuation recovery is most heavily determined by the sparing in
588 the hand area of the primary motor cortex and of direct CST projections, while strength
589 recovery may also depend on other spared descending pathways.

613

In a large-scale longitudinal study, we tracked recovery of two independent behavioral components of hand function: strength and finger control. Patients were tested at five time points over a one-year period after stroke, using a novel paradigm that separately measures maximum voluntary contraction force (a measure of strength) and finger individuation ability (a measure of control), and crucially controls for any obligatory dependency between these two measures. This approach allowed us to determine how recovery of strength and control interrelate. Our main question was to ask whether there is a causal relationship between strength and control at the level of recovery mechanisms, after the two variables had been experimentally uncoupled. If they are truly dissociable, then hypothetically patients could show perfect control of individual fingers, even with significant weakness (except for complete hemiplegia, in which case no individuation measure would be obtainable).

We showed that involuntary movements in passive fingers (enslaving) increased with the level of force production of the active finger. This phenomenon is analogous to what Dewald and colleagues (Sukal *et al.*, 2007; Ellis *et al.*, 2009) have described for the paretic arm: a decrease in arm reaching workspace as the force requirement to resist gravity increases. We showed that the ratio of enslaving and active force can account for this dependency and thereby provides a sensitive measure of finger control independent of the level of force deficit.

614 We first examined the time courses of recovery for strength and individuation.
615 Consistent with what has been described with traditional clinical scales (Duncan *et al.*,
616 1992; Jørgensen *et al.*, 1995; Krakauer *et al.*, 2012), both measures showed most
617 recovery over the first three months after stroke. This similarity between the time courses
618 does not, however, necessarily imply that recovery of strength and individuation is
619 dependent on a single underlying neural substrate or mechanism. It remains possible that
620 recovery of these two components occurs in parallel because of commonalities in basic
621 tissue repair mechanisms post-ischemia but they are nevertheless independent modules.
622 Indeed, we found a small but robust difference in the time course of recovery of strength
623 compared to control: finger strength showed a faster rate of change compared to
624 individuation over the first month. This finding raises the interesting possibility that
625 different neurological substrates underlie recovery of strength and individuation.

626 Closer examination of the two variables revealed a time-invariant non-linear
627 relationship between strength and individuation in the paretic hand. This function has two
628 distinct parts: individuation and strength were highly correlated below a strength
629 threshold of ~60% of the non-paretic side; beyond this point, they were uncorrelated. The
630 shape of this function remained the same across all time points. Recovery of hand
631 function could be characterized as movement along this invariant function: patients with
632 good recovery traveled further along the function, whereas patients with poor recovery
633 remained in the first segment. The strong correlation between strength and individuation
634 for severely impaired patients is consistent with a single system mediating recovery of
635 both. Indeed, in our cohort there was no patient with relatively good strength but severe
636 impairment of individuation, which also suggests that recovery of finger control

637 correlates with recovery of strength in patients with severe hemiparesis. However, two
638 pieces of behavioral evidence suggest that strength and finger control might rely on
639 partially separate mechanisms of recovery. First, a correlation between strength and
640 individuation was absent for the subset of well-recovered patients – i.e. patients with a
641 Strength Index above 60%. This breakdown in correlation cannot be attributed to a
642 ceiling effect for Individuation. Secondly, analysis of the residuals around the mean
643 recovery function revealed that patients differed consistently in the amount of their
644 individuation recovery relative to the level predicted by their strength recovery. Notably,
645 their positioning relative to the mean recovery curve seemed to be set early in the
646 recovery process and then remained relatively stable at later time points.

