**Background and aims:** The insulin receptor (IR) is expressed as two isoforms, IRA (exon 11-) and IRB (exon 11+), which originate from the alternative splicing of exon 11 and differ from 12 amino acids located at the carboxyl terminus of the extracellular  $\alpha$ -subunit. The most significant difference between the two IR isoforms is that IRA is more responsive to activation by IGF2 than IRB. Thus, it is suggested that IRA and IRB are both responsible for metabolic effects (triggered by insulin) whereas, only IRA is responsible for the mitogenic/proliferate effects (triggered by IGF2). The two IR isoforms are matured in the Golgi apparatus by the proteolytic activity of the proprotein convertase furin. We analyzed if the absence or presence of exon 11 could affect the maturation of IR isoforms.

**Materials and methods:** IR isoforms were overexpressed in different cell lines. Proprotein convertases activity was modulated by pharmacological inhibition, specific knockdown and overexpression. IR maturation was analyzed by western blot.

**Results:** In furin-defective LoVo cells, IRB is more matured than IRA. In furin-expressing cells, both IR isoforms are equally matured and furin knockdown is more efficient in reducing the maturation of IRA than that of IRB. The global inhibition of proprotein convertase activity abolishes the furin-independent maturation of IRB, indicating the involvement of a proprotein convertase other than furin in this maturation. We demonstrate that in the absence of furin activity the proforms of IR are exposed at the cell surface where IRB (but not IRA) is matured by PCSK6. This difference in the maturation of IRA and IRB was used as an opportunity to modulate the balance metabolic/mitogenic signals emanating from IR. Furin inhibition reduces the signals triggered by IGF2 (emanating from IRA) without unduly affecting those triggered by insulin (emanating from IRB).

**Conclusion:** Our results are the first to reveal a difference in the maturation of IR isoforms. The maturation of IRA is almost strictly under the control of furin whereas that of IRB involves furin and PCSK6. Furin inhibition reduces the amount of mature IRA without drastically altering that of IRB, which reduces the signals triggered by IGF2 but not those triggered by insulin.

## 576

### FKBP5 gene polymorphisms and expression in human adipose tissue are associated with insulin resistance and type 2 diabetes

M.J. Pereira<sup>1</sup>, J. Palming<sup>2</sup>, M.K. Svensson<sup>2</sup>, M. Rizell<sup>3</sup>, J. Dalenbäck<sup>4</sup>,  
M. Hammar<sup>5</sup>, T. Fall<sup>1</sup>, C.O. Sidibe<sup>1</sup>, P.-A. Svensson<sup>6</sup>, J.W. Eriksson<sup>1</sup>;

<sup>1</sup>Department of Medical Sciences, Uppsala University,

<sup>2</sup>Department of Molecular and Clinical Medicine, <sup>3</sup>Sahlgrenska University Hospital, Gothenburg, <sup>4</sup>Frölunda Specialist Hospital, Gothenburg,

<sup>5</sup>AstraZeneca R&D, Mölndal, Sweden, <sup>6</sup>Department of Molecular and Clinical Medicine, University of Gothenburg, Sweden.

**Background and aims:** Central obesity is associated with a cluster of metabolic alterations, which include insulin resistance (IR), dyslipidemia and cardiovascular disease. Glucocorticoid excess is associated with redistribution of fat from peripheral to central depots and with IR and development of diabetes. To identify potential novel mechanisms for IR we investigated dexamethasone-induced changes of gene expression in human adipose tissue.

**Materials and methods:** Subcutaneous and omental adipose tissue, obtained from 25 non-diabetic subjects (28-60 yrs; 20.7-30.6 kg/m<sup>2</sup>), was incubated without or with dexamethasone (0.003-3  $\mu$ M) for 24 h. Gene expression was assessed by microarray and real time-PCR. Protein levels were assessed by immunoblotting.

**Results:** FKBP5 (FK506 binding protein 5) was one of the genes responding most to dexamethasone. Gene expression increased up to 7-fold in a dose-dependent manner in both subcutaneous and omental fat depots ( $p < 0.001$ ). The protein coded by this gene, the FKBP51, is an immunophilin, which means that it plays a role in the immune system. FKBP5 mRNA is widely expressed

in metabolically active tissues with the highest gene expression in muscle and adipose tissue. However, FKBP51 protein was about 10-fold higher in the omental than in the subcutaneous fat depot ( $p < 0.05$ ), whereas the mRNA levels were similar. 80-90% of the FKBP5 protein in adipose tissue could be attributed to the adipocytes, while the stromal vascular cells contribute to 10-20% ( $p < 0.05$ ). FKBP5 gene expression in the subcutaneous fat depot was positively correlated with markers of IR including, HOMA-IR and subcutaneous adipocyte diameter ( $r = 0.59$ ,  $p < 0.001$ ;  $r = 0.48$ ,  $p < 0.05$ , respectively). In addition, FKBP5 gene expression in omental adipose tissue was associated with reduced insulin effects on glucose uptake in subcutaneous and omental adipocytes ( $p < 0.05$ ). Interestingly, FKBP5 SNPs (e.g. rs2817056, rs2395635, rs1334894) were found to be significantly associated with type 2 diabetes and with 2-h OGTT glucose, HDL-cholesterol and triglycerides in publicly available datasets from large, population-based cohorts.

**Conclusion:** The FKBP5 gene is regulated by glucocorticoids in both subcutaneous and omental adipose tissue, and its expression in human adipose tissue is correlated to markers of IR. In addition, SNPs in the FKBP5 region are associated with type 2 diabetes and diabetes-related traits. We hypothesize that FKBP5 is a mechanism linking alterations in nutrient metabolism with immune function, both following glucocorticoid excess and in other conditions with IR. Further studies will address whether FKBP5 is causally linked to IR and whether the related mechanisms can provide novel pharmacological targets for the treatment of IR.

### Local overexpression of urocortin 3 in skeletal muscle of rats activates AMPK and Akt pathways and enhances glucose disposal

M.E. Cleasby<sup>1</sup>, M.M. Rousti<sup>1</sup>, J.M. Vaughan<sup>2</sup>, P.M. Jamieson<sup>3</sup>;

<sup>1</sup>Comparative Biomedical Sciences, Royal Veterinary College, London, UK, <sup>2</sup>Laboratory of Neuronal Structure and Function, Salk Institute for Biological Studies, La Jolla, USA, <sup>3</sup>Centre for Cardiovascular Science, Queen's Medical Research Institute, Edinburgh, UK.

**Background and aims:** Insulin resistance (IR) in skeletal muscle is an important component of both type 2 diabetes (T2D) and the syndrome of sarcopaenic obesity, for which there are no effective therapies. Urocortins (Ucns), ligands for corticotropin releasing factor receptors, are well-established as neuropeptides but also have roles in metabolism in peripheral tissues. We showed recently that global overexpression (OE) of Ucn3 resulted in muscular hypertrophy and resistance to the adverse metabolic effects of a high fat diet. Here, we aimed to establish whether short-term local Ucn3 OE could improve glucose disposal and insulin sensitivity in skeletal muscle through a paracrine mechanism.

**Materials and methods:** Ucn3 was overexpressed in right *tibialis cranialis* and *extensor digitorum longus* muscles of rats by *in vivo* electrotransfer and the effects on muscle size, metabolism, gene expression and signalling were studied versus the contralateral control muscles (electroporated with empty vector) after one week.

**Results:** No increase in whole muscle mass was detected after one week, but Ucn3 OE muscles showed 19% larger muscle fibre diameter ( $p = 0.030$ ), perhaps mediated through the associated increases in insulin-like growth factor-1 (IGF1) and IGF1 receptor mRNA and increased Ser256 phosphorylation of forkhead transcription factor (FOXO1). Glucose clearance into test muscles, measured using tritiated 2-deoxyglucose after an intraperitoneal glucose load, was increased by 23% ( $p = 0.018$ ) per unit mass, implying an insulin sensitising effect of Ucn3 OE on glucose disposal additional to the effect of hypertrophy alone to enhance total glucose uptake. This effect was associated with increased total glucose transporter protein levels (GLUT1: 34% increase,  $p = 0.026$ ; GLUT4: 48% increase,  $p = 0.0009$ ) and activation of two key signalling pathways mediating glucose disposal, the phosphoinositol 3-kinase/Akt (insulin signalling) and AMP-activated protein kinase (AMPK) pathways. Phosphorylation of insulin receptor substrate-1 (Tyr609), Akt (Ser473; by 72%,  $p = 0.005$ ), Akt substrate of 160kDa (Thr642), glycogen synthase kinase-3 $\beta$  (Ser9), AMPK (Thr172; by 27%,  $p = 0.024$ ) and its substrate acetyl coA carboxylase (Ser79) were all significantly increased by Ucn3 OE.

**Conclusion:** Ucn3 OE enhances glucose disposal and insulin sensitivity in muscle by an autocrine/paracrine mechanism that is separate from its prohypertrophic effects, implying that such a manipulation may have promise for treatment of IR syndromes including T2D and sarcopaenic obesity.

## 578

**Physical inactivity and high fat diet synergistically enhance the accumulation of intramyocellular diacylglycerol and induce insulin resistance in murine soleus muscle**S. Kakehi<sup>1</sup>, Y. Tamura<sup>2</sup>, S.-I. Ikeda<sup>3</sup>, R. Kawamori<sup>3</sup>, H. Watada<sup>2</sup>;<sup>1</sup>Sportology Center, <sup>2</sup>Metabolism and Endocrinology,<sup>3</sup>Sportology Center, Juntendo University, Tokyo, Japan.

**Background and aims:** Intramyocellular lipids (IMCL), especially intramyocellular diacylglycerol (IMDG) has been reported as one of the causes of insulin resistance in skeletal muscle. It has been demonstrated that physical inactivity and high fat diet (HFD) increase IMCL levels and induce insulin resistance, respectively. However, the combined effect of these two factors on insulin resistance has not been clarified yet.

**Materials and methods:** To elucidate them, C57BL/6J mice were randomly assigned to four groups; control group, 24h hind-limb cast immobilization (HCI) group, short-term (2wk) HFD group, and 24h HCI after 2wk HFD group. Then, we evaluated ex-vivo insulin-stimulated 2-deoxy glucose uptake (2DG-uptake), insulin signal and intracellular fat composition in skeletal muscle.

**Results:** Twenty four hours HCI significantly decreased insulin-stimulated 2DG-uptake by 40%, while 2wk HFD did not alter 2DG-uptake. On the other hand, 24h HCI after 2wk HFD dramatically decreased insulin-stimulated 2DG-uptake by 74%. In parallel with decreased insulin-stimulated 2DG-uptake, we observed decreased insulin stimulated serine phosphorylation of Akt and tyrosine phosphorylation of insulin receptor substrate (IRS)-1 after 24h HCI, which were more exacerbated in 24h HCI after 2wk HFD group, while only 2wk HFD did not change these phosphorylation states. Concerning, it has been hypothesized that IMDG accumulation and PKC activation impairs insulin signal transduction. Consistent with this hypothesis, we found that 24h HCI increased IMDG in soleus by 192%, while the amount of intramyocellular triacylglycerol (IMTG) was not changed. In addition, whereas IMDG and IMTG were not changed by 2wk HFD feeding, 24h HCI after 2wk HFD dramatically increased IMDG and IMTG by 330% and 144%, respectively. In parallel with IMDG accumulation, we observed increased PKC $\epsilon$  activity in 24h HCI group and 24h HCI after HFD group by 151% and 210%, respectively. Associated with the IMDG accumulation, expression level of diacylglycerol acyltransferase (DGAT)-1, which converts diacylglycerol to triacylglycerol, was decreased in both HCI group and HCI after 2wks HFD group. In addition, activity of Lipin1, which converts phosphatidic acid to diacylglycerol, was increased in 24h HCI group and 24h HCI after HFD group by 141% and 210%, respectively

**Conclusion:** These results suggested that physical inactivity and HFD synergistically induce IMDG accumulation and insulin resistance in soleus muscle. Increased Lipin1 activity and decreased DGAT-1 expression might be involved in the mechanism of IMDG accumulation after physical inactivity and HFD.

**PS 036 Mechanisms of insulin resistance in vivo**

## 579

**Impact of hepatic lipid accumulation and composition on glucose tolerance and insulin sensitivity: a longitudinal study in male and female mice**A.F. Soares<sup>1</sup>, H. Lei<sup>2</sup>, R. Gruetter<sup>1,2</sup>;<sup>1</sup>Laboratory of Functional and Metabolic Imaging, <sup>2</sup>Biomedical Imaging Research Center, École Polytechnique Fédérale de Lausanne, Switzerland.

**Background and aims:** Metabolic disruptions characterized by high hepatic lipid content (HLC) are associated with impairments in whole body glucose homeostasis. To gain insight on the role of hepatic lipids in the metabolic performance in the absence artificial metabolic stresses we measured non-invasively and longitudinally the HLC and profile in mice during adult development by Magnetic Resonance (MR) Spectroscopy *in vivo*. In parallel, mice were challenged with insulin and glucose tolerance tests.

**Materials and methods:** Male (N=10) and female (N=10) C57Bl/6J mice were studied at 3 (3Mo), 7 (7Mo) and 10 months (10Mo) of age. Mice were scanned in a 14.1 T magnet with a <sup>1</sup>H quadrature surface coil over the abdomen. Localized <sup>1</sup>H spectra were acquired from a 8  $\mu$ l volume with stimulated echo acquisition mode sequence and the HLC expressed as the percent of total <sup>1</sup>H MR signal, with corrections for spin-spin relaxation effects. Additional spectra were acquired from the same volume with suppression of the water signal to enable the detection and quantification of all the lipid protons. The lipid profile was characterized by the following indices: saturated component (SC); unsaturated fatty acyl chains (UFA); mean number of double bonds per fatty acyl chain (ndb/FA), mean number of poly-unsaturated double bonds per fatty acyl chain (PUdb/FA) and per UFA (PUdb/UFA); mean chain length (MCL). OGTTs (1.5 g/Kg) and i.p. insulin tolerance tests (ITTs) were performed after a 6h-fast. Plasma insulin was determined by ELISA and insulin sensitivity estimated with the quantitative insulin check index (QUICKI) as the inverse of the log<sub>10</sub> sum of fasting insulin ( $\mu$ IU/ml) and fasting glucose (mg/dl). Data are expressed as mean  $\pm$  SEM. Statistical significance was accepted for a P < 0.05 (one-way ANOVA with Newman-Keuls post test) and correlations assessed by the Pearson r coefficient.

**Results:** In males, the HLC at 3Mo was 1.35  $\pm$  0.15%, increasing to 3.06  $\pm$  0.38% at 7Mo, not different from 2.70  $\pm$  0.31% at 10Mo. Females had higher HLC at 3Mo (2.63  $\pm$  0.19%) but no further changes henceforward (2.31  $\pm$  0.20% at 7Mo; 2.36  $\pm$  0.20% at 10 Mo). In males, the SC and MCL of hepatic lipids increased with age, with a trend for decreased PUdb/FA and PUdb/UFA with no changes in ndb/FA or UFA content. Females showed the same trends. Glycemia 3h-post ITT and 2h-post OGTT was lower in females, while QUICKI was higher. These scores were preserved until 10Mo in females. In males, glycemia 2-h post OGTT increased with age and the area above the curve (AAC) for the ITT decreased. In males, but not females, higher body weight correlated with hepatic lipid accumulation (r = 0.7); worse ITT scores correlated with higher body weight (r = -0.6) and HLC (r = -0.7) and lower PUdb/UFA (r = 0.5); worse OGTT scores correlated with higher HLC (r = 0.4).

**Conclusion:** In male mice, loss of insulin sensitivity correlated with weight gain, HL accumulation and lower poly-unsaturation. Glucose intolerance was specifically associated with HLC, suggesting a deleterious effect of lipids on the adaptation of hepatic metabolism to the fed state. This behaviour was not observed in females even if they showed similar HLC. In fact, the poly-unsaturation of HL in females didn't change with HLC, suggesting a positive effect of PUFA on preserving the hepatic metabolic performance.

**Liver specific G0/G1 switch gene 2 (G0S2) overexpression exacerbates hepatic insulin resistance by exacerbating hepatic steatosis but ameliorates hepatic fibrosis**

Y. Sugaya, H. Satoh, T. Watanabe;

Department of Nephrology, Hypertension, Diabetology, Endocrinology, and Metabolism, Fukushima Medical University, Japan.

**Background and aims:** Hepatic steatosis is strongly associated with insulin resistance. Recently it has been reported that G0/G1 switch gene 2 (G0S2) inhibited the lipolysis activity of adipose triglyceride lipase. Moreover, we

confirmed that G0S2 protein content was increased in the livers of high fat diet (HFD) fed rats. However, the precise physiological role of hepatic G0S2 is still unknown. In the current studies, we investigated the effect of hepatic G0S2 on insulin sensitivity in HFD-fed male Wistar rats by overexpressing G0S2 proteins using an adenovirus (Ad) encoding mouse G0S2.

**Materials and methods:** Male Wistar rats were fed with 60% HFD for a total of 4 weeks. After 3-week feeding, the rats were injected with control Ad-GFP or Ad-G0S2. On day 7 post injection, glucose tolerance test and euglycemic-hyperinsulinemic clamp studies were performed after an 8-hour fast.

**Results:** There were no significant changes in the body weight and fasting Glucose levels between Ad-GFP and Ad-G0S2 rats. However, after the glucose load, the glucose levels were significantly higher in the Ad-G0S2 rats at 15 and 30 min. During the clamp studies, the glucose infusion rate required to maintain euglycemia was significantly decreased by 16% in Ad-G0S2 rats. Clamp hepatic glucose output was significantly increased by 31% in Ad-G0S2 rats, but there was no significant changes in insulin-stimulated glucose disposal rate between two groups. Furthermore, the Oil Red O staining revealed that overexpression of G0S2 significantly increased lipid accumulation in the liver. However, Masson trichrome staining revealed that overexpression of G0S2 significantly ameliorated fibrosis in the liver. Consistent with histological data, expression of TGF- $\beta$  and Smad2 were significantly decreased in the livers of Ad-G0S2 rats

**Conclusion:** Overexpression of hepatic G0S2 protein exacerbates hepatic insulin resistance by the exacerbation of hepatic steatosis but ameliorates hepatic fibrosis.