647 -----
648 Insert Figure 6
649 -----

650 Thus we propose that recovery of strength and individuation relies on at least
651 partially separate systems. One system primarily contributes strength, but also has some
652 limited control capacity. The isolated contribution of this system would determine the
653 lower bound of the data points in the strength-individuation plot (dashed line in Fig. 6):
654 when a patient regains some strength, he or she automatically regains a limited amount of
655 control with it. However, the amount of individuation is limited and does not increase
656 above a certain level. This would explain both the strong correlation between strength
657 and individuation for the severely impaired patients, and the fact that no patient occupied
658 the lower right corner of strength-individuation space, i.e. no patients had good strength
659 but minimal control.

660 The second system would then add additional control capacities to the first system
661 (vertical arrows in Fig. 6). Patients with a strong contribution from this second system
662 may gain full recovery of individuation; patients with no or only partial contribution from
663 the second system may recover completely in strength, but not in individuation.
664 Importantly the recovery of this second system also occurs early after stroke,
665 subsequently a patient's relative position above or below the mean recovery function
666 remains relatively fixed (Fig. 4D).

667 The lesion analysis adds support to the two-systems model for recovery suggested
668 by the behavioral data. A wealth of evidence in humans and non-human primates
669 implicates the role of CST in finger control, especially the monosynaptic cortico-
670 motoneuronal connections originating from “new” M1 (Lawrence and Kuypers, 1968;
671 Porter and Lemon, 1993; Rathelot and Strick, 2009). Notably, these connections do not
672 generate high levels of force but rather finely graded forces riding on top of larger forces
673 (Maier *et al.*, 1993). Consistent with this idea, lesions in the gray matter of the hand areas
674 in M1- the main origin of corticospinal projections- as well as the CST, correlated more
675 with impaired individuation than with strength.

676 In contrast, finger strength may rely on other neural pathways, including the
677 reticulospinal tract (RST), which can support strength and gross movements (Buford and
678 Davidson, 2004; Davidson and Buford, 2004). Although the RST has been found to
679 participate in some degree of finger control, its functional range is limited and biased
680 towards flexor muscles (Riddle *et al.*, 2009; Baker, 2011).

681 Recovery after stroke is likely to result from the dynamic interplay between the
682 CST and other descending pathways, particularly the RST. In this scenario, the

683 correlation between strength and control at low levels of strength may represent the state
684 of both the residual CST and of cortical projections to reticular nuclei in the brainstem. In
685 this framework, recovery along the lower bound of the invariant function would represent
686 the contribution of the RST and other non-CST descending pathways. Those patients
687 with less damage to the CST would consistently ride above this function.

688 The dichotomy proposed here may be too simplistic. While the origin of the
689 corticoreticular inputs is more diffuse (Keizer and Kuypers, 1989) and bi-laterally
690 organized (Buford and Davidson, 2004; Sakai *et al.*, 2009; Soteropoulos *et al.*, 2012),
691 many of the projections to the reticular formation arise from the primary motor cortex
692 (Catsman-Berrevoets and Kuypers, 1976; Jones and Wise, 1977). Thus, our lesion ROIs
693 will have included the corticoreticular tract to some degree, possibly explaining the
694 lower, but nevertheless significant correlation with strength. Furthermore, it is very likely
695 that direct corticospinal projections contribute to hand strength to some degree.

696 Interestingly, there was a small degree of impairment, especially in strength, in
697 the hand ipsilesional to the stroke. This finding confirms previous reports of deficits in
698 the non-paretic hand using clinical scales, e.g. muscle weakness measured by
699 dynamometry (Colebatch and Gandevia, 1989), and dexterity measured with the Nine
700 Hole Peg Test (9HPT) in (Noskin *et al.*, 2008). This ipsilesional impairment is consistent
701 with positing a strength role for the RST because it projects bilaterally.

702 A limitation of the current study is that the paradigm is designed to assess
703 weakness and enslaving in finger flexors, but not extensors. Because finger extensors
704 play an important role in finger individuation, and have been particularly associated with
705 the CST, it is possible that individuation in the extensors would also be more CST-

706 dependent and the dual systems we are implying for the flexor might not apply to the
707 same degree.

708

709 **Conclusions**

710 Here we found that hand function after stroke can be partitioned into strength and
711 strength-independent control. Most recovery of both these components occurred in the
712 first three months after stroke, although strength continued to improve for up to six
713 months. At any time point after stroke, strength and strength-independent control were
714 related by an invariant curvilinear function: strength and some degree of control are
715 correlated up to a certain strength level and then control saturates; some subjects showed
716 additional improvement in individuation riding on top of the main recovery function. The
717 results suggest that hand recovery is supported by two separable systems: one that mainly
718 contributes to the generation of large forces, as in the power grip, and another that is
719 responsible for more precise control of the digits at all levels of force. This behavioral
720 and imaging evidence for two systems contributing to recovered hand function after
721 stroke is consistent with the known characteristics of the CST and RST.

872

	Strength Index	Individuation Index	FMA	ARAT
Strength Index		0.73	0.76	0.74
Individuation Index			0.68	0.72
FMA				0.91

873

874 **Figure 1.** *Strength and Individuation task. (A) Ergonomic hand device. The participant's*
875 *fingers are securely placed on the keys using Velcro straps. (B) Computer screen*
876 *showing the instructional stimulus, which indicates both which finger to press and how*
877 *much force to produce (height of the green bar). In the MVF task, maximal force was*
878 *required; in the Individuation task a specific force level had to be reached. (C, D)*
879 *Example trials from two healthy control participants during the Individuation task. Four*
880 *trials are shown, one at 20% and one at 80% of MVF for the two participants. In this*
881 *case the fourth finger (red) was the active finger. Note the higher level of enslaving of the*
882 *passive fingers for higher active force level. (E) Mean deviation from baseline in the*
883 *passive fingers plotted against the force generated by the active finger for (C) and (D).*
884 *Increased enslaving with higher active force levels is clearly visible. The Individuation*
885 *Index is the $-\log(\text{slope})$ of the regression line between active force and passive mean*
886 *deviation, measured as root mean square (RMS) force from baseline force produced by*
887 *passive fingers.*

888

889 **Figure 2.** *Temporal profiles of recovery for strength and individuation. (A-B) Group*
890 *recovery curves for the Strength and Individuation Indices for patients and controls.*
891 *Asterisks indicate significant week-to-week change for the paretic hand (Bonferroni*
892 *corrected p-values for each segments of Strength Index: $p(W1-4) = 0.0045$, $p(W4-12) =$*
893 *0.0082 , $p(W12-24) = 0.068$, $p(W24-52) = 0.87$; Individuation Index: $p(W1-4) = 0.81$,*
894 *$p(W4-12) = 0.0024$, $p(W12-24) = 1.92$, $p(W24-52) = 2.91$). (C) Rate of change (i.e.,*
895 *change per week) in Z-normalized Strength and Individuation Indices during the first two*
896 *intervals (Week 1 to 4 and Week 4 to 12). The two intervals show a significant interaction*

897 *between strength and individuation, indicating faster initial improvement of strength; (D)*
898 *Week-to-week correlations between adjacent time points for the Strength and*
899 *Individuation Indices. Dashed lines are the noise ceilings based on the within-session*
900 *split-half reliabilities.*

901

902 **Figure 3.** *Temporal recovery profiles measures with clinical assessments. (A) Fugl-*
903 *Meyer for the arm (FMA) and (B) hand (FMH); (C) ARAT; (D-F) strength for hand grip,*
904 *FDI, and FCR muscles, as measured by Dynamometry. All measures showed significant*
905 *change over time for the paretic hand. FMA: $\chi^2 = 37.73, p = 8.13 \times 10^{-10}$; FMH: $\chi^2 =$*
906 *29.03, $p = 7.14 \times 10^{-8}$; ARAT: $\chi^2 = 36.33, p = 1.67 \times 10^{-9}$; grip: $\chi^2 = 33.02, p = 9.21 \times 10^{-9}$;*
907 *FDI: $\chi^2 = 19.21, p = 1.67 \times 10^{-5}$; FCR: $\chi^2 = 28.47, p = 9.50 \times 10^{-8}$.*