## 581

### Fasting and postprandial hepatic energy metabolism in insulin resistant states

M.J. Fritsch<sup>1,2</sup>, C. Koliaki<sup>1</sup>, R. Livingstone<sup>1</sup>, E. Phielix<sup>1</sup>, A. Bierwagen<sup>1</sup>, M. Meisinger<sup>1</sup>, T. Jelenik<sup>1</sup>, J.-H. Hwang<sup>1</sup>, J. Szendroedi<sup>1,3</sup>, M. Roden<sup>1,3</sup>,  
<sup>1</sup>Institute for Clinical Diabetology, German Diabetes Center, Düsseldorf, Germany, <sup>2</sup>Department of Pediatrics and Adolescent Medicine, Medical University of Vienna, Austria, <sup>3</sup>Department of Endocrinology and Diabetology, Heinrich-Heine University, Germany.

**Background and aims:** Alterations of hepatic energy metabolism are discussed as a mechanism contributing to hepatic steatosis and insulin resistance. However, it remains unclear whether meal ingestion differently affects hepatic energy metabolism in insulin sensitive and insulin resistant humans.

**Materials and methods:** Young lean insulin sensitive (body mass index; 23.2±0.5 kg/m<sup>2</sup>), age-matched obese insulin resistant nondiabetic (OBE: 34.3±0.5 kg/m<sup>2</sup>) and elderly type 2 diabetes patients (T2D: 32.0±0.8 kg/m<sup>2</sup>) were examined (n=10 per group). Hepatic phosphorous compounds and fat content were quantified *in vivo* with <sup>31</sup>P/<sup>1</sup>H magnetic resonance spectroscopy before, 160 min and 240 min after ingestion of a high caloric mixed meal (652 kcal, 55% CHO, 15% protein, 30% fat). Whole body insulin sensitivity (M-value) was assessed with the hyperinsulinemic-euglycemic clamp and skeletal muscle oxidative capacity was assessed *ex vivo* with high-resolution respirometry applied in biopsy samples.

**Results:** OBE and T2D patients were similarly insulin resistant (M-value; OBE: 3.6±0.4 mg.kg<sup>-1</sup>.min<sup>-1</sup>; T2D: 2.5±0.7 mg.kg<sup>-1</sup>.min<sup>-1</sup>). OBE and T2D had 14fold (p=0.01) and 20fold (p=0.002) higher hepatic fat contents than lean persons. Fasting hepatic inorganic phosphate (Pi) was 42% lower in OBE (p=0.002) and 32% lower T2D (p=0.02) than in lean persons and correlated positively with M-value (r=0.63, p=0.001). After meal ingestion, hepatic ATP and Pi increased by 27% (p=0.02) and 33% (p=0.05) only in OBE. Circulating lipid peroxides transiently increased by 24% (p<0.05) at 180 min after the meal only in T2D. In parallel, mitochondrial oxidative capacity was reduced (p=0.01) along with augmented lipid storage (p=0.02) in skeletal muscle of T2D.

**Conclusion:** Obese insulin resistant persons respond to meal ingestion with augmented hepatic energy metabolism, whereas diabetes patients exhibit an oxidative stress response. These data indicate that obesity-associated adaptation of hepatic mitochondrial function is absent with the onset of type 2 diabetes.

## 582

### Serum hepassocin contributes to insulin resistance in type 2 diabetes

C.-J. Chang<sup>1</sup>, H.-T. Wu<sup>1</sup>, H.-Y. Ou<sup>2</sup>, H.-C. Hung<sup>2</sup>, Y.-C. Yang<sup>1</sup>, J.-S. Wu<sup>1</sup>,  
<sup>1</sup>Department of Family Medicine, College of Medicine,  
<sup>2</sup>Department of Internal Medicine, College of Medicine,  
National Cheng Kung University and Hospital, Tainan, Taiwan.

**Background and aims:** Increased serum hepassocin concentrations were observed in patients with non-alcoholic fatty liver disease and diabetes. Although the mechanisms that hepassocin induces hepatic steatosis were clarified, the role that hepassocin plays in the development of insulin resistance and diabetes is still obscure.

**Materials and methods:** A total of 100 age- and sex-matched normal glucose tolerance (NGT), and newly diagnosed diabetic (NDD) patients were included (n=50 in each group) for the measurement of serum hepassocin concentrations by enzyme-linked immunosorbent assay. Insulin sensitivities in animals were determined using glucose tolerance test, insulin tolerance test, and euglycemic hyperinsulinemic clamp, as well as insulin signaling. Manipulations of hepassocin expression were achieved by portal vein injection of lenti-viral vectors containing hepassocin or short hairpin ribonucleic acid targeted to hepassocin.

**Results:** We found that the serum concentrations of hepassocin were significantly increased in patients with NDD (p<0.001) as compared with NGT subjects. Fasting plasma glucose (p<0.001), NDD vs. NGT (p<0.001) were significantly associated factors with serum hepassocin concentrations. Overexpression of hepatic hepassocin, as well as injection of hepassocin recombinant protein in mice increased fasting glucose levels, impaired glucose utility and induced insulin resistance. In addition, knockdown of hepatic hepassocin ameliorated insulin resistance in high fat diet-induced diabetic mice.

**Conclusion:** Hepassocin plays a role in the development of insulin resistance, and might be a novel therapeutic target for the treatment of diabetes.

## 583

### The vicious circle of prostaglandin- and cytokine-dependent hepatic insulin resistance: a key role of prostaglandin E2

J. Henkel, R.G. Camargo, N. Schanze, G.P. Püschel,  
Nutritional Biochemistry, University of Potsdam, Nuthetal, Germany.

**Background and aims:** Hepatic insulin resistance and the ensuing impairment of hepatic glucose metabolism, which is a major contributor to hyperglycemia in metabolic syndrome and type II diabetes, are elicited by a variety of factors that act in parallel. In obesity, impaired fatty acid handling results in an activation of PKC isoforms. In addition, a low-grade inflammation prevails. Both contribute to the development of insulin resistance. The impact of cytokines on the insulin signalling cascade is well established. By contrast, the role of small lipid mediators like prostaglandins, which are released from resident liver macrophages and infiltrating immune cells in the course of inflammation, is not well characterized. The current study addressed this question.

**Materials and methods:** Male C57BL/6 mice were fed a modified western diet containing 50% of calories from fat, 1.25% cholesterol and 0.5% sodium cholate as well as 15% fructose in drinking water versus chow and water for 4 or 8 weeks. The human macrophage cell line U937, primary mouse and rat macrophages were incubated with LPS or PGE2. HepG2 cells or primary rat hepatocytes were pre incubated either with PGE2, IL 6, OSM or with conditioned media of PGE2-stimulated macrophages and subsequently stimulated with insulin. Gene expression and activation of insulin- and cytokine signaling were quantified by Western blot and quantitative RT PCR.

**Results:** Hepatic expression of key enzymes in prostaglandin E2 (PGE2) formation, namely cyclooxygenase 2 (COX2) and microsomal PGE2 synthase 1 (mPGES1), was induced 2-4-fold in mice fed a modified western diet compared to controls suggesting an enhanced capacity of local PGE2 formation in these mice. In rat hepatocytes PGE2 interrupted Akt-dependent insulin signalling. It enhanced hepatic lipid accumulation by inhibiting mitochondrial fatty acid oxidation and VLDL formation. PGE2 acted by a distinct mechanism from cytokines, namely a sustained ERK1/2 activation, and synergistically with the cytokines interleukin-6 (IL-6) and oncostatin M (OSM), which attenuated insulin signalling by inducing SOCS3. In rat, mouse and human macrophages the release of these cytokines was stimulated by PGE2. Cytokines and PGE2 induced the PGE2-generating enzymes COX2 and mPGES1. While PGE2 besides IL-6 and OSM enhanced IL-1 $\beta$  formation, TNF $\alpha$  expression remained unchanged or reduced. Conditioned

medium of murine or human macrophages treated with low doses of PGE2 stimulated the phosphorylation of STAT3 and induced SOCS3 in rat and human hepatocytes, while insulin-dependent glucokinase induction in hepatocytes was attenuated. These effects were abolished after parallel treatment of macrophages with the COX2-inhibitor indomethacin or incubation with an OSM-neutralizing antibody. In summary, in addition to directly interrupting insulin signalling pathway in hepatocytes, PGE2 may further impair hepatic insulin sensitivity in an autocrine feed-forward vicious cycle by inducing cytokines like OSM and its own synthesis in macrophages.

**Conclusion:** The study provides first evidence that in addition to established mechanisms prostaglandins have an impact on the development of hepatic insulin resistance. The enzymes involved in the prostaglandin synthesis and the receptors to which they bind on the different liver cell types might therefore be potential new drug targets for the treatment of hepatic insulin resistance.

## 584

### Mitochondrial respiration in skeletal muscle, liver and fat does not differ in morbidly obese patients with and without type 2 diabetes

M.T. Lund<sup>1,2</sup>, M. Hansen<sup>1</sup>, A. Floyd<sup>2</sup>, J.W. Helge<sup>1</sup>, F. Dela<sup>1</sup>;

<sup>1</sup>Biomedical Sciences, University of Copenhagen,

<sup>2</sup>Department of Surgery, Koege Hospital, Denmark.

**Background and aims:** After an oral glucose load the uptake in skeletal muscle and liver accounts for ~80–90% of the ingested glucose. In patients with type 2 diabetes the ability to take up glucose in both tissues are severely impaired leading to decreased whole body glucose uptake and prolonged hyperglycemia. It has been speculated that the impaired glucose uptake partly is the result of an underlying mitochondrial dysfunction limiting the ability to oxidize glucose and fat. We have now compared the maximal coupled mitochondrial respiration in morbidly obese patients with and without type 2 diabetes by studying three different tissues (skeletal muscle, liver and fat) obtained from all patients.

**Materials and methods:** 16 morbidly obese patients (5M/11F; 7 with (T2D) and 9 (OB) without type 2 diabetes) reported to the lab twice 2 months prior to their scheduled Roux-En-Y gastric bypass operation. Body composition was assessed by a dual Energy X-ray Absorption scan and maximal oxygen uptake (VO<sub>2</sub>max) was measured during a graded bicycle test. On a separate day skeletal muscle (m. vastus lateralis) and subcutaneous fat samples (abdomen) were acquired by a Bergstrom needle biopsy and subsequently a hyperinsulinaemic euglycemic clamp (80 mU/m<sup>2</sup>/min) was performed to measure whole body insulin mediated glucose uptake. Finally, a liver biopsy was obtained during the gastric bypass procedure. Prior to respiration analysis the skeletal muscle fibers were split and permeabilized in Saponin (50µg/ml) for 20 min. Liver and fat tissue were dissected in 2 x 2 mm tissue samples before transferred to the respirometer. 2 µl digitonin (2.5 mg/ml) were initially added to the respirometer to permeabilize the fat tissue. Substrates were added consecutively: Malate (2 mM (liver: 6 mM)) and glutamate (10 mM); ADP (5 mM (liver: 1 mM)) and magnesium (20 mM (liver: 4 mM)); octanoyl carnitine (1.5 mM); succinat (10 mM).

**Results:** Weight (133±6 vs. 122±9 kg), BMI (43±2 vs. 41±1 kg/m<sup>2</sup>), age (36±3 vs. 40±6 years) and VO<sub>2</sub>max (20±1 vs. 23±2 ml/min/kg) were similar in OB and T2D, respectively. Whole body glucose uptake tended to be higher in OB compared to T2D (4.8±0.5 vs. 3.6±0.3 mg/min/kg, respectively, P = 0.05). Maximal coupled respiration in skeletal muscle, liver and fat tissue are shown in Figure 1.

**Conclusion:** The main finding in the current study was the similar maximal coupled respiration in tissue samples from two different groups of patients with 25% different insulin sensitivity. Differences in body weight, age or aerobic fitness are not confounding factors. Thus, the mitochondria in patients with type 2 diabetes are able to consume oxygen at similar rates as healthy

obese patients and this speaks against an underlying mitochondrial dysfunction in insulin resistance. These data do not rule out that substrate sensitivity at physiological concentrations is altered in patients with type 2 diabetes.

### Failure of the skeletal muscle to contribute to diurnal glucose homeostasis in type 2 diabetes

M.E.O. Macauley, E.E. Smith, P. Thelwall, R. Taylor;

Institute of Cellular Medicine, Newcastle Magnetic Resonance Centre, Newcastle University, Newcastle upon Tyne, UK.

**Background and aims:** In health, food carbohydrate is stored as glycogen in skeletal muscle and liver, preventing a deleterious rise in osmotically active plasma glucose after eating. Glycogen concentrations increase sequentially after each meal to peak in the evening. Skeletal muscle accounts for the larger part of this diurnal buffering capacity. Approximately 30% of meal carbohydrate is stored in skeletal muscle compared with 20% in liver after a single meal. The effectiveness of this diurnal mechanism has not been previously studied in type 2 diabetes. We have quantified the changes in skeletal muscle and liver glycogen concentration before and after 3 meals consumed at 4 hours interval.

**Materials and methods:** We studied 40 (25M;15F) well controlled type 2 diabetes subjects on metformin only (HbA1c 6.4±0.07% or 47±0.8 mmol/mol) and 14 (8M;6F) glucose tolerant controls matched for age, weight and BMI. <sup>13</sup>C Magnetic resonance spectroscopy at 3.0- Tesla, was used to quantify calf muscle and liver glycogen concentration in the fasting state (0830h) and at 2000h after 3 defined meals (2700kcal(M) and 2200kcal(F); 60% carbohydrate, 20%protein, 20%fat).

**Results:** Mean fasting plasma glucose and insulin concentrations were higher in the type 2 diabetes group (7.7±0.2 vs. 5.1±0.1mmol/l; P<0.0001) and (13.8±1.2 vs. 7.9±0.9mU/L; P=0.01) respectively. HOMA-IR was higher in the type 2 diabetes group (5.0±0.4 vs. 1.9±0.2; P<0.0001). Plasma glucose concentration measured 4 hours after the last meal (2000h) was higher in the type 2 diabetes group compared to the control group (6.5±0.2 vs. 5.7±0.2mmol/l; P=0.03). Plasma glucagon concentration rose similarly in the type 2 diabetes and control groups (70.4±4.7 to 108.5±7.5ng/L; P<0.0001 and 48.4±4.8 to 67.7±7.3ng/L; P=0.001). Muscle glycogen concentration increased by 17% in the control group (68.1±4.8 to 79.7±4.2mmol/l; P=0.006), and the change in diurnal muscle glycogen inversely correlated with HOMA-IR (r = -0.56; P=0.02). In contrast, there was no change in muscle glycogen in the type 2 diabetes group after day-long eating (68.3±2.6 to 67.1±2.0mmol/mol; P=0.62). Liver glycogen rose similarly in both normal control (325.9±25.0 vs. 388.1±30.3mmol/L; P=0.005) and type 2 diabetes groups (296.1±16.0 to 350.5 ± 6.7mmol/l; P<0.0001).

**Conclusion:** In type 2 diabetes, the major physiological mechanism for skeletal muscle postprandial glycogen storage is completely inactive. This is directly related to insulin resistance, although liver glycogen storage is normal. Even in early well-controlled type 2 diabetes, failure of the buffering capacity of muscle glycogen stores is a major contributing factor to post prandial hyperglycemia.

**Skeletal muscle develops insulin resistance before subcutaneous adipose tissue. Study on obese post-menopausal women**

A. Sultan<sup>1,2</sup>, O. Fabre<sup>3</sup>, C. Amouzou<sup>3</sup>, C. Breuker<sup>3,1</sup>, K. Lambert<sup>3</sup>, C. Fedou<sup>1</sup>, A. Dupuis<sup>1</sup>, J. Cristol<sup>1</sup>, F. Galtier<sup>4</sup>, A. Avignon<sup>1,3</sup>, J. Mercier<sup>3</sup>, C. Bisbal<sup>3</sup>;

<sup>1</sup>CHU Lapeyronie, <sup>2</sup>INSERM Unit 1046, <sup>3</sup>INSERM Unit 1046,

<sup>4</sup>CIC, Montpellier, France.

**Background and aims:** Obesity has deleterious effects on human health by enhancing the development of chronic diseases such as insulin resistance (IR) and type 2 diabetes (T2D). Nowadays, the hypothesis commonly admitted is that, during obesity, there is a hypertrophy and a hyperplasia of subcutaneous adipose tissue leading to its dysfunctions and increase lipolysis. Consequently to this adipose tissue dysfunctions, subcutaneous adipose tissue cannot expand more. Then free fatty acid (FFA) concentration increases in systemic circulation and lipids are ectopically stored in visceral adipose tissue, liver and skeletal muscle which affect importantly their function. Moreover, macrophages infiltration of adipose tissue induces a local chronic low-grade inflammation which develops to become systemic. This inflammation impairs the insulin response of insulin sensitive tissues (muscle, liver and fat) leading to peripheral IR. However, some obese people (25–30%) do not develop IR, and are metabolically healthy. In order to identify the early mechanisms leading from obesity to IR, we conducted a translationnal study both at systemic and tissue levels

**Materials and methods:** 31 post-menopausal women 50–65 years old, with no personal or familial history of type 2 diabetes were involved in this study: (i) 10 were leans (BMI 30kg/m<sup>2</sup>) and insulin sensitive (HOMA-ir 3); OIR. Skeletal muscle and subcutaneous adipose tissue were obtained from biopsies respectively in the vatus lateralis and abdominal subcutaneous adipose tissue. We analyzed the insulin response, inflammatory state at systemic and tissues level, intramuscular fatty acid accumulation, angiogenesis and adipocytes size of subcutaneous adipose tissue. This protocol was approved by the local Ethic Committee (N°:2011.01.04, ANSM: B110204-20) and informed written consent was obtain from all participants.