908

909 **Figure 4.** *Time-invariant impairment function relating strength and control. (A) Scatter*
910 *plots for Individuation against Strength Indices at each time point. Each black dot is one*
911 *patient's data; blue dots and ellipse indicates the mean and standard error for controls at*
912 *the time point. Two patients' data are highlighted: one with good recovery (yellow dot)*
913 *and one with poor recovery (red dot). (B) Scatter plot with data from all time points*
914 *superimposed with the best fitting two-segment piecewise-linear function with one*
915 *inflection point at Strength Index = 0.607. (C) Residuals from each week subtracting out*
916 *the mean impairment function (B, red line). The tendency of the residuals to stay above*
917 *or below the typical Strength-Individuation relationship indicates that there are stable*
918 *factors that determine Individuation recovery over and above strength recovery. (D)*
919 *Correlations of residuals from (C) across adjacent time points increased over time*

920 *(Bonferroni corrected $p(W1-4) = 2.12$, $p(W4-12) = 0.00064$, $p(W12-24) = 0.0024$,*
921 *$p(W24-52) = p = 3.39 \times 10^{-6}$). Dashed line is the noise ceilings based on the within-*
922 *session split-half reliabilities.*

923

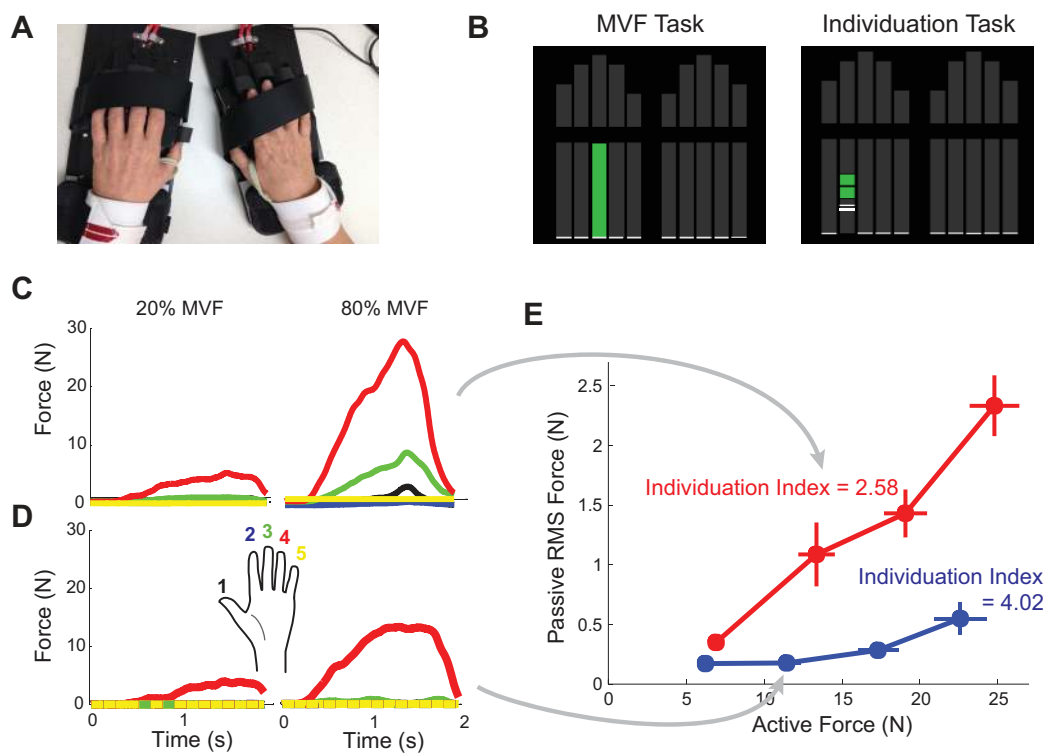

924 **Figure 5.** *Lesion distribution and correlation with behavior. (A) Averaged lesion*
925 *distribution mapped to JHU-MNI space (see Materials and Methods), with lesion flipped*
926 *to one hemisphere. Color bar indicates patient count. (B) Correlation of behavior*
927 *measures (Strength and Individuation Indices) at each time point with the percentage of*
928 *damaged cortical gray matter within the M1 hand area ROI, corticospinal tract (CST).*
929 *(D) Mean of week-by-week correlations between the two behavior measures and percent*
930 *lesion volume measures for the cortical gray matter hand area and CST ROI. Black*
931 *asterisks indicate significant correlations (tested against zero), and red asterisks indicate*
932 *a significant difference between the correlation for Strength and Individuation for each*
933 *week ($p < 0.005$).*

934

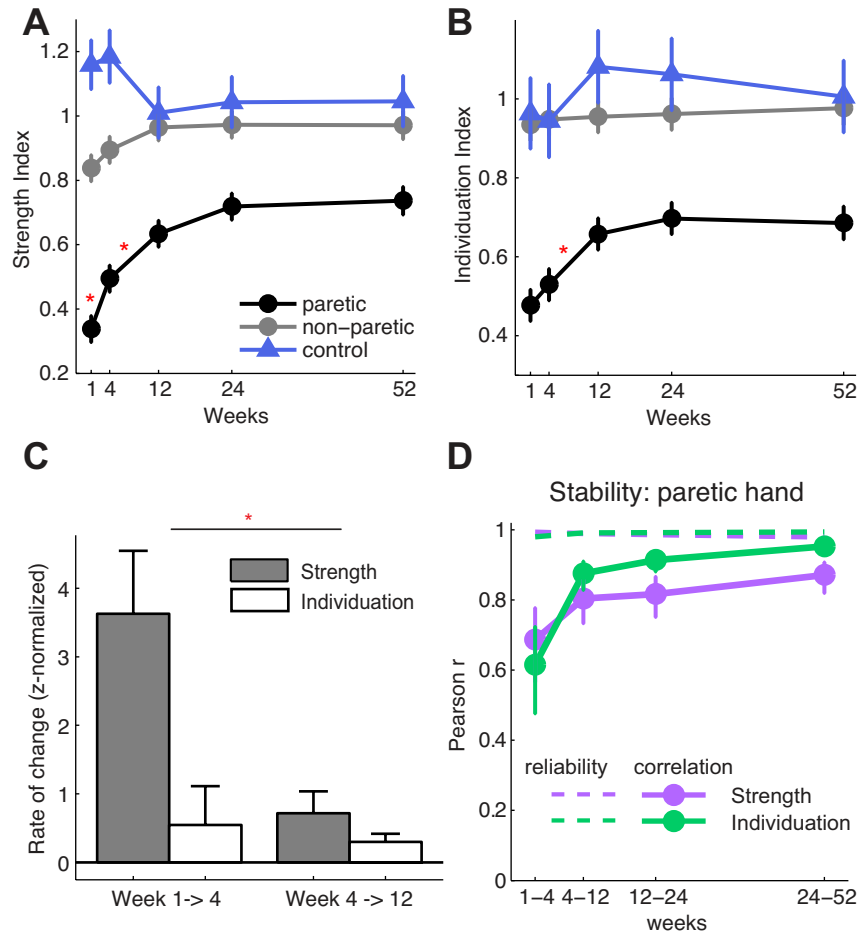

935 **Figure 6.** *A schematic diagram of the hypothesis of two recovery systems. The first*
936 *system (basic strength recovery) underlies strength recovery and a restricted amount of*
937 *individuation recovery. This system therefore defines the lower bound (dashed line) of the*
938 *space occupied by recovering patients (gray cloud). A second system (additional*
939 *individuation recovery) adds further individuation abilities on top of the basic strength*
940 *recovery.*