**Results:** Ours results show a significant decrease in insulin sensitivity of OIR skeletal muscle compared to control (p=0.03) and OIS (p=0.04) skeletal muscle while subcutaneous adipose tissue remain insulin sensitive in all three groups of volunteers. Further, there is an increase of fatty acid accumulation in type I muscular fiber of OIR compare to control (p=0.02). Histological analysis show that macrophages infiltration is low in OIR's subcutaneous adipose and absent from OIS and CT volunteer's subcutaneous adipose tissue. Adipocytes size remains the same among three groups. However angiogenesis is significantly decreased in subcutaneous adipose tissue of OIR (p=0.02) and OIS (p=0.007) compared to control.

**Conclusion:** All these results suggest that skeletal muscle seem to be affected by IR before subcutaneous adipose tissue during IR development. The only one impairment which occurs in subcutaneous adipose tissue is the decrease in adipose tissue angiogenesis

## 587

**Serum myostatin and insulin resistance in postmenopausal women**

V. Avila-Rubio, C. Novo-Rodriguez, B. Garcia-Fontana, A. Garcia-Martin, R. Reyes-Garcia, S. Morales-Santana, M. Muñoz-Torres;

Bone Metabolism Unit of Endocrinology division of University Hospital Cecilio, Granada, Spain.

**Background and aims:** Myostatin is a secreted growth factor expressed in skeletal muscle, which negatively regulates skeletal muscle mass. Recent animal studies suggest an additional role for myostatin in glucose metabolism. We evaluated the possible associations between circulating levels of myostatin and glucose metabolism parameters in non obese women with postmenopausal osteoporosis.

**Materials and methods:** Prospective study including 28 women with postmenopausal osteoporosis, matched for age, BMI and bone mineral density (BMD), divided into two groups according to the antiosteoporotic drug: A) 60 mg Denosumab subcutaneous semiannually (n = 17) and B) 20 µg Teriparatide subcutaneous daily (n = 11), both for 3 months. The monitoring was conducted by the Bone Metabolism Unit of our hospital. We performed fasting plasma determinations of myostatin, glucose, peptide C, insulin, insulin resistance index (HOMA2-IR), insulin sensitivity (HOMA2-%S), insulin secretion (HOMA2-%β) and HbA1c at baseline and one week, one month and three months after treatment.

**Results:** Both groups were comparable at baseline in the analyzed parameters without significant differences between them. Serum myostatin levels remained unchanged regardless of treatment group. A global analysis of all determinations (108) shows a positive correlation between myostatin and peptide C (r = 0.231, p = 0.02), insulin (rs = 0.215, p = 0.02), HOMA2-IR (rs = 0.200, p = 0.04), HOMA2-%β (rs = 0.210, p = 0.03) and HbA1c (r = 0.209, p = 0.03) and an inverse correlation with HOMA2-%S (rs = -0.197, p = 0.04). No correlations were observed between myostatin and other related carbohydrate metabolism parameters as undercarboxylated osteocalcin, osteocalcin, IGF-1, vitamin D and BMI.

**Conclusion:** The findings of the present study show significant association between circulating myostatin and insulin resistance in non obese women with postmenopausal osteoporosis. This study supports the idea that myostatin may exert a negative effect on glucose metabolism acting as an independent mechanism in the pathogenesis of type 2 diabetes mellitus.

## PS 037 Mechanisms of insulin action and inter-organ cross-talk

**Intracerebroventricular administration of vaspin triggers a brain-liver circuit to improve hepatic glucose homeostasis via the hepatic branch of the vagus**

W. Zhu<sup>1,2</sup>, L. Li<sup>1,2</sup>, K. Li<sup>3</sup>, G. Yang<sup>3</sup>;

<sup>1</sup>College of Laboratory Medicine, <sup>2</sup>Key Laboratory of Diagnostic Medicine (Ministry of Education), <sup>3</sup>Endocrinology, The Second Affiliated Hospital, Chongqing Medical University, China.

**Background and aims:** Visceral adipose tissue-derived serpin (vaspin) is a member serpin A12 of the serine protease inhibitor family, which plays an important role in the modulation of glucose metabolism and insulin sensitivity. More and more findings raise the possibility that, vaspin regulates glucose metabolism and energy balance through its act on the central (hypothalamic) site. However, the regulatory role of vaspin in the brain in the control of liver glucose fluxes is unknown. In this study, we investigated the effects of vaspin signal conveyed by the hypothalamus on liver glucose fluxes in normal-chow-diet (NCD) or high fat diet (HFD)-fed male rats with or without hepatic branch vagotomy. We reported here a novel role of central vaspin in triggering a brain-liver molecular signaling pathway and neuronal network to control glucose production in vivo

**Materials and methods:** We established a model of central administration of vaspin. Hyperinsulinemic-euglycemic clamp and hepatic branch vagotomy were used to assess the effects of central vaspin on glucose metabolism and changes in liver and signaling pathway. [<sup>3</sup>H-3H] glucose radioactivity was determined by scintillation counter. mRNA and protein expressions were measured by qRT-PCR and Western blot, respectively.

**Results:** We showed that central infusion of vaspin in HFD-fed animals significantly increased glucose uptake in peripheral tissues and decreased HGP. These changes were accompanied by a significant decrease in the hepatic glucose-6-phosphatase (G6Pase) and phosphoenolpyruvate carboxykinase (PEPCK) expression. In agreement with this, we also found that central vaspin in HFD rats activates the insulin receptor (InsR) → insulin receptor substrate-1 (IRS-1) → Akt kinase (Akt) → forkhead box-containing protein of the O subfamily 1 (FoxO1) signaling cascade in the liver leading to the increased insulin sensitivity and improved glucose metabolism.

**Conclusion:** Our findings suggest that hypothalamus is a site of vaspin action, where vaspin triggers a brain-liver circuit via the hepatic branch of the vagus nerve to inhibit glucose production and improve insulin resistance.

**Abnormal hepatic energy metabolism in type 1 diabetes associates with long-term metabolic control**

S. Gancheva<sup>1</sup>, A. Bierwagen<sup>1</sup>, P. Begovatz<sup>1</sup>, J. Lundbom<sup>1</sup>, P. Nowotny<sup>1</sup>, G. Gianfranceschi<sup>2</sup>, B. Hoffmann<sup>3</sup>, J. Szendroedi<sup>1,4</sup>, M. Roden<sup>1,4</sup>;

<sup>1</sup>Institute for Clinical Diabetology, German Diabetes Center, <sup>2</sup>Institute for Biometry and Epidemiology, German Diabetes Center, <sup>3</sup>Leibniz Research Institute for Environmental Medicine, <sup>4</sup>Department of Endocrinology and Diabetology, University Hospital Duesseldorf, Duesseldorf, Germany.

**Background and aims:** Insulin resistant patients with type 2 diabetes exhibit lower hepatic energy metabolism, which has been explained by increased lipid availability and/or impaired glycemic control. This study set out to examine the role of insulin resistance and glycemic control for hepatic energy metabolism in type 1 diabetes mellitus (T1D) patients with good glycemic control.

**Materials and methods:** Thirty-seven newly diagnosed T1D patients (age: 34±9 years; body mass index (BMI): 24.4±3.3 kg/m<sup>2</sup>) with known diabetes duration of less than one year underwent euglycemic-hyperinsulinemic clamps to assess whole-body (M-value) and hepatic insulin sensitivity (insulin-mediated percent suppression of endogenous glucose production). Hepatic fat content (HCL), γ-adenosine triphosphate (γATP) and inorganic phosphate (Pi) concentrations were quantified via magnetic resonance spectroscopy (<sup>31</sup>P/<sup>1</sup>H-MRS) on a 3-T clinical MR scanner (Philips, Best, The Netherlands).

BMI- and age-matched healthy controls (CON; n=27, age: 38±9 years; BMI: 24.4±3.4 kg/m<sup>2</sup>) were also studied with <sup>31</sup>P/<sup>1</sup>H-MRS.

**Results:** Well-controlled T1D patients (HbA1c: 6.5±1.1%) presented high whole-body and moderate hepatic insulin sensitivity (7.8±2.9 mg\*kg<sup>-1</sup>\*min<sup>-1</sup> and 62±24%). HCL was comparable between T1D and CON (1.7±3.1% and 1.9±3.9%). Hepatic γATP concentrations were 16% lower in T1D (2.22±0.54 vs CON: 2.61±0.55 mmol/l, P<0.01), whereas Pi levels were not different between groups. Within the T1D group, hepatic γATP related negatively with HbA1c (r=-0.42, P=0.01), whereas Pi related negatively to BMI (r=-0.39, P=0.02), waist circumference (r=-0.47, P=0.003) and HCL (r=-0.55, P<0.001). Neither hepatic γATP, nor Pi displayed correlations with whole-body and hepatic insulin sensitivity.

**Conclusion:** Hepatic γATP is reduced in patients with T1D even in the absence of liver steatosis, and associates with measures of long-term glycemic control, but not with hepatic and peripheral insulin sensitivity.

**Insulin resistance and beta cell function in nonalcoholic fatty liver disease (NAFLD)**

K. Wyne<sup>1</sup>, Y.S. Shen<sup>2</sup>, L. Folb<sup>3</sup>, H.P. Monsour<sup>4</sup>;

<sup>1</sup>HMH, <sup>2</sup>UT Houston, <sup>3</sup>Endocrinology, HMH, <sup>4</sup>Hepatology, HMH, Houston, USA.

**Background and aims:** The global epidemic of non-alcoholic fatty liver disease (NAFLD) has led to the recognition of associated complications that include diabetes and cardiovascular disease in addition to the liver failure and/or hepatocellular carcinoma related to the nonalcoholic steatohepatitis (NASH). The increased risk of cardiovascular disease suggests that NAFLD is the hepatic component of the Metabolic Syndrome. The goal of this study is to evaluate β-cell function and insulin resistance in correlation to metabolic parameters in NAFLD/NASH patients to determine parameters to identify NAFLD patients at increased risk of diabetes.

**Materials and methods:** Charts were reviewed retrospectively from 200 consecutive patients in the Metabolic Liver Clinic. After excluding those with viral or autoimmune hepatitis, gluco-regulatory status was assessed by A1c and by OGTT with glucose & insulin measured at 0, 30, 60, 90 & 120 minutes plus c-peptide & proinsulin measured at 0 & 30 minutes. Homeostatic model assessment (HOMA) of β-cell function and insulin resistance (IR) were calculated. Subjects treated with insulin were excluded from this part of the analysis. We assessed correlations with fasting insulin, proinsulin, fasting c-peptide, insulin resistance as measured by HOMA-IR, pancreatic β-cell function, as measured by HOMA-β, BMI, lipids, liver enzymes and NASH FibroSURE<sup>®</sup>. Spearman correlation coefficient was used to measure the association between metabolic parameters.

**Results:** After excluding diabetes (whether known or newly diagnosed; n=64) 58 patients were found to have NAFLD and prediabetes. In the subjects with prediabetes the following significant correlations were found: HOMA-IR with BMI (p=0.022) but not A1c; fasting proinsulin with BMI (p=0.0081) and A1c (p=0.04), fasting glucose (p=0.006) with HDL (p=0.0007); fasting C-peptide with BMI (p<0.02), HDL (p=0.01) and HOMA-IR (p=0.0018); and FibroSURE<sup>®</sup> Steatosis Score with BMI (p < 0.0001) and A1c (p<0.05). There was a significant negative correlation between HDL and fasting insulin level (p =0.0079). There was no correlation between c-peptide and FibroSURE<sup>®</sup> Steatosis Score. When evaluated by gender the majority of the significant correlations remained present in men but not in women with the exception of BMI (p<0.05 in women) and A1c (p<0.05 in women).

**Conclusion:** The majority of the patients referred to the Metabolic Liver Clinic for evaluation of NAFLD were found to have either Type 2 Diabetes or prediabetes, most of which was not previously diagnosed. Analysis of those with prediabetes found insulin resistance with elevated insulin, proinsulin and c-peptide levels suggesting that identification of the NAFLD had facilitated early diagnosis of prediabetes in these patients who still had significant beta-cell function. These data demonstrate that screening NAFLD patients is an opportunity to identify prediabetes at a stage when therapy has the potential to slow or prevent the progression to not only Type 2 Diabetes but also the cardiovascular disease that is significantly increased in this population. Studies are ongoing to identify medical strategies to improve the gluco-regulatory status of these NAFLD patients with prediabetes.

## 591

**The association of serum fibroblast growth factor 21 with insulin secretory function and metabolic parameters in type 2 diabetes**M.-J. Kim<sup>1</sup>, M.-K. Kim<sup>2</sup>, I. Song<sup>2</sup>, H. Kim<sup>2</sup>, Y.-K. Choi<sup>3</sup>, K.-H. Bae<sup>3</sup>, K.-G. Park<sup>3</sup>, I.-K. Lee<sup>3</sup>, J.-E. Lee<sup>4</sup>, E. Jung<sup>5</sup>, E. Kim<sup>6</sup>;<sup>1</sup>Pooren Meerae Internal Medicine Clinic, <sup>2</sup>Department of Internal Medicine, Keimyung University School of Medicine, <sup>3</sup>Kyungpook National University School of Medicine, <sup>4</sup>CHA Gumi Medical Center, <sup>5</sup>Department of Internal Medicine, Catholic University of Daegu School of Medicine, <sup>6</sup>Daegu Fatima Hospital, Republic of Korea.

**Background and aims:** Fibroblast growth factor 21 (FGF21) is a cytokine produced by the liver, adipose tissue, skeletal muscle, and the pancreas. Recently, FGF21 is suggested as a key metabolic regulator in glucose and lipid metabolism and its level in serum is higher in the patients with metabolic syndrome, type 2 diabetes and non-alcoholic steatohepatitis. On the other hand, diminished expression of FGF21 is shown in type 1 diabetes and latent autoimmune diabetes in adult (LADA). Type 2 diabetes is a heterogenic disease entity and patients with type 2 diabetes have diverse insulin secretory dysfunction. So, we investigated the association of serum FGF21 and insulin secretory function in patients who admitted our institute for poorly controlled blood glucose and needed insulin therapy.

**Materials and methods:** We recruited 154 patients (men 52; women 152) with type 2 diabetes who were not treat with insulin prior to informed consent from January 2011 to July 2013, who admitted Keimyung University Dongsan Medical Center. We reviewed personal history including drug history, anthropometric parameters, other metabolic parameters, and measured serum adiponectin and FGF21.

**Results:** Mean age was 55.4±14.0 in men and 61.4±14.1 in women and body mass index was 24.2±4.7 kg/m<sup>2</sup> in men and 25.0±4.2kg/m<sup>2</sup> in women. There was no significant difference in hemoglobin A1c (10.4% in men; 10.3% in women). Fasting C-peptide, insulin and homeostasis model assessment of insulin secretion (HOMA-IS) were used as assessment of insulin secretory function. Serum FGF21 level shows correlations with HOMA-IS and fasting insulin in men, but not in women. In addition, serum FGF21 level shows correlations with serum triglyceride, insulin and homeostasis model assessment of insulin resistance (HOMA-IR) in men, however, shows correlations with urine albumin/creatinine and HOMA-IR in women. As a result of multivariate linear regression analysis, only HOMA-IS has a significant correlation with serum FGF21 level. Serum adiponectin level shows negative correlations with duration of diabetes, BMI, total cholesterol and low density lipoprotein in men and shows negative correlation with BMI, waist circumference, total cholesterol and triglyceride, high density lipoprotein in women.

**Conclusion:** Consequently, this study exhibits a positive correlation of serum FGF21 level with an index of insulin secretory function in men with type 2 DM and supports the result of another study with type 1 diabetes and LADA.

## 592

**Novel paracetamol glucuronide derivative for quantifying gluconeogenesis using the deuterated water method**J. Jones<sup>1,2</sup>, S. Kahl<sup>3,4</sup>, F. Carvalho<sup>1</sup>, C. Barosa<sup>1</sup>, M. Roden<sup>3,4</sup>;<sup>1</sup>Metabolic Control Group, Center for Neurosciences, Coimbra, Portugal,<sup>2</sup>Portuguese Diabetes Association (APDP), Lisbon, Portugal,<sup>3</sup>Institute of Clinical Diabetology, Deutsches Diabetes-Zentrum,<sup>4</sup>Department of Endocrinology and Diabetology, Heinrich-Heine University, Düsseldorf, Germany.

**Background and aims:** In fasted humans, the analysis of plasma glucose <sup>2</sup>H-enrichment in position 5 relative to position 2 (H5/H2) following ingestion of deuterated water (<sup>2</sup>H<sub>2</sub>O) is widely used to measure the fractional contribution of gluconeogenesis to endogenous glucose production (EGP). This information can be noninvasively obtained via urinary Paracetamol glucuronide (PG): a product that is more stable and abundant compared to blood glucose. However, current methods for derivatizing urinary PG to a form that can be analyzed for positional <sup>2</sup>H-enrichment by NMR or MS are laborious and ill-suited for high-throughput studies. We developed a novel procedure where urinary PG is derivatized to 5-O-acetyl monoacetone glucuronic lactone (MAGLA). The chemical transformation and purification steps are robust and amenable to automation and parallel processing and yield resolved signals for H5/H2 analysis by <sup>2</sup>H NMR (see Figure). We applied this procedure to a study where <sup>2</sup>H<sub>2</sub>O and Paracetamol were given to overnight fasted

healthy subjects and compared H5/H2 of plasma glucose with that of urinary glucuronide.

**Materials and methods:** Eleven subjects were admitted to the clinical research unit on the evening before the study and provided a standard supper at 17.30. Each ingested 0.5 g <sup>2</sup>H<sub>2</sub>O/kg body water in three equally divided doses at 20:00, 22:00, and 24:00. At 05:00 the following day, Paracetamol (0.5g) was given and a primed infusion of [6,6-<sup>2</sup>H<sub>2</sub>]glucose was initiated. Urine was sampled from 06:00-08:00 and blood was sampled at 07:40. Plasma glucose and urinary PG enrichments of positions 5 and 2 were measured by <sup>2</sup>H NMR following their derivatization to monoacetone glucose and MAGLA, respectively. The fractional gluconeogenic contributions to EGP were calculated from plasma glucose H5/H2. These were compared with estimates obtained from urinary glucuronide H5/H2.

**Results:** The overall yield of MAGLA from urinary glucuronide was 20–40% and the preparations gave well-resolved <sup>2</sup>H NMR signals for quantifying H5/H2. Analysis of MAGLA yielded identical estimates of fractional gluconeogenic contributions to EGP to that of plasma glucose (54 ± 2% versus 55 ± 3%, respectively). Furthermore, a Bland-Altman analysis indicated agreement at the 95% confidence level between the sets of plasma glucose and urinary MAGLA measurements.

**Conclusion:** The conversion of urinary Paracetamol glucuronide to MAGLA is a relatively simple and robust procedure for obtaining estimates of gluconeogenesis using <sup>2</sup>H<sub>2</sub>O, or indeed any gluconeogenic tracer. For overnight-fasted healthy subjects, <sup>2</sup>H NMR analysis of MAGLA provides identical estimates of fractional gluconeogenesis to that of plasma glucose.

## 593

**BTG2 regulates hepatic gluconeogenesis through Nur77 in diabetes**S.-S. Im<sup>1</sup>, Y.-D. Kim<sup>1</sup>, B.-C. Oh<sup>2</sup>, J.-H. Bae<sup>1</sup>, D.-K. Song<sup>1</sup>;<sup>1</sup>Physiology, Keimyung University School of Medicine, Daegu,<sup>2</sup>Lee Gil Ya Cancer and Diabetes Institute, Incheon, Republic of Korea.

**Background and aims:** Beta cell translocation gene 2 (BTG2) is a member of a family that is involved in cellular functions. Herein, we demonstrate that BTG2 regulates glucose homeostasis via up-regulation of Nur77 in diabetic mice.

**Materials and methods:** Diabetes was induced in wild-type (WT) and db/db mice by i.p injections of streptozotocin (80 mg/kg body weight). GTT and ITT were performed with db/db mice. Mice were infected with adenoviral vector expressing Btg2(1×10<sup>9</sup> pfu) by tail vein injection. Gene expression and induction level were measured by qPCR and immunoblotting.

**Results:** Hepatic BTG2 gene expression was elevated by fasting and forskolin. Overexpression of BTG2 increased the expression of hepatic gluconeogenic genes, glucose output, and subsequently impaired glucose and insulin tolerance. Up-regulation of the transcriptional activity of Nur77 and gluconeogenic genes, and glucose production by forskolin were observed by BTG2 transduction, but not in BTG2 knockdown. BTG2-stimulated glucose production and G6pc promoter activity was attenuated by dominant-negative Nur77, but not in Pck1 promoter. Chromatin immunoprecipitation assays showed that BTG2 induced Nur77 occupancy on the glucose-6-phosphatase gene promoter via a physical interaction. BTG2 gene expression was increased in streptozotocin-treated and db/db mice. Finally, impairment of

glucose homeostasis such as the increase of blood glucose, glucose intolerance and insulin intolerance was elevated in diabetic mice, whereas this phenomenon was abolished in knockdown of BTG2.

**Conclusion:** These data suggest that BTG2 participates in the regulation of hepatic glucose homeostasis, which involves that BTG2 might serve as a potential therapeutic target for combating metabolic dysfunction.

### New diabetes drug targets from structural characterisation of liver glycogen

R.G. Gilbert<sup>1,2</sup>, M.A. Sullivan<sup>2,1</sup>, S.A. Aroney<sup>2</sup>, S. Li<sup>2</sup>, P.O. Powell<sup>2</sup>, E.J. Warren<sup>2</sup>;

<sup>1</sup>Tongji School of Pharmacy, Huazhong University of Science and Technology, Wuhan, China, <sup>2</sup>Centre for Nutrition and Food Science, University of Queensland, Brisbane, Australia.

**Background and aims:** Glycogen is a highly branched polymer of glucose, functioning as a blood-glucose buffer. It comprises relatively small beta particles, which may be joined as larger aggregate alpha particles. The molecular size distributions from size-exclusion chromatography of liver glycogen from non-diabetic and diabetic mice show that diabetic mice have impaired alpha particle formation in liver glycogen, with diabetic mice unable to form as many large glycogen particles as non-diabetic controls. There is also reason to believe that the degradation of larger particles back to glucose will be slower, and hence under better control, than smaller beta particles. Further analysis into the nature of “healthy” glycogen has provided evidence that these alpha particles are held together via an unknown glue that is most likely proteinaceous. This study probes the structure of glycogen alpha particles by analyzing their digestion during acid hydrolysis and by comparing the *in vitro* digestion rate of glycogen phosphorylase for glycogen of various sizes. This greater insight into the internal nature of alpha particles is an important step into finding potential drug targets that would allow diabetic sufferers to form these larger alpha particles and hence have better blood-sugar control.

**Materials and methods:** The digestion of glycogen by acid hydrolysis was investigated by analyzing the size distributions, obtained using size-exclusion chromatography, of pig-liver glycogen and phytoglycogen at various time points in a low-pH buffer. In addition, glycogen from the livers of wild-type mice were extracted and fractionated into different sizes using sucrose density centrifugation. The size distributions of these fractions were compared using size-exclusion chromatography. The *in vitro* kinetics of the initial rates of phosphorylase degradation were examined and compared for each fraction using an assay that utilized the production of NADPH in the reaction mixture, which has an absorbance at 340 nm.

**Results:** The acid hydrolysis experiments show that the alpha particles in the liver glycogen degrade via a different mechanism to that of the smaller beta particles, indicating a different type of chemical bonding (most likely proteinaceous). The *in vitro* kinetics analysis of glycogen phosphorylase on fractionated glycogen showed that larger glycogen particles indeed had a lower initial rate of phosphorylase degradation.

**Conclusion:** The difference in kinetics of the acid hydrolysis of alpha and beta particles indicates that they have a different mechanism of biosynthesis. The hypothesis that larger glycogen alpha particles are more slowly degraded by glycogen phosphorylase, presumably due to a lower surface area to volume ratio, was supported by the present data. This shows that diabetic mice, which have been shown to lack the larger alpha particles, may be vulnerable to having a fast, uncontrolled release of glucose. Because alpha particles have been shown here to have a separate mechanism of formation to smaller beta particles, the activation of this process in diabetic sufferers is now a potential drug target.

## 595

### Post-prandial and ChREBP mediated PANDER expression

W.A. Danse, M.N. Kuehl, A.C. Chechele, B.R. Burkhardt; Cell Biology, Microbiology and Molecular Biology, University of South Florida, Tampa, USA.

**Background and aims:** Pancreatic-Derived Factor (PANDER, FAM3B) is a novel endocrine pancreatic secreted protein mainly characterized from this tissue. PANDER regulates hepatic insulin sensitivity and overall glycaemic levels. However, recent research now suggests that PANDER is poten-

tially expressed within the liver as well. Our previous data have shown the PANDER promoter to be highly active and glucose-responsive in a murine liver-derived cell line. To further investigate the regulation and expression of hepatic derived PANDER, we examined hepatic PANDER levels in mice and characterized the minimal element of the PANDER promoter in a liver-derived cell line.

**Materials and methods:** Western analysis was performed to evaluate the presence of PANDER protein within murine tissues. Promoter deletion analysis and co-transfection experiments were performed using PANDER promoter-luciferase constructs and ChREBP expression plasmids in a murine liver-derived cell line, BNL-CL2.

**Results:** Initial western analysis performed on 15 different murine-derived tissues revealed robust PANDER expression within the murine liver and to a lesser extent in the brain and ovary. Furthermore, hepatic PANDER levels were measured in the fasted and fed state of our PANDER transgenic and control mice and revealed increased levels in the post-prandial state. The minimal element was identified between -293 to -3 bp of the hepatic transcriptional start site. The region between -193 to -93 bp of the TSS was demonstrated as being necessary for basal promoter activity. This region contains three E-box elements which may serve as a binding site for the critical hepatic transcription factor carbohydrate responsive element binding protein (ChREBP). Co-transfection reporter studies revealed that PANDER promoter activity is significantly upregulated ( $p < 0.05$ ) in response to increased levels of ChREBP under both starved and elevated glucose conditions.

**Conclusion:** Our western analysis results confirm the presence of PANDER protein within murine liver tissue as well as the upregulation of PANDER protein in the fed state. This supports our previous finding that elevated glucose levels result in increased PANDER promoter activity. In addition, we identified a minimal element within the PANDER promoter which contains a putative binding site for the glucose-responsive transcription factor ChREBP. Our co-transfection experiments suggest that ChREBP may play a role in mediating the glucose-responsiveness of the PANDER promoter within the liver, and indicates another mechanism for regulation of hepatic insulin signaling via PANDER.

## 596

### Soluble RAGE is unlikely to induce type 2 diabetes by inducing insulin resistance or beta cell dysfunction

S.K. Biswas<sup>1</sup>, S. Mohtarin<sup>1</sup>, S.R. Mudi<sup>2</sup>, T. Anwar<sup>1</sup>, S.M.K. Alam<sup>1</sup>, M.I. Arslan<sup>1</sup>;

<sup>1</sup>Department of Biochemistry, Bangabandhu Sheikh Mujib Medical University (BSMMU), <sup>2</sup>Department of Biochemistry and Cell Biology, Bangladesh Institute of Research and Rehabilitation in Diabetes, Endocrine and Metabolic Disorders (BIRDEM), Dhaka, Bangladesh.

**Background and aims:** Soluble receptor for advanced glycation end product (sRAGE) is considered as protective against diseases originating from RAGE activation. However, recent studies have suggested that sRAGE may be involved in the pathogenesis diabetes mellitus. A declining level of sRAGE has been suspected to be a predictor of type 1 diabetes, and an independent association has been found between low levels of sRAGE and development of type 2 diabetes. To further explore the involvement of sRAGE in the pathogenesis of type 2 diabetes, present study was designed to assess whether sRAGE level alters in prediabetic subjects and whether sRAGE level correlates with insulin resistance and beta cell function.

**Materials and methods:** A total of 128 subjects were recruited from those who came for diabetes screening at our medical university. Subjects were grouped as control (normoglycemic), pre-diabetic and diabetic based on their blood glucose (fasting and 2 hrs after 75 grams glucose load) and HbA1c levels following ADA criteria. Subjects suffering from complications of diabetes mellitus, hypertension, chronic liver and kidney diseases, and regular drug users were excluded. Fasting serum sRAGE levels were measured by ELISA (R&D Systems), and insulin levels were measured by enzyme immunoassay technique (Abbott AxSym System). Insulin resistance (HOMA2-IR) and beta cell function (HOMA2-%B) were calculated using HOMA2 calculator. To achieve a normal distribution some values were appropriately transformed before statistical analysis in SPSS 17.0 software. A  $p$  value of  $< 0.05$  was considered statistically significant.

**Results:** Age ( $40.2 \pm 8.7$  years) and sex ( $m=58, f=70$ ) distribution of the study subjects were not different among control ( $n=30$ ), pre-diabetic ( $n=42$ ) and diabetic ( $n=56$ ) groups. Fasting glucose and HbA1c levels were found significantly ( $p < 0.001$ ) elevated in diabetic group compared to control and pre-diabetic groups. Fasting insulin levels were found similar among control

(11.8±6.8), pre-diabetic (14.2±8.7) and diabetic (13.8±11.0 μU/mL) groups. However, HOMA2-IR values [median (IQR)] were 1.37 (0.99-2.12) for control, 1.71 (1.27-2.60) for pre-diabetic and 1.95 (1.13-3.23) for diabetic groups ( $p < 0.05$ ); and HOMA2-%B values were 140% (99-198) for control, 132% (107-167) for pre-diabetic and 46% (24-89) for diabetic groups ( $p < 0.001$ ). However, serum sRAGE levels did not show any difference among control [626 (413-826) pg/mL], pre-diabetic [656 (463-968)] and diabetic [646(493-817)] groups. More importantly, serum sRAGE level did not show any significant correlation with HOMA2-IR, HOMA2-%B, fasting glucose, insulin and HbA1c levels in all subjects. Serum sRAGE level also did not show any correlation with the above parameters in diabetic patients or in pre-diabetic subjects.

**Conclusion:** Serum sRAGE level did not show any change in pre-diabetic subjects compared with control and diabetic subjects. Moreover, sRAGE level did not show any correlation with insulin resistance or beta cell function. These data therefore suggest that sRAGE is unlikely to induce type 2 diabetes by inducing insulin resistance or beta cell dysfunction.

**The effect of bariatric surgery on fat distribution and glucose uptake in abdominal and femoral regions in morbidly obese patients**

P.Y. Dadson;

Turku PET Center, Finland.

**Background and aims:** Bariatric surgery reduces weight and improves insulin sensitivity. We investigated the effects of bariatric surgery on fat distribution and insulin-stimulated glucose uptake in fat tissue in abdominal and femoral regions in morbidly obese patients compared with non-obese healthy controls.

**Materials and methods:** Twenty five morbidly obese patients (age 46±9, body mass index 43.2±3.8 kg/m<sup>2</sup>) and 10 non-obese controls (age 47.3±6.0, BMI 23.6±1.9) were studied using positron emission tomography to assess glucose uptake in fat tissue in the abdomen and in femoral area during insulin stimulation. Whole body magnetic resonance imaging was performed to measure abdominal and femoral fat content of obese and controls. Obese patients were studied before and six months after the surgery. The abdominal subcutaneous fat was divided into anterior and posterior regions. The posterior region was further divided into deep and superficial layers using the presence of fascia. The visceral fat was divided into intraperitoneal and extraperitoneal regions using specific anatomical reference points. Subcutaneous fat mass was segmented 10 cm in the mid-section of the thigh.

**Results:** Total body fat (kg) in obese decreased after surgery, but remained higher compared to non-obese controls ( $P < 0.001$ ). Compared to baseline, obese subjects lost 39% fat mass in posterior deep, 32% in posterior superficial and 40% in total anterior region ( $p < 0.001$ ). Subcutaneous fat in the thigh decreased by 28% ( $P < 0.001$ ). For visceral fat, intraperitoneal fat decreased by 44% while extraperitoneal fat by 29% after surgery ( $P < 0.001$ ). In spite of the decreases in abdominal fat masses, the waist to hip ratio did not change after surgery ( $P = 0.10$ ). Whole body insulin sensitivity increased by 94% at follow up ( $P < 0.001$ ). Insulin-stimulated glucose uptake in abdominal adipose in deep layer increased by 19% ( $P = 0.001$ ), 49% in superficial ( $P = 0.01$ ) and 28% in subcutaneous fat in the thigh ( $P = 0.03$ ) after surgery. When the various insulin-stimulated glucose uptakes were expressed per kilogram of fat, there were no changes after surgery and the results were similar to the non-obese controls.

**Conclusion:** Over 30% of fat mass is lost 6 months after surgery from all abdominal fat depots and adipose tissue insulin sensitivity improves in line with lipolysis. Adipose tissue metabolism in different depots remained the same after surgery and was close to the healthy controls.

## 598

**Impact of adiposity on glycaemic variability with type 2 diabetes**

T. Mayu, H. Makino, T. Tamanaha, Y. Ohata, R. Koezuka, A. Hishida, I. Kishimoto;  
Diabetes, National cerebral and Cardiovascular Center, Suita City, Japan.

**Background and aims:** High glycaemic variability generates oxidative stress and contributes to the development of endothelial dysfunction and cardiovascular complications in patients with type 2 diabetes. However, the factors affecting glycaemic variability have not been fully studied. In the present study, we examined the effect of body status, body composition and abdominal fat area on the parameters of glycaemic variability determined by continuous blood glucose monitoring system (CGMS) in subjects with type 2 diabetes.

**Materials and methods:** Among patients referred to our department between August 2012 and February 2014, 41 patients with type 2 diabetes (mean age 68.7 years; 70 % men; HbA1c 8.4 %; BMI 24.2; energy intake; 22–32 kcal/ideal body weight (60 % carbohydrate)) who underwent CGMS were selected. Their antihyperglycaemic therapy consisted of oral hypoglycaemic agents (n=31) and/or insulin (n=32) (None were diet alone). Based on CGMS data, we evaluated the following criteria for variability of glycaemic control from data of the intermediate 48 hours (midnight to midnight): average glucose levels, standard deviation (SD) values, mean amplitude of glycaemic excursions (MAGE), percentage of time spent in hyperglycaemia (> 140 mg/dL) and percentage of time spent in hypoglycaemia (< 70 mg/dL). We investigated the effect of body status (body mass index (BMI)) for these glycaemic variability indices. Furthermore, the impact of body composition (body fat mass (kg), skeletal muscle mass (kg); n=19) and of abdominal fat area (subcutaneous fat area (SFA, m<sup>2</sup>), visceral fat area (VFA, m<sup>2</sup>); n=31) on glycaemic variability is also evaluated in the subgroup analyze.

**Results:** Among all participants, the mean  $\pm$  SD of average glucose levels, SD of glucose variability and MAGE were 140  $\pm$  27 mg/dl, 32  $\pm$  13 mg/dl and 81  $\pm$  28 mg/dl, respectively. When patients were divided into two categories by median (74 mg/dl) split of MAGE, higher MAGE category had a significantly lower BMI (p=0.004) than those with lower MAGE category. In univariate analysis, BMI was significantly negatively correlated with SD (p<0.001), MAGE (p=0.015) and percentage of time spent in hypoglycaemia (p=0.005), whereas BMI was not related to average glucose levels or percentage of time spent in hyperglycaemia. In multivariate analysis relationships between BMI and MAGE or SD remained significant after adjustment of age, gender, diabetes duration and HbA1c (R<sup>2</sup>=0.29 for the model including MAGE and R<sup>2</sup>=0.41 for the model including SD), and no correlation was found with percentage of time spent in hypoglycaemia. Among body composition, body fat mass was negatively correlated to SD with a statistical significance (p=0.036), while no relationship was observed between skeletal muscle mass and SD (p=0.974). Multivariate analysis showed that body fat mass was significantly related to SD (R<sup>2</sup>=0.39) after adjustments of age and sex. Among abdominal fat area, both SFA and VFA were significantly negatively associated with MAGE (SFA; p=0.004, VFA; p=0.011) and SD (SFA; p=0.002, VFA; p=0.040). In multivariate analysis, SFA and VFA was significantly related to MAGE (SFA; R<sup>2</sup>=0.46, VFA; R<sup>2</sup>=0.50) and SD (SFA; R<sup>2</sup>=0.50, VFA; R<sup>2</sup>=0.57). **Conclusion:** In patients with type 2 diabetes, adiposity is negatively correlated with glycaemic variability independent of age, sex, diabetes duration, HbA1c or skeletal muscle mass. Our data raise the possibility that low fat mass indicates the presence of insulin secretory disorder.

## 599

**Insulin resistance predicts cardiovascular morbidity in men without diabetes mellitus and this effect is modified by level of physical activity**

C.A. Larsson<sup>1,2</sup>, M.I. Hellgren<sup>3</sup>, B. Daka<sup>2</sup>, P.-A. Jansson<sup>3</sup>, U. Lindblad<sup>2</sup>;

<sup>1</sup>Department of Clinical Sciences, Malmö, Social Medicine and Global Health, Lund University, Malmö, <sup>2</sup>Department of Public Health and Community Medicine and Global Health/Primary Health Care, University of Gothenburg, <sup>3</sup>The Wallenberg Laboratory, Department of Molecular and Clinical Medicine, University of Gothenburg, Sweden.

**Background and aims:** Type 2 diabetes, as well as different measures of insulin resistance, has been shown to predict cardiovascular disease (CVD). Although type 2 diabetes is known to have a more adverse cardiovascular effect in women than in men, it is not clear whether the same is true for insulin resistance. The potentially mediating effect of physical activity on the association between insulin resistance and CVD is also yet to be fully explored. The aim of the present study was thus to assess how well insulin resistance

predicts CVD in non-diabetic men and women, and to explore the influence of physical activity.

**Materials and methods:** In 2002–2005, 2816 randomly selected men and women in two municipalities in Sweden, aged 30–75 years, were examined for CVD risk factors (76% participation). Anthropometric measurements were conducted, blood pressure was measured, and a standard oral glucose tolerance test was performed. Questionnaires about lifestyle and physical activity were also completed. For this prospective cohort study, 2563 subjects without diabetes and prior history of CVD were surveyed for first events of CVD through record-linkage with the National Swedish Inpatient and Mortality registers. Insulin resistance was estimated by fasting concentrations of plasma insulin and by HOMA index for insulin resistance (HOMA<sub>IR</sub>; fasting insulin  $\times$  fasting glucose / 22.5). After controlling for proportionality, Cox proportional regression model was used to analyse the association between insulin resistance and CVD. Log transformation of Homa-ir was used in all analyses to induce normality.

**Results:** After a mean follow-up of 8 years, HOMA<sub>IR</sub> was significantly associated with increased CVD morbidity in men (50 events) and women (26 events) combined (HR 1.3, 95% CI 1.1–1.6). However, when stratified by gender, HOMA<sub>IR</sub> was predictive for CVD solely in men (HR 1.8, CI 1.3–2.4) and not in women (HR 1.1, CI 0.1–1.5). When stratifying also for high and low physical activity the predictive value of insulin resistance became stronger in sedentary men (HR 2.3, CI 1.5–3.4), whereas it abolished in men performing moderate to vigorous physical activity (HR 1.0, CI 0.1–1.6). These results remained when also adjusting for age, APOB/APOA1, BMI, hypertension, smoking, alcohol consumption, and education, despite that almost all such risk factors showed significantly more beneficial levels in participants reporting high levels of physical activity as compared to those reporting low levels. Furthermore, a three-way interaction analysis between sex, HOMA<sub>IR</sub>, and physical activity, was highly significant (p=0.002). The CVD risk associated with fasting plasma insulin was similar to the risk of HOMA<sub>IR</sub>.

**Conclusion:** Although men may be more vulnerable to insulin resistance than women, only physically inactive men seemed to be at increased CVD risk from insulin resistance in this study. These results emphasise the importance of a high level of physical activity, as physical activity substantially increases insulin sensitivity and may also limit the negative cardiovascular effects of an increased insulin resistance in men.

**Android and gynoid fat are independently associated with hepatic and whole-body insulin resistance in non-diabetic males from the Oxford Biobank**

K.E. Pinnick<sup>1</sup>, K. Brismar<sup>2</sup>, F. Karpe<sup>1</sup>;

<sup>1</sup>Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, UK, <sup>2</sup>Department of Molecular Medicine and Surgery, Karolinska Institutet, Stockholm, Sweden.

**Background and aims:** Upper- and lower-body fat depots exhibit opposing associations with insulin resistance and type 2 diabetes risk independent of overall obesity. Most associations have been detected using conventional anthropometrics, yet these measurements do not accurately quantify regional fat depots compared with techniques such as dual-energy X-ray absorptiometry (DXA). In this study we aimed to investigate whether android and gynoid DXA-quantified fat depots are independently associated with hepatic and peripheral insulin resistance in a healthy, non-diabetic, adult cohort.

**Materials and methods:** Subjects (406 (M) males, 387 (F) females), aged 30–50 years, were recruited from the Oxford Biobank. All subjects underwent detailed screening which included a fasting blood sample, anthropometric measurements and quantification of regional fat depots (% fat) by DXA. Plasma glucose was measured enzymatically. Plasma insulin and insulin-like growth factor binding protein 1 (IGFBP1) were measured by radioimmunoassay. Whole-body and hepatic insulin resistance were estimated using HOMA-IR and plasma IGFBP1, respectively. Spearman's Rank ( $r_s$ ) and partial correlation coefficients ( $r$ ) are presented.

**Results:** In both sexes, HOMA-IR positively correlated with android (M: 0.511, p=1.4x10<sup>-28</sup>; F: 0.501, p=4.9x10<sup>-26</sup>) and gynoid (M: 0.452, p=2.5x10<sup>-18</sup>; F: 0.317, p=1.6x10<sup>-10</sup>) % fat, whereas plasma IGFBP1 was inversely related to android (M: -0.612, p=3.2x10<sup>-43</sup>; F: -0.524, p=6.1x10<sup>-29</sup>) and gynoid (M: -0.443, p=4.7x10<sup>-21</sup>; F: -0.248, p=7.2x10<sup>-7</sup>) % fat. Partial correlation analysis identified a depot-specific relationship between % fat content and markers of insulin resistance in males. After controlling for total fat mass, android % fat remained inversely associated with IGFBP1 (-0.223, p=5.7x10<sup>-6</sup>) while the association

with HOMA-IR was abolished ( $-0.077$ ,  $p=0.121$ ). Furthermore, when HOMA-IR was corrected for, the inverse association between android % fat and IGFBP1 was retained ( $-0.241$ ,  $p=9.2 \times 10^{-7}$ ). By contrast, gynoid % fat was inversely associated with HOMA-IR after controlling for total fat mass ( $-0.154$ ,  $p=1.8 \times 10^{-3}$ ) and the association with IGFBP1 was abolished ( $0.095$ ,  $p=0.054$ ). These findings could not be replicated using anthropometric measures of regional fat depots. For example, after adjusting for total fat mass, waist circumference was equally associated with HOMA-IR ( $0.116$ ,  $p=1.9 \times 10^{-2}$ ) and IGFBP1 ( $-0.113$ ,  $p=2.3 \times 10^{-2}$ ). In females, after controlling for total fat mass, android and gynoid % fat also displayed opposite directions of association with HOMA-IR (android:  $0.124$ ,  $p=1.4 \times 10^{-2}$ ; gynoid:  $-0.197$ ,  $p=9.0 \times 10^{-5}$ ) and IGFBP1 (android:  $-0.145$ ,  $p=4.2 \times 10^{-3}$ ; gynoid:  $0.161$ ,  $p=1.4 \times 10^{-3}$ ) however the strength of association was similar for both depots.

**Conclusion:** Our findings highlight the advantage of quantifying specific fat depots by DXA over anthropometric measures when assessing insulin resistance. In males, hepatic insulin resistance (assessed by IGFBP1) was independently associated with greater android fat content whereas whole-body insulin resistance (HOMA-IR) was associated with diminished gynoid fat content. These findings lend further support to the paradoxical relationship between diabetes risk and body fat distribution.

### A study of the mechanisms through which the biogenesis of adiponectin is regulated in white adipose tissue

L. Zhang<sup>1</sup>, M.M. Li<sup>1</sup>, M. Corcoran<sup>1</sup>, S. Zhang<sup>1</sup>, G.J.S. Cooper<sup>1,2</sup>;

<sup>1</sup>School of Biological Sciences, University of Auckland, New Zealand,

<sup>2</sup>Manchester Biomedical Research Centre, University of Manchester, UK.

**Background and aims:** Adiponectin is an adipose tissue-derived hormone with anti-diabetic, anti-atherogenic and anti-inflammatory functions. Defects in adiponectin multimerization are associated with decreased adiponectin levels, obesity and insulin resistance. In this study, we investigated the enzyme systems responsible for adiponectin multimerization and production, and other factors also contributing to this process.

**Materials and methods:** OB mice (10- or 27-week) and age-matched C57 controls were used in this study. Fully differentiated 3T3-L1 adipocytes were also used. Quantitative real time-PCR was performed to measure the mRNA expression levels of a number of genes in white lipid tissue (WAT) from mice and 3T3-L1 adipocytes. ELISA/western blots were used to measure the expression of relative protein levels. Statistical analysis was performed by *t*-test or analysis of variance (ANOVA) with appropriate post-hoc tests.

**Results:** In fully-differentiated 3T3-L1 adipocytes, we observed that decreased insulin signalling caused by blocking the insulin receptor (InsR) with a blocking anti-InsR antibody, increased extracellular adiponectin levels, whereas coexisting hyperinsulinaemia counteracted this effect. Blocking the adenosine monophosphate-activated protein kinase (AMPK) pathway by using an inhibitor (compound C) significantly decreased extracellular adiponectin levels. Furthermore, we demonstrated the expression of lysyl hydroxylases (LHs), prolyl hydroxylases (PHs) and glycosyltransferase 25-domain-containing proteins 1&2 (Glt25D1&2) in the WAT of mice. Expression of LH3 was markedly increased in the WAT of OB mice compared with controls. In differentiated 3T3-L1 adipocytes, non-specific inhibition of LHs and PHs by the hydroxylase inhibitor, dipyriddy markedly suppressed adiponectin production, particularly of the higher molecular-weight isoforms, but increased the low molecular-weight isoform. Specific inhibition of prolyl-4-hydroxylase (P4H) with ethyl-3,4-dihydroxybenzoate had effects comparable to dipyriddy: however, it had different effects on the intracellular composition of adiponectin isoforms. Specific inhibition of LHs with minoxidil also suppressed adiponectin production, especially of the high molecular-weight (HWM) isoform. In addition, transient gene knock-down of LH3 (*Plod3*) suppressed adiponectin production, especially of the HMW isoform.

**Conclusion:** Our results indicate that: hyperinsulinaemia and decreased insulin signalling exert countervailing effects on adiponectin production; AMPK pathway signalling also regulates adiponectin production; both PHs and LHs are required for adiponectin production; and the hydroxylation/glycosylation of lysyl residues and hydroxylation of prolyl residues are essential for formation and secretion of higher-order adiponectin isoforms.

### The plasma levels of adipokines and incretins in patients with Alzheimer's disease

B. Bendlová<sup>1</sup>, J. Vcelak<sup>1</sup>, D. Vejrazkova<sup>1</sup>, P. Lukasova<sup>1</sup>, O. Bradnova<sup>1</sup>, K. Dvorakova<sup>1</sup>, G. Vacinova<sup>1</sup>, R. Rusina<sup>2</sup>, I. Holmerova<sup>3</sup>, M. Vankova<sup>1</sup>;

<sup>1</sup>Molecular Endocrinology, Institute of Endocrinology,

<sup>2</sup>Neurology, Thomayer Hospital,

<sup>3</sup>Faculty of Humanities, Charles University, Prague, Czech Republic.

**Background and aims:** Alzheimer's disease (AD) is linked to type 2 diabetes (T2D). T2D is a risk factor for vascular dementia but also for a progressive neuron damage, which is probably associated with insulin resistance in central nervous system. AD is therefore sometimes called "diabetes of the brain". The aim of the study was to compare the plasma levels of adipokines, incretins and other biomarkers associated with T2D in AD patients and in non-diabetic subjects without pathological changes in the brain.

**Materials and methods:** The study included 38 females (19 age and BMI matched pairs AD patient and control; age  $70 \pm 8$  years and BMI  $26 \pm 4$  kg/m<sup>2</sup>) and 24 males (12 age and BMI matched pairs AD patient and control; age  $67 \pm 7$  years and BMI  $27 \pm 3$  kg/m<sup>2</sup>) who underwent neuropsychological examination and magnetic resonance imaging of the brain. The characteristics of fasting glucose and lipid metabolism and parameters of body composition including body adiposity index (BAI) were determined. Multiplex methods for evaluation of fasting plasma biomarkers were used: Bio-Plex ProHuman Diabetes 10-Plex Assay - C-peptide, ghrelin, GIP, GLP-1, glucagon, insulin, leptin, total PAI-1, resistin, visfatin and Bio-Plex ProHuman Diabetes Adipin and Adiponectin Assays (Bio-Rad). Statistical analyses were performed using NCSS 2004 software (ANOVA).

**Results:** Compared groups of AD patients and controls (men/women separately) did not differ in either age, BMI, WHR, waist and abdomen circumferences, body adiposity index (BAI) or insulin resistance (HOMAR). In women, AD patients had significantly higher levels of visfatin ( $p=0.0006$ ), ghrelin ( $p=0.03$ ), GLP-1 ( $p=0.006$ ) and glucagon ( $p=0.00002$ ) compared with control women. Similar results were found in men, they had higher levels of visfatin ( $p=0.02$ ) and ghrelin ( $p=0.02$ ) compared with control men, GLP-1 and glucagon did not reach statistical significance.

**Conclusion:** Alzheimer's disease is associated with increased levels of plasma visfatin, ghrelin, GLP-1 and glucagon. Plasma visfatin is a pro-inflammatory cytokine that increases risk of endothelial cell deterioration due to the inflammation and oxidative stress. Visfatin is a marker of ageing and age-dependent diseases. Ghrelin, GLP-1 and glucagon are considered as neuroprotective hormones. Dysregulation of these hormones in AD could be caused by impaired secretion/degradation and/or resistance of the target tissues.

### Anti-TNF therapy has a possible favorable effect on insulin sensitivity in non-diabetic, non-obese patients with inflammatory bowel disease

S.A. Paschou<sup>1</sup>, F. Kothonas<sup>2</sup>, A. Myroforidis<sup>2</sup>, V. Loi<sup>1</sup>, T. Terzi<sup>1</sup>, O. Karagianni<sup>1</sup>, A. Poulou<sup>2</sup>, K. Goumas<sup>2</sup>, A. Vryonidou<sup>1</sup>;

<sup>1</sup>Department of Diabetes and Endocrinology, <sup>2</sup>Department of Gastroenterology, Hellenic Red Cross Hospital, Athens, Greece.

**Background and aims:** Insulin resistance is very common in autoimmune systemic diseases and recently it was also found in children and adults with inflammatory bowel disease (IBD). Inflammation and insulin resistance are closely linked, and inflammatory cytokines such as tumor necrosis factor alpha (TNF $\alpha$ ) may inhibit insulin signaling and promote insulin resistance. The aim of this study was to investigate the effect of anti-TNF therapy on glucose and lipid metabolism in non-diabetic, non-obese patients with IBD.

**Materials and methods:** We studied 41 patients with IBD (25M/16F,  $36.4 \pm 11$  (19-64) years old, 28 with Crohn's disease and 13 with ulcerative colitis), without known history of diabetes. Eighteen patients (9M/9F,  $33.6 \pm 8.8$  years) were on anti-TNF therapy for more than 1 year, while the other 23 patients (16M/7F,  $38.7 \pm 12.5$  years) were treated with azathioprine and mesalazine (Aza/Mes). Nine of the patients from the second group were then treated with anti-TNF and studied again 6 months after. Fasting glucose, insulin, c-peptide, HbA1c, lipids, and CRP levels were determined and HOMA-IR index was calculated, in all patients. Statistical analysis of the data was performed using SPSS 16.00.

**Results:** Three of the patients were diagnosed with overt diabetes and were excluded from the analysis. Patients from the two therapy groups were

matched for age (anti-TNF:  $33.6 \pm 8.8$  years vs Aza/Mes:  $38.7 \pm 12.5$  years,  $p > 0.05$ ) and BMI (anti-TNF:  $23.3 \pm 3.4$  vs Aza/Mes:  $23.1 \pm 1.7$ ,  $p > 0.05$ ), and were not obese. We did not find any statistical differences between the patients from the two therapy groups in the levels of fasting glucose (anti-TNF:  $88 \pm 10.7$  vs Aza/Mes:  $93.4 \pm 14.9$  mg/dl,  $p > 0.05$ ), insulin (anti-TNF:  $10.9 \pm 7.9$  vs Aza/Mes:  $12.1 \pm 6.6$  mIU/ml,  $p > 0.05$ ), c-peptide (anti-TNF:  $1.9 \pm 0.9$  vs Aza/Mes:  $2.2 \pm 1.4$  ng/ml,  $p > 0.05$ ), HbA1c (anti-TNF:  $5.2 \pm 0.3$  vs Aza/Mes:  $5.3 \pm 0.4$  %,  $p > 0.05$ ), total cholesterol (anti-TNF:  $168.6 \pm 32.7$  vs Aza/Mes:  $162.8 \pm 34.3$  mg/dl,  $p > 0.05$ ), HDL (anti-TNF:  $57.5 \pm 15.7$  vs Aza/Mes:  $53.8 \pm 20.3$  mg/dl,  $p > 0.05$ ), LDL (anti-TNF:  $95.8 \pm 28.7$  vs Aza/Mes:  $90.7 \pm 24.4$  mg/dl,  $p > 0.05$ ), triglycerides (anti-TNF:  $75.8 \pm 37.6$  vs Aza/Mes:  $90.8 \pm 61.3$  mg/dl,  $p > 0.05$ ), CRP (anti-TNF:  $3 \pm 5.4$  vs Aza/Mes:  $4.9 \pm 6.1$ ,  $p > 0.05$ ) and in the HOMA-IR index (anti-TNF:  $2.77 \pm 2$  vs Aza/Mes:  $3.1 \pm 1.9$ ,  $p > 0.05$ ). In patients who were treated for 6 months with anti-TNF, a statistically significant decrease in insulin (before:  $15.4 \pm 5.8$  vs after:  $10.2 \pm 2.7$  mIU/ml,  $p = 0.049$ ) and c-peptide (before:  $2.4 \pm 1.2$  vs after:  $1.4 \pm 0.4$  ng/ml,  $p = 0.038$ ) levels as well as the HOMA-IR index (before:  $4.1 \pm 2.1$  vs after:  $2.3 \pm 0.7$ ,  $p = 0.047$ ) was observed, without any statistically significant changes in weight, BMI, glucose, HbA1c, lipids and CRP levels (in all comparisons  $p > 0.05$ ).

**Conclusion:** These preliminary data indicate that anti-TNF therapy may have a favorable effect on insulin sensitivity in non-diabetic, non-obese patients with inflammatory bowel disease.

## 604

### Dual character of osteoprotegerin as a metabolic biomarker in a healthy/prediabetic population

B. Buday<sup>1</sup>, F.P. Pach<sup>2</sup>, B. Literati-Nagy<sup>1</sup>, Z. Vecsei<sup>1</sup>, M. Vitai<sup>1</sup>, L. Koranyi<sup>1</sup>;

<sup>1</sup>Department of Metabolism, Drug Research Center, Balatonfüred,

<sup>2</sup>Department of Medical Informatics, Bay Zoltán Nonprofit Ltd. for Applied Research, Budapest, Hungary.

**Background and aims:** Osteoprotegerin (OPG) is a member of the tumor necrosis factor receptor superfamily involved in bone metabolism (OPG/RANK/RANKL axis), cardiovascular (CV) system and the bone - energy homeostasis. It protects against vascular calcification in animal models while its high level has been linked to diabetic complications, CV death, inflammation and poor glycemic control in humans. However some conflicting data show that in normal glucose tolerant (NGT) subjects, these connections do not exist or show opposite results. To clarify this issue and the possible sex difference we investigated the metabolic connections of OPG in a cohort of healthy or prediabetic male and female subjects.

**Materials and methods:** We included 155 males and 154 females (aged  $49.18 \pm 9.43$  vs  $41.62 \pm 12.95$  years) in our study. They were diagnosed as NGT or glucose intolerant (GI = IGT, IFG or drug naïve 2DM) by OGTT, with no known diabetic/CV complication. IVGTT and a hyperinsulinemic euglycemic clamp were done to determine insulin secretion and sensitivity ( $IS = M_m$  muscle glucose uptake). Serum glucose, insulin, free fatty acid (FFA), adipocytokines, bone markers, lipid subfractions (SF: small-dense (SD): LDL-3,4,5, large-buoyant (LB): LDL-1-2), apoproteins, anthropometric data (body fat percent, abdominal circumference (AC)) were measured. Serum OPG levels were determined by Biomedica ELISA kits.

**Results:** OPG levels did not differ significantly between the NGT and GI groups in either gender. In both genders it showed a significant ( $p < 0.05$ ) positive association with TNF-alpha levels, as expected ( $R = +0.178$  in males and  $+0.359$  in females, both NGT and GI), which was independent of age, HbA1c and BMI. However in all males OPG has showed a significant negative correlations with BMI, FFA, triglyceride, ( $R = -0.286$ ,  $-0.325$  and  $-0.266$ ), and positive correlation with  $M_m$  and adiponectin (AN), ( $R = +0.176$  and  $0.224$  respectively), i.e. with improving metabolic state. The correlation with  $M_m$  ceased after correction with BMI but stayed significant with AN. In all females there was a significant ( $p < 0.05$ ) negative correlation between OPG and FFA levels ( $R = -0.359$ ), similar to the male group. Although the percent of LDL-3,4,5 (SD SFs) significantly increased ( $R = +0.380$ ,  $0.386$ ,  $0.213$ ) while that of the LDL-1 (LB-SF) decreased ( $R = -0.4469$ ) with increasing OPG levels. These associations were not mediated by TNF-alpha because they stayed significant after data were adjusted with its levels. Feature selection analysis confirmed FFA and TNF-alpha in both genders as important determinants of OPG (mean  $Z = 9.75$  and  $4.12$  vs  $10.16$  and  $3.68$  respectively), while SD and LB-LDL SFs were also confirmed as important attributes in females (mean  $Z = 9.176$  and  $2.851$ , respectively).

**Conclusion:** Our study confirmed a gender-specific, conflicting metabolic character of OPG: it predicted improving metabolic state in both genders which was more emphasized in males. Besides, in females it predicted an

unfavourable lipid profile with increased SD and decreased LB-LDL SFs, independent of BMI or TNF-alpha levels. The nature and cause of this “dual” character of OPG has not been addressed before and needs some further prospective investigations.

## 605

### Cannabinoid receptor type 1 expression in human adipose tissue is upregulated by glucocorticoids and is associated with insulin resistance

C.O. Sidibeh<sup>1</sup>, M.J. Pereira<sup>1</sup>, M. Hammar<sup>2</sup>, P. Katsogiannis<sup>1</sup>, M. Rizell<sup>3</sup>, M.K. Svensson<sup>4</sup>, J.W. Eriksson<sup>1</sup>;

<sup>1</sup>Department of Medical Sciences, Uppsala University, <sup>2</sup>AstraZeneca R&D, Mölndal, <sup>3</sup>Department of Surgery, <sup>4</sup>Department of Molecular and Clinical Medicine, Sahlgrenska University Hospital, Gothenburg, Sweden.

**Background and aims:** Glucocorticoids are often used for treatment of auto-immune or inflammatory conditions, including in post-transplant patients to prevent graft rejection. Elevated plasma glucocorticoid levels, as in Cushing's syndrome or during exogenous administration, are associated with a multitude of adverse effects such as obesity, dyslipidemia and insulin resistance (IR) and can eventually trigger onset of type 2 diabetes (T2D). We aimed to investigate the glucocorticoid-induced IR mechanisms in order to find unique mechanisms that could provide potential pharmacological targets or biomarkers in insulin resistant conditions.

**Materials and methods:** Paired subcutaneous (sc) and omental (om) adipose tissue samples were collected from non-diabetic subjects undergoing elective surgery mainly for kidney donations (M/F 10/15, 28-60 yr, BMI 20.7-30.6 kg/m<sup>2</sup>). Fasting blood samples were collected for the analysis of plasma glucose, insulin and lipid levels. In addition, anthropometric measurements were obtained. Adipose tissue was incubated for 24 h in DMEM containing 6 mM glucose and 10% fetal bovine serum in 37 °C, 5% CO<sub>2</sub> with or without the synthetic glucocorticoid dexamethasone (Dex) at varying concentrations (0.003-3.0 μM). Following incubation, parts of the tissue were snap-frozen for gene expression (microarray analysis, n=4, with/without Dex; real time PCR, n=10). Moreover, adipocytes isolated with collagenase underwent glucose uptake assays (n=12) with or without insulin-stimulation (1000 μU/ml).

**Results:** Through affymetrix mRNA microarray analysis, it was shown that cannabinoid receptor type 1 (CNR1) is one of the genes with the highest increase in mRNA expression after incubation with a supra-physiological concentration (3 μM) of Dex in subcutaneous and omental adipose tissue (~11- and ~7-fold, respectively;  $p < 0.05$ ). The upregulation by Dex of CNR1 gene expression was further verified by real time PCR analysis ( $p < 0.05$ ) and shown to be dose-dependent (0.03-3 μM). Basal CNR1 gene expression in subcutaneous adipose tissue positively correlated with HOMA-IR ( $p < 0.05$ ,  $r = 0.60$ ), serum insulin ( $r = 0.65$ ,  $p < 0.01$ ) and BMI ( $r = 0.56$ ,  $p < 0.05$ ). In addition, CNR1 expression in subcutaneous adipose tissue treated with dexamethasone negatively correlated with basal and insulin-stimulated glucose uptake ( $r = -0.74$ ,  $p < 0.05$  and  $r = -0.79$ ,  $p < 0.01$ ). Furthermore, a negative correlation was seen between the Dex-induced increase in CNR1 gene expression and the basal and insulin-stimulated glucose uptake in the respective adipose tissue depots (sc basal and insulin:  $r = -0.80$ ,  $p < 0.01$ ; om basal:  $r = -0.65$ ,  $p < 0.05$ ; om insulin:  $r = -0.55$ ,  $p = 0.098$ ).

**Conclusion:** Dexamethasone promotes gene expression of CNR1 in adipose tissue, and significant associations between CNR1 expression and measures of insulin resistance were found. This study gives further support to the concept of a role of the peripheral endocannabinoid system in obesity and insulin resistance, and peripheral CNR1 may thus be an attractive target for new anti-diabetic drugs.

### Fasting hyperglucagonaemia in patients with non-alcoholic fatty liver disease with and without type 2 diabetes

A.E. Junker<sup>1</sup>, L. Gluud<sup>2</sup>, F.K. Knop<sup>1</sup>, J.J. Holst<sup>3</sup>, T. Vilsbøll<sup>1</sup>;

<sup>1</sup>Diabetes Research Division, Hellerup, <sup>2</sup>Department of Gastroenterology, Hvidovre, <sup>3</sup>Department of Biomedical Science, Copenhagen, Denmark.

**Background and aims:** Non-alcoholic fatty liver disease (NAFLD) and hyperglucagonemia seems to influence glucose metabolism and both features are associated with type 2 diabetes (T2D). We investigated glucagon responses during oral and intravenous glucose administration in biopsy-verified NAFLD patients with and without T2D.

**Materials and methods:** We performed a 50 g-OGTT, and isoglycaemic intravenous glucose infusion (IIGI) in participants with I) normal glucose tolerance (NGT) and no NAFLD (N=10; age (median±interquartile range): 58±17 years; BMI: 29±1 kg/m<sup>2</sup>; HbA1c: 34±6 mmol/mol (5.5±0.2%)), II) NGT+NAFLD (N=9; age: 54±22 years; BMI: 28±7 kg/m<sup>2</sup>; HbA1c: 33±4 mmol/mol (5.2±0.3%)), III) T2D and no NAFLD (N=8; age: 59±18 years; BMI: 27±3 kg/m<sup>2</sup>; HbA1c: 45±9 mmol/mol (6.2±1.1%)), or IV) T2D+NAFLD (N=8; age: 65±3 years; BMI: 30±4 kg/m<sup>2</sup>; HbA1c: 53±19 mmol/mol (7.0±1.4%)).

**Results:** In all groups, isoglycaemia was achieved during oral and intravenous glucose administrations. Fasting plasma glucagon was elevated in participants with NAFLD and NGT (7.0±2.7 pM) and T2D (6.7±2.3 pM), compared to participants without NAFLD and NGT (2.8±4.0 pM, P<0.001) or T2D (4.5±2.9 pM, P<0.05). Increased glucagon responses (ΔAUC0-50 min) during OGTT vs. IIGI were seen in both groups with T2D (no NAFLD: 40±78 (OGTT) vs. -63±43 pM×50min (IIGI), P<0.05; NAFLD: 30±99 (OGTT) vs. -38±44 pM×50min (IIGI), P<0.05) whereas no differences in glucagon responses to OGTT and IIGI were seen in NGT subjects (no NAFLD: -20±26 (OGTT) vs. -88±60 pM×50min (IIGI), P=NS; NAFLD: -40±75 (OGTT) vs. -90±70 pM×50min (IIGI), P=NS).

**Conclusion:** Fasting hyperglucagonemia seems to be a pathophysiological trait of NAFLD independently of concomitant T2D. In contrast, patients with T2D have an inappropriate glucagon response to oral glucose independently of NAFLD.

### High fasting glucagon-like peptide 2 levels potentiate greater glucagon response during OGTT in patients with type 2 diabetes risk factors and newly-diagnosed type 2 diabetes

E.A. Shestakova, A.V. Ilyin, M.V. Shestakova, I.I. Dedov;

Endocrinology Research Centre, Moscow, Russian Federation.

**Background and aims:** The glucagonostatic action of glucagon-like peptide-1 (GLP-1) is established, whereas the influence of glucose-dependent insulinotropic polypeptide (GIP) and glucagon-like peptide-2 (GLP-2) on glucagon secretion is not fully understood. The aim of the study was to investigate the contribution of GLP-1, GIP and GLP-2 to glucagon response during the OGTT in patients with type 2 diabetes (T2D) risk factors.

**Materials and methods:** 127 patients with T2D risk factors (mean BMI 33.7±7.54 kg/m<sup>2</sup>, mean age 57.6±12.77 years) and without prior glucose-lowering therapy underwent 75 g OGTT. Plasma glucose levels, glucagon and total GLP-1, GIP and GLP-2 levels were estimated in fasting state, at 30 and 120 minutes after glucose load and area under curve (AUC) for glucagon, GLP-1, GIP and GLP-2 response was measured.

**Results:** According to the OGTT results 28 subjects had normal glucose tolerance (NGT), 44 patients were either at impaired glucose tolerance (IGT) or impaired fasting glycemia (IFG) state and 55 had newly-diagnosed T2D. The stimulated glucagon secretion was suppressed in NGT group, whereas paradoxical initial increase in glucagon levels was observed in IGT+IFG and T2D patients (p<0.05). Total GLP-1 AUC was higher in NGT subjects comparing to IGT+IFG or T2D patients (p<0.01). Total GIP AUC was also higher in NGT comparing to other two groups and total GLP-2 AUC was higher in T2D group vs NGT and IGT+IFG groups, but these results were nonsignificant. When all participants were divided into tertiles by baseline total GLP-1, GIP and GLP-2 levels statistically significant difference in glucagon AUCs was reached only in patient groups divided by GLP-2 baseline lev-

els (0,008±0,064 ng/ml\*min vs 0,117±0,061 ng/ml\*min vs 0,638±0,065 ng/ml\*min in tertiles with minimum, mean and maximum total GLP-2 fasting level, p=0,0001). Glucagon AUC was also positively related to fasting total GLP-2 level (r = 0,61, p=0,0001) in Spearman correlation analyses.

**Conclusion:** Positive correlation of total GLP-2 baseline levels and glucagon secretion rate suggests glucagonotropic properties for GLP-2. We conclude that glucagon stimulation by GLP-2 may play a role in the absence of glucagon suppression in T2D patients.

### The impact of autonomic neuropathy and hypoglycaemia unawareness on amino acids stimulated glucagon response to hypoglycaemia in subjects with type 1 diabetes

F. Porcellati, P. Lucidi, P. Cioli, P. Candeloro, A. Marinelli Andreoli, G. Bolli, C.G. Fanelli;

Internal Medicine, University of Perugia, Italy.

**Background and aims:** To examine the effects of autonomic neuropathy (AN) and hypoglycemia unawareness (HU) on amino acids (AA) stimulated response of glucagon to insulin-induced hypoglycemia (H)

**Materials and methods:** we studied 41 subjects with type 1 diabetes (mean±SD: age 32.5±7.5 yrs; BMI 22.7±1.5 kg/m<sup>2</sup>; A1C 7.3±0.7%, diabetes duration 15.5±9.6 yrs) who were divided in three groups: no complications (ANneg, HUneg, [group A, N=15]), ANpos (group B, N=13) and HUpos (group C, N=13). Subjects were studied on two different occasions during low dose i.v. insulin (0.3 mU/kg/min) and variable glucose infusions to induce a slow hypoglycemia plateau (50 mg/dl) at 150 min maintained for 40 minutes. Then euglycemia was re-instituted and maintained for 40 minutes, until the end of study. On both occasions, at time 30 min, subjects ingested either placebo (P) or an AA mixture (42 g).

**Results:** In all subjects plasma insulin and glucose concentrations during the studies were not different with P and AA (p>0.1). The amount of glucose infused during the clamp was higher in the P than in the AA study (p<0.02). Plasma glucagon responses did not increase during H with P in the three groups (p=0.254). In contrast, with AA, glucagon response increased in all groups (p<0.001 vs P), less in C (p<0.05 vs A and B) although this difference disappeared after adjusting for duration (p=0.052). The linear regression analysis indicated that there was a negative correlation between diabetes duration and glucagon response to H, both with P and AA. Plasma adrenaline responses and maximal total symptom scores were not affected by AA as compared to P in all groups (p=0.621 and p=0.248, respectively).

**Conclusion:** AA can support responses of glucagon to hypoglycemia not only in non-complicated Type 1 diabetes, but also in conditions well known for risk of severe hypoglycemia, i.e. AN and HU. Duration of diabetes has a significant negative impact on the AA-stimulated responses of glucagon to hypoglycemia

### Glucose transporter SGLT2 inhibition triggers glucagon secretion in alpha cells

C. Bonner<sup>1</sup>, J. Kerr-Conte<sup>1</sup>, V. Gmyr<sup>1</sup>, G. Queniat<sup>1</sup>, E. Moerman<sup>1</sup>, J. Thevenet<sup>1</sup>, C. Beaucamps<sup>1</sup>, N. Delalleau<sup>1</sup>, W.J. Malaisse<sup>2</sup>, A. Sener<sup>2</sup>, B. Deprez<sup>1</sup>, A. Abderrahmani<sup>1</sup>, B. Staels<sup>1</sup>, F. Pattou<sup>1</sup>;

<sup>1</sup>European Genomic Institute for Diabetes, Lille Cedex, France,

<sup>2</sup>Université Libre de Bruxelles, Belgium.

**Background and aims:** Type 2 diabetes mellitus (T2D) is a metabolic disorder characterized by chronic hyperglycemia resulting from defects in insulin secretion, insulin action, and an increase in gluconeogenesis. The gliflozins are a new class of oral antidiabetic agents acting as inhibitors of the glucose cotransporter 2 (SGLT2). By preventing renal glucose reabsorption, SGLT2 inhibition reduces the renal threshold for glucose, resulting in glycosuria. In diabetic patients, the decline in plasma glucose induced by gliflozins is, however, blunted by an increase in endogenous glucose production. Yet, the underlying mechanisms are not known. The aim of this study was to determine whether the paradoxical effect of glucagon increase in subjects with T2D might be related to a direct action on the endocrine pancreas.

**Materials and methods:** Human or mouse islets, alphaTC1.9 cells, human pancreatic grafts and liver from fasted mice were studied. SLC5A1/2 gene

expression was assessed by qPCR analysis and SGLT1/2 proteins by histology and ELISA. RNA interference or SGLT inhibitors such as phlorizin or dapagliflozin was used to inhibit SGLT2 in alpha cells, human islets or healthy mice.

**Results:** Here, we demonstrate that SGLT1/2 proteins (encoded by the SLC5A1/2 genes) are specifically expressed in human pancreatic alpha cells. SLC5A2 gene expression is lower in islets isolated from T2D patients ( $*p<0.05$ ) and decreases in normal human islets after transplantation in insulin resistant immuno-deficient mice ( $*p<0.05$ ). Lower SLC5A2 gene expression is accompanied by an increase of SLC5A1 ( $**p<0.01$ ) and glucagon (GCG) gene expression ( $***p<0.001$ ). siRNA knockdown of SGLT2 in alpha cells, or its inhibition with phlorizin or dapagliflozin stimulated GCG gene expression ( $***p<0.001$ ) and glucagon secretion ( $*p<0.05$ ). In healthy mice, dapagliflozin treatment elevated fasting plasma glucose levels ( $***p<0.001$ ) and hepatic gluconeogenic gene expression (G6pase and Pepck) ( $*p<0.05$ ).

**Conclusion:** Collectively, these results reveal that inhibition of SGLT2 activity induces glucagon secretion, identifying a hereto unknown role of glioflozins as alpha cell secretagogues.

### Paradoxical synchronisation of $Ca^{2+}$ oscillations between alpha and beta cells within intact pancreatic islets

Q. Yu, J. Li, A. Tengholm, E. Gylfe;

Medical Cell Biology, Uppsala University, Sweden.

**Background and aims:** Insulin and glucagon are secreted in anti-synchronous pulses causing pronounced variations in the insulin/glucagon ratio that determines hepatic glucose production. The insulin pulses are generated by oscillations of the cytoplasmic  $Ca^{2+}$  concentration, which is regarded the main trigger of both insulin and glucagon release. To clarify how the glucagon release pattern is generated it is important to understand the relationship between the cytoplasmic  $Ca^{2+}$  dynamics in  $\alpha$ - and  $\beta$ -cells.

**Materials and methods:** Pancreatic islets were isolated from transgenic GLU-RFP mice expressing red fluorescent protein (RFP) in the  $\alpha$ -cells. The  $Ca^{2+}$  concentration in the sub-plasma membrane space ( $[Ca^{2+}]_{pm}$ ) of superficial islet cells was recorded with total internal reflection microscopy and the fluorescent indicator Fluo-4.

**Results:** Introduction of 1 mM glutamate in the presence of the hyperpolarizing agent diazoxide triggered a pronounced elevation of  $[Ca^{2+}]_{pm}$  in 84% of the RFP-positive cells but had no effect in the RFP-negative ones, suggesting that glutamate responses can be used as a complementary tool to distinguish  $\alpha$ - from  $\beta$ -cells. At 3 mM glucose,  $\alpha$ -cells showed pronounced, unsynchronized  $[Ca^{2+}]_{pm}$  oscillations, whereas  $[Ca^{2+}]_{pm}$  was low and stable in the  $\beta$ -cells. When the glucose concentration was increased to 20 mmol/l,  $\beta$ -cells showed an initial decrease of  $[Ca^{2+}]_{pm}$  followed by a protracted increase, succeeded by oscillations that were almost perfectly synchronized among neighbouring  $\beta$ -cells. The  $\alpha$ -cell oscillations were often temporarily suppressed in parallel with the initial  $[Ca^{2+}]_{pm}$  increase in the  $\beta$ -cells. When subsequently recurring, the  $\alpha$ -cell oscillations tended to synchronize with those in the  $\beta$ -cells, a phenomenon consistently evident when averaging Fluo-4 fluorescence from several  $\alpha$ -cells within an islet.

**Conclusion:** Pancreatic  $\alpha$ - and  $\beta$ -cells show distinguishing  $[Ca^{2+}]_{pm}$  signaling patterns in low and high glucose and in response to glutamate. Synchronization of  $[Ca^{2+}]_{pm}$  oscillations between  $\alpha$ -cells and  $\beta$ -cells at 20 mM glucose surprisingly indicates that pulsatile glucagon release is not generated by  $\alpha$ -cell oscillations of  $[Ca^{2+}]_{pm}$  unless  $Ca^{2+}$  becomes an inhibitory messenger under these conditions.

## 611

### Possible contribution of taurine to distorted glucagon secretion in insulin deficiency: a metabolome analysis using a novel alpha cell model of type 1 diabetes

M. Bessho<sup>1</sup>, Y. Murase-Mishiba<sup>1</sup>, J. Terasaki<sup>1</sup>, A. Imagawa<sup>2</sup>, T. Hanafusa<sup>1</sup>;

<sup>1</sup>The Department of Internal Medicine(I), Osaka Medical College, Takatsuki, Japan, <sup>2</sup>The Department of Metabolic Medicine, Graduate School of Medicine, Osaka University, Suita, Japan.

**Background and aims:** Glycemic instability is a serious problem in patients with type 1 diabetes (T1D). We recently reported that glucagon secretory capacity is positively associated with the degree of glucose fluctuation in T1D patients whose endogenous insulin was completely depleted, suggesting that glycemic instability may be due in part to paradoxically increased endogenous glucagon secretion. However, the intracellular metabolic mechanism(s) involved in the aberrant glucagon response under the condition of insulin deficiency has not yet been elucidated.

**Materials and methods:** We generated an  $\alpha$ TC6 cell line with lentiviral shRNA-mediated stable knockdown of the insulin receptor (IRKD), i.e., an *in vitro*  $\alpha$ -cell model for T1D. The glucagon secretion in response to varying glucose concentrations (1.5, 5.6 and 30 mM) was studied in both control and IRKD cells. To investigate the cellular metabolic changes in  $\alpha$ -cells under pathophysiological conditions of T1D, a comprehensive intracellular metabolomic analysis of the IRKD  $\alpha$ TC6 cells (IRKD cells) was performed using capillary electrophoresis time-of-flight mass spectrometry (CE-TOFMS). The various metabolites, which were identified as being significantly altered in the IRKD cells and could potentially affect the glucagon secretion, were chosen for further uptake and biosynthetic analyses.

**Results:** The IRKD cells tended to secrete less glucagon compared to the controls at the 1.5 mM glucose concentration ( $p=0.13$ ). On the other hand, the IRKD cells exhibited significantly higher glucagon secretion in response to the 30 mM glucose concentrations than controls ( $60.1\pm 4.2$  vs.  $18.0\pm 1.1$  pg/ $\mu$ g protein,  $p<0.01$ ). By metabolome analysis, the cellular contents of 33 metabolites in the control and IRKD cells were significantly different, with  $p<0.05$  for at least two points at each concentration of glucose. Of these metabolites, taurine was remarkably increased in the IRKD cells and was one of the most likely candidate metabolite stimulating glucagon secretion. The cellular uptake of [<sup>3</sup>H] taurine was increased time-dependently in IRKD cells compared to control cells. The expression of cysteine sulfinic acid decarboxylase (*cas4*), the rate-limiting enzyme required for taurine synthesis, was increased in IRKD cells compared to control cells ( $p<0.05$ ). Supplementation of taurine (100 mM) to the culture medium enhanced the glucagon secretion in a concentration-dependent manner in the  $\alpha$ TC6 cells. When the IRKD cells were treated with 30 mM glucose plus 10 mM taurine, the glucagon secretion was significantly augmented compared with that in vehicle-treated cells ( $63.3\pm 2.5$  vs.  $49.1\pm 0.9$  pg/ $\mu$ g protein,  $p<0.01$ ).

**Conclusion:** Our study indicates that the metabolic alterations induced by IRKD in  $\alpha$ -cells, especially the increase of taurine, may lead to a distorted glucagon response in IRKD cells, suggesting the importance of taurine in the paradoxical glucagon response and the resultant glucose instability in T1D.

### Expression and function of the atypical purinergic receptor GPR17 in endocrine pancreas

E.S. Di Cairano<sup>1</sup>, S. Moretti<sup>1</sup>, F. Daniele<sup>1</sup>, V. Meraviglia<sup>2</sup>, A. Ulivi<sup>2</sup>, P. Rosa<sup>3</sup>, F. Bertuzzi<sup>3</sup>, S. LaRosa<sup>4</sup>, F. Folli<sup>5</sup>, F.V. Sacchi<sup>1</sup>, C. Peregó<sup>1</sup>;

<sup>1</sup>DiSFB Dept of Pharmacological and Biomolecular Sciences, University of Milano, <sup>2</sup>Institute of Neuroscience, CNR-Biometra, Milano, <sup>3</sup>Niguarda Cà Granda Hospital, Milan, <sup>4</sup>Dept of Pathology, Ospedale di Circolo, Varese, Italy, <sup>5</sup>Dept. of Medicine Diabetes Division, University of Texas Health Science Center, San Antonio, USA.

**Background and aims:** Islets of Langerhans control glucose homeostasis and metabolism by sensing blood glucose and nutrients. Factors secreted within the islet create a parallel tuning, defined autocrine-paracrine signaling, that modulates hormone release and cell viability. Studying the molecular actors of this signaling and their physiological significance may help in understanding diabetes pathogenesis thus providing novel therapeutic targets. G-protein coupled receptors (GPCRs) are expressed in islets of Langerhans, regulate hormone secretion and cell survival, and are emerging as new targets for type-2 diabetes therapies. In this work, we focused on the expression and

role of the atypical orphan receptor GPR17, which is activated by uracil nucleotides and can be partially antagonized by ATP, a well known autocrine/paracrine signal in islets. We first verified the GPR17 expression in endocrine cell lines and in human islets, and then we investigated its possible role in islet physiology

**Materials and methods:** The expression of GPR17 was analysed by RT-PCR analysis, western blot and immunofluorescence techniques in cell lines ( $\alpha$ TC3,  $\beta$ TC3, the  $\delta$  cell line RIN14B), in human isolated islets of Langerhans, and human pancreatic sections. The possible involvement of GPR17 in the control of hormone release and cell proliferation/viability was studied in cell lines and in human isolated by means of ELISA assays.

**Results:** By means of RT-PCR, we detected GPR17 mRNA in human islets, in  $\alpha$  and  $\delta$  cell lines, but not in  $\beta$  cell lines (n=5). By means of western blot experiments, we confirmed GPR17 protein expression in  $\alpha$  and  $\delta$  cell lines and in human islets, where its abundance was upregulated by hyperglycemia (2.13±0.15 fold increase over normoglycemic conditions; p<0.05, n=4). To investigate the specific endocrine cells where GPR17 was expressed *in vivo*, we carried out double immunofluorescence and confocal analysis on human pancreas sections, using hormones as markers of the different cell populations. We confirmed the expression of GPR17 in a sub-population of  $\delta$  cells but no expression was detected in  $\beta$ -cells, in physiological conditions. To understand the possible role of GPR17 in islet physiology we activated GPR17 with its agonist UDP-glucose, and we measured its effect on cell viability and hormone release in cell lines and human isolated islets. 3-day incubation of  $\alpha$ TC3 with 100  $\mu$ M UDP-G caused a significant increase in cell viability, measured by MTT test (108±2.56% UDP-G vs ctr, p<0.005 T-Test; n= 10). A similar behavior was observed in human islets, where we found a reduction of apoptosis in presence of 100  $\mu$ M UDP-G (38±7% UDP-G vs ctr). Preliminary data on hormone release in static conditions indicated that incubation of human islets with 100  $\mu$ M UDP-G, caused a decrease in the glucagon and somatostatin release in normoglycemia (37±10% and 25±5%, respectively) (Elisa assay, 2 islets preparations, duplicate)

**Conclusion:** We demonstrated for the first time that GPR17 is expressed and functional in human islets of Langerhans. Studies are in progress to better define its role in islet cell physiology and pathology.

## 613

### Elevation of cAMP promotes an Epac2 dependent, L-type Ca<sup>2+</sup>-channel coupled, Ca<sup>2+</sup>-induced Ca<sup>2+</sup> release in mouse alpha cells

Q. Zhang<sup>1</sup>, A. Salehi<sup>2</sup>, R. Ramracheya<sup>1</sup>, P. Rorsman<sup>1</sup>;

<sup>1</sup>OCDEM, Oxford, UK, <sup>2</sup>Department of Clinical Science, UMAS, Division of Islet Cell Physiology, Lund, Sweden.

**Background and aims:** Glucagon is a potent glucose elevating hormone that is secreted from pancreatic  $\alpha$ -cells in response to hypoglycaemia. Glucagon secretion in mouse islets is inhibited by elevation of glucose and strongly stimulated by adrenaline. Although glucose and adrenaline have differential effects on glucagon secretion, these two different factors exert similar effects on  $\alpha$ -cell electrical activity. This indicates that the stimulatory effect of adrenaline is exerted distal to the firing of action potentials, i.e. cell exocytosis. Cell exocytosis is Ca<sup>2+</sup>-dependent and relies on Ca<sup>2+</sup> from the extracellular environment or released from intracellular Ca<sup>2+</sup> stores (by a process namely Ca<sup>2+</sup>-induced Ca<sup>2+</sup> release). cAMP is known to regulate several pathways in Ca<sup>2+</sup> signaling via phosphorylation by protein kinase A (PKA) and/or Epac (exchange protein activated by cAMP). This study aims to address whether this amplifying pathway is governed by cAMP in pancreatic  $\alpha$ -cells.

**Materials and methods:** Mouse pancreatic islets were acutely isolated by enzyme digestion. Hormone secretion was measured by batch incubation experiments. Ca<sup>2+</sup> signal was ratiometrically monitored using indo-1. Cell exocytosis was measured using capacitance measurements. Membrane potential was measured using intact mouse islets with perforated patch clamping technique under current clamp mode.

**Results:** Adrenaline (5  $\mu$ M) stimulated glucagon secretion 2 fold, an effect that was also produced by 10 $\mu$ M of the adenylyl cyclase activator forskolin (n=8). Adrenaline-stimulated glucagon secretion can be reversed following application of the L-type Ca<sup>2+</sup> channel blocker isradipine (2.5 $\mu$ M) or 100 $\mu$ M ryanodine (an intracellular Ca<sup>2+</sup> releasing channel blocker).  $\alpha$ -cell exocytosis evoked by 300ms depolarization (from -70mV to 0mV) was strongly stimulated when 0.1mM cAMP was applied intracellularly; from 37±9fF (n=16) to 233±32fF (n=17). This was accompanied by a marked increase in Ca<sup>2+</sup> transients (AUC from 1.4±0.3 to 2.5±0.8, p<0.05). cAMP delayed the decay of depolarization evoked Ca<sup>2+</sup> transients (time constant  $\tau$ , from 0.6±0.1s to 1.7±0.5s, p<0.05). Neither the amplitude, nor the decay of Ca<sup>2+</sup> transient were

reduced when the PKA inhibitor Rp-CAMPS or PKI were applied in the presence of cAMP. In  $\alpha$ -cells from mice lacking Epac2 (Epac2<sup>-/-</sup> mice), the cAMP amplification of cell exocytosis was markedly reduced to an insignificant level (from 32±7fF to 53±12fF, n=16 for control and n=8 for cAMP, p=0.1). Furthermore, cAMP did not produce a significant change in the kinetics of depolarization triggered Ca<sup>2+</sup> transients in epac2<sup>-/-</sup>  $\alpha$ -cells. Adrenaline exerted a weaker stimulatory effect on glucagon secretion in epac2<sup>-/-</sup> mouse islets (2 fold compared to 5 fold in wildtype, n=8). The PKA inhibitor Rp-cAMPS partially reduced adrenaline stimulated glucagon secretion in wildtype islets, but completely abolished that in epac2<sup>-/-</sup> islets.

**Conclusion:** Adrenaline stimulates glucagon secretion in mouse islet  $\alpha$ -cells via a cAMP /Epac2 dependent pathway. This effect is likely to be exerted distally to electrical activity by promoting L-type Ca<sup>2+</sup> channel coupled Ca<sup>2+</sup>-induced Ca<sup>2+</sup> release from the endoplasmic reticulum via ryanodine receptor. This study provides a novel insight into the regulation of glucagon secretion by adrenaline and highlights the importance of appropriate neuronal control in preventing life-threatening episodes of hypoglycaemia in diabetes.

### Alpha cell derived glucagon-related peptides are required for normal beta cell function and glucose homeostasis

S. Xu<sup>1</sup>, E. Dror<sup>1</sup>, F. Schulze<sup>1</sup>, T. Nordmann<sup>1</sup>, S. Häuselmann<sup>1</sup>, F. Thorel<sup>2</sup>, P.L. Herrera<sup>2</sup>, M. Böni-Schnetzler<sup>1</sup>, M.Y. Donath<sup>1</sup>;

<sup>1</sup>Endocrinology, Diabetes and Metabolism and Department of Biomedicine, University Hospital Basel and University of Basel,

<sup>2</sup>Department of Genetic Medicine and Development, University of Geneva Medical Centre, Switzerland.

**Background and aims:** Recent data indicate that pancreatic alpha cell derived glucagon-like peptide-1 (GLP-1) and glucagon contribute to beta cell function. We studied the importance of these locally acting hormones versus systemically derived insulin secretagogues on beta cell function and glucose homeostasis.

**Materials and methods:** Selective and massive alpha cell ablation was achieved by diphtheria toxin injection into mice with alpha cell specific expression of human diphtheria toxin receptor at the age of 5 weeks. *In vivo* intraperitoneal glucose tolerance tests, and *in vitro* glucose-stimulated insulin secretion assay on isolated islet were performed.

**Results:** In agreement with previously published data, we did not observe any difference in intraperitoneal glucose tolerance between alpha cell ablated mice and their littermate controls up to the age of 12 weeks. At the age of 28 weeks, alpha cell ablated mice had impaired intraperitoneal glucose tolerance and lower insulin secretion compared to littermate controls despite similar baseline systemic active GLP-1 levels (3.6 ± 0.9 pg/ml in alpha cell ablated mice versus 3.0 ± 0.8 pg/ml in littermate controls). The ileum content of active GLP-1 was compensatory increased by 32% (p = 0.06) in alpha cell ablated mice. Body weight was comparable in both groups. Both sitagliptin injection to stabilize systemic GLP-1 or glucagon injection prior to intraperitoneal glucose load restored glucose tolerance in alpha cell ablated mice. In isolated islets from alpha cell ablated mice, glucose-stimulated insulin secretion was reduced by 69% (p < 0.0001) compared to wildtype islets. Administration of exogenous GLP-1 or glucagon as well as the adenylyl cyclase activator forskolin during high glucose stimulation fully restored insulin secretion *in vitro*.

**Conclusion:** Alpha cell derived GLP-1 and glucagon are required for normal glucose homeostasis and beta cell function *in vivo*. Further, these findings indicate that the presence of cyclic AMP mediated beta cell priming by local glucagon-related peptides is crucial for full glucose-stimulated insulin secretion.

#### Improvement in insulin sensitivity following exercise training is independent of mitochondrial changes in older adults

F. Amati<sup>1</sup>, C. Greggio<sup>1</sup>, N.T. Broskey<sup>1</sup>, W. Janssens<sup>1</sup>, A. Boss<sup>2</sup>, R. Kreis<sup>2</sup>, C. Boesch<sup>2</sup>;

<sup>1</sup>University of Lausanne, <sup>2</sup>University of Bern, Switzerland.

**Background and aims:** Previous studies reported lower skeletal muscle mitochondrial oxidative capacity as one of the links between type 2 diabetes and aging. This gave rise to the interesting indication that mitochondrial deficiency may be an important factor in the pathogenesis of insulin resistance. We have recently shown that exercise training improves mitochondrial content and function in older sedentary adults. The purpose of this study was to link these improvements with improvements in insulin sensitivity.

**Materials and methods:** Twenty sedentary older (age range 61 to 72) men and women (11M, 9F), with average BMI  $28 \pm 4$  kg/m<sup>2</sup> and either impaired or normal glucose tolerance (11 IGT, 8 NGT), participated in a four months supervised endurance exercise intervention with a pre/post-intervention design. Investigations included glucose clamps to measure insulin sensitivity, dual X-ray absorptiometry for overall body composition, magnetic resonance imaging for visceral adipose tissue (VAT) and graded exercise testing for maximal oxygen consumption (VO<sub>2</sub>max). Maximal ATP production capacity (ATPmax) was used as marker for mitochondrial function and was estimated by phosphocreatine recovery following exercise using 31P magnetic resonance spectroscopy. *Vastus lateralis* muscle biopsies specimen were used to measure mitochondrial content by electron microscopy and western blotting. Transcription factors involved in mitochondrial biogenesis were measured in a subset of volunteers by quantitative RT-PCR.

**Results:** The following changes were observed with intervention (data are mean change $\pm$ SEM): insulin sensitivity (glucose infusion rate, GIR)  $+41 \pm 6\%$  ( $P < 0.001$ ), BMI  $-1.6 \pm 0.7\%$  ( $P = 0.02$ ), body fatness  $-7.3 \pm 1.6\%$  ( $P < 0.001$ ), VAT  $-6.3 \pm 2.8\%$  ( $P = 0.04$ ), VO<sub>2</sub>max  $+11.7 \pm 3.5\%$  ( $P < 0.001$ ), ATPmax  $+18.7 \pm 6.3\%$  ( $P = 0.02$ ), mitochondrial volume density (MitoVd)  $+54.9 \pm 11.8\%$  ( $P < 0.001$ ), PGC1 $\alpha$  mRNA  $+84.5 \pm 36.3\%$  ( $N = 12$ ,  $P < 0.001$ ) and TFAM mRNA  $+60.6 \pm 30.6\%$  ( $N = 6$ ,  $P = 0.04$ ). Significant differences in these responses were not observed between IGT vs. NGT, neither between obese vs. lean volunteers. Although GIR correlated with ATPmax and MitoVd at baseline ( $P < 0.05$ ), changes in insulin sensitivity were not associated to changes in ATPmax nor MitoVd.

**Conclusion:** In this cohort of older subjects, four months of exercise intervention significantly enhanced skeletal muscle mitochondrial content and function. Insulin sensitivity was markedly improved in the whole cohort, as well as in both IGT and NGT volunteers. Interestingly, the improvements in insulin sensitivity were not related to the increases of mitochondrial content or function. Although the existence of mitochondria dysfunction may worsen insulin resistance, the lack of relationship between improvements in both mitochondria and insulin sensitivity questions the function of mitochondria on insulin resistance. Further studies are needed to elucidate the debated pathogenic role of mitochondria in insulin resistance of aging. In other terms is mitochondrial dysfunction a cause or a consequence of insulin resistance?

#### Endurance exercise training reduces inflammation and apoptosis of the hypothalamic neurons in obese mice

R. Marinho<sup>1</sup>, L.P. de Moura<sup>1</sup>, B.A. Rodrigues<sup>2</sup>, L.S.S. Pauli<sup>2</sup>, J.D. Botezelli<sup>2</sup>, E.C.C. Ropelle<sup>2</sup>, A.R.S. Cintra<sup>2</sup>, A.S.R. da Silva<sup>3</sup>, C.T. de Souza<sup>4</sup>, D.E. Cintra<sup>2</sup>, E.R. Ropelle<sup>2</sup>, J.R. Pauli<sup>2</sup>;

<sup>1</sup>Programa de Pós-Graduação Ciências da Motricidade, Universidade Estadual Paulista - UNESP, Rio Claro, <sup>2</sup>Programa de Pós-Graduação Ciências da Nutrição, Esporte e Metabolismo, Faculdade de Ciências Aplicadas - Universidade Estadual de Campinas (FCA-UNICAMP), Limeira, <sup>3</sup>Escola de Educação Física e Esporte de Ribeirão Preto (EEFERP), Universidade de São Paulo, Ribeirão Preto, <sup>4</sup>Laboratório de Fisiologia e Bioquímica do Exercício, Universidade do Extremo Sul Catarinense - UNESC, Criciúma, Brazil.

**Background and aims:** Consumption of fat-rich diets blunts leptin and insulin anorexigenic signaling in the hypothalamus by a mechanism dependent on the in situ activation of inflammation. Since inflammatory signal transduction can lead to the activation of apoptotic signaling pathways, we evaluated the effect of endurance exercise training on the reduction of apoptosis of hypothalamic cells.

**Materials and methods:** Swiss mice was divided into 6 groups (with 5-8 each): Control Group 1 and 2 (C1 and C2): sedentary animals fed with balanced diet for 8 or 16 weeks, respectively; Obese 1 and 2 (OB1 and OB2): sedentary animals fed with high-fat diet (HFD) for 8 or 16 weeks, respectively; Trained obese 1 (OBT1): animals fed HFD for 8 weeks and submitted to physical training protocol (PTP) during 8 weeks; Trained obese 2 (OBT2): animals fed HFD for 16 weeks and submitted to PTP during the second half of the experiment (8 weeks). The exercise program consisted of treadmill running 1h, 5 days/week during 8 weeks at a speed equivalent to 60% of maximum potency determined at the beginning of training period. For determination of food intake, mice were intracerebroventricular treated with insulin or leptin. Twenty-four hours after the last bout exercise, the mice were submitted to an insulin tolerance test. Next, the hypothalamus was removed and Western blotting and immunoprecipitation were performed to analyze the expression and phosphorylation of IR, IRS-2, Akt, JAK, STAT3, Foxo1, JNK, IKK, Bax, Casp9, Casp8, FADD, APAF, PERK, eIF2 $\alpha$ .

**Results:** PTP was effective in improving the IR/IRS-2/Akt and JAK2/STAT3 signaling pathway in the hypothalamus and reduced food intake of obese animals. The HFD led to an increased hypothalamic expression of proteins involved in inflammatory signal transduction (pJNK and pIKK). In addition, proteins from apoptotic pathways were affected by HFD. Expression of Bax and the association of APAF1 with caspase-9, and the association of FADD with caspase-8 were increased in the hypothalamus of obese mice. Further evidence for apoptotic or harmful activity in the hypothalamus was shown by the increased expression of PARP1, and by the phosphorylation of proteins involved in endoplasmic reticulum stress, eIF2 $\alpha$  and PERK. Oppositely, PTP was able to reduce inflammatory and apoptotic proteins in the hypothalamus of these animals. Interestingly, the results obtained were more pronounced in mice of OBT1 than OBT2. This shows that the effects of exercise were more effective when the inflammatory and apoptotic process were absent.

**Conclusion:** Our study provides substantial evidence that physical activity could help to reorganize the set point of nutritional balance and therefore aid in counteracting the energy imbalance induced by overnutrition through the anti-inflammatory and anti-apoptotic response in hypothalamic neurons.

#### The effect of chronic exercise training on exercise efficiency and fat oxidation in older previously sedentary adults

N.T. Broskey, E.-J. Fares, C. Greggio, F. Amati;

University of Lausanne, Switzerland.

**Background and aims:** Chronic aerobic exercise has been shown to increase exercise efficiency, which allows us to spend less energy for a similar amount of work. Exercise efficiency can be expressed as gross efficiency, computed as mechanical power (wattage) over the metabolic rate (calories expended); thus, representing whole-body efficiency. Other efficiencies are also used such as delta efficiency, which is the change in power over the change in metabolic rate between different intensities of exercise. Furthermore, it is known that substrate usage during exercise also changes with chronic training to rely more on fat than carbohydrates for a given submaximal exercise intensity. All

of these training adaptations have not yet been explored in older subjects at risk for type 2 diabetes. The purpose of this study was to examine the changes in exercise efficiencies and exercise fat oxidation in older sedentary adults undergoing an exercise intervention and compare these values to athletes of the same age.

**Materials and methods:** In this pre/post intervention design, 11 sedentary obese (age 67.0±1.1) and 12 sedentary lean (age 64.6±1.0) men and women underwent four months of endurance exercise intervention. Volunteers trained 3 supervised sessions per week at 60–75% of their maximal heart rate. Fifteen athletes matched by age (age 68.5±1.5) were also used for comparison purposes. Peak oxygen consumption (VO<sub>2peak</sub>) was determined by a graded exercise testing (GXT). Gross efficiency (GE, %) and exercise fat oxidation (EFO, μmol/min) were determined during one-hour of submaximal (55% of VO<sub>2peak</sub>) cycle ergometry exercise in tightly controlled conditions (fasting and 72 hours from last exercise bout). Delta efficiency (DE, %) was calculated from the GXT. Leg mass, used to normalize efficiency data, was measured by dual X-ray absorptiometry. Statistical comparisons between groups at baseline were done with ANOVA. Intervention effects were measured by Paired T Test. Results are presented in mean ± SEM.

**Results:** At baseline, athletes had a higher GE than lean sedentary, which had a higher GE than the obese sedentary (p<0.001). Both the obese and lean increased their GE after four months of exercise training (respectively p=0.0012 and p=0.001). DE followed the same pattern as GE at baseline (p<0.001). Also similar to GE, both obese and lean increased their DE following exercise intervention (respectively p<0.001 and p=0.001) EFO was the same between all three groups at baseline (p=0.35). EFO did not change in the lean sedentary group (p=0.47) after the intervention but did increase in the obese (p=0.01).

**Conclusion:** This data shows that older adults are able to respond to a moderate intensity exercise training protocol in terms of improvements in GE and DE, as shown in younger and performance-oriented studies. Thus, they expend fewer calories for the same power output. These observations point to the fact that exercise routines need to be modified in order to elicit metabolic adaptations and keep optimal caloric expenditure also at an older age. Former studies show that training improves the reliance on fat. Surprisingly, in our cohort fat oxidation was not different between the three groups at baseline. The obese group was the only one to improve fat oxidation after four months of exercise training, which can be explained by changes in body composition. *Clinical Trial Registration Number: NCT01224886*

### Changes in muscle lipid stores after exercise training in subjects with prediabetes and healthy controls

K.I. Birkeland<sup>1,2</sup>, Y. Li<sup>3</sup>, S. Lee<sup>3</sup>, F. Norheim<sup>3</sup>, S. Pourteymour<sup>3</sup>, T. Storaas<sup>4</sup>, S. Davanger<sup>5</sup>, J. Jensen<sup>6</sup>, C.A. Drevon<sup>3</sup>, T. Holen<sup>3</sup>;

<sup>1</sup>Dep. of Endocrinology, Oslo University Hospital, <sup>2</sup>Institute of Clinical Medicine, University of Oslo, <sup>3</sup>Dep. of Nutrition, University of Oslo, <sup>4</sup>Dep. of Cardiovascular Radiology, Oslo University Hospital, <sup>5</sup>Dep. of Anatomy, University of Oslo, <sup>6</sup>Norwegian School of Sport Sciences, Norway.

**Background and aims:** There is an association between muscle lipid stores and insulin sensitivity, but the mechanism is unclear. We examined how exercise intervention influenced muscle lipid stores in sedentary normal-weight control subjects and overweight prediabetic subjects impaired fasting glucose or impaired Glucose tolerance.

**Materials and methods:** Ten sedentary male control subjects and eight sedentary male prediabetic subjects participated in 12 weeks supervised training. Insulin sensitivity (euglycaemic clamp) and VO<sub>2max</sub> were measured. Muscle lipid stores were quantified by magnetic resonance spectroscopy (MRS), electron microscopy (EM) point counting, and direct EM lipid droplet measurements of subsarcolemmal (SS) and intermyofibrillar (IMF) regions, and indirectly, by deep sequencing and real-time PCR of mRNA of lipid droplet-associated proteins.

**Results:** Insulin sensitivity (+28% and +36%) and VO<sub>2max</sub> (+14% and +15%) increased significantly in both the prediabetic and the control groups after 12 weeks of training. Muscle lipid stores were reduced, as measured by MRS at baseline before and after the intervention, whereas EM point counting showed no change in LD stores post-exercise, indicating a reduction in LD store utilization with lowered LD levels. Large scale EM quantification of the sub-sarcolemmal LD population demonstrated reductions in LD density and LD diameters. The SS LD diameters were reduced by 28% and 26%, and SS LD numbers were reduced by 37% and 43%, for the prediabetic and the control groups, respectively. Thus, lipid droplet volume in the SS LD popu-

lation was reduced by ~80%, in both prediabetics and normal weight controls. Interestingly, the lipid droplet diameters (n = 10 958) distribution was skewed, with a lack of small diameter lipid droplets (smaller than ~200 nm), both in the SS and IMF regions.

**Conclusion:** We demonstrate reduced muscle lipid stores in the control and prediabetic groups, using MRS, but no corresponding differences post-exercise, using EM point counting, suggesting reduced LD utilization with lower LD stores. A large-scale EM quantification of LD numbers and diameters showed a differential behavior of two populations of LD. The SS LD were reduced by ~80% in both groups, whereas the intramyofibrillar population of LD did not show any consistent changes. The EM quantification provided a skewed distribution of lipid droplet size, with a lack of small (< 200 nm) diameter LDs both in the SS and IMF regions, before as well as after the intervention.

## 619

### The improvement in beta cell function after intense aerobic exercise is directly related to the increase in vitamin D levels

G.P. Sorice, S. Moffa, C. Conte, T. Mezza, A. Giaccari; Endocrinology, Catholic University, Rome, Italy.

**Background and aims:** Low concentrations of 25-hydroxy-vitamin D [25(OH)D], the best indicator of vitamin D status, have been associated with alterations in glucose tolerance, insulin sensitivity and β cell function. Few data are available on the effects of a single session of aerobic exercise on 25(OH)D levels and the possible correlation with insulin secretion and sensitivity

**Materials and methods:** We therefore recruited 20 young (25-31 years-old), healthy, normal weight volunteers, with a sedentary/moderate active lifestyle; OGTT was performed before and on the day-after a bout of aerobic exercise (a single workout of jogging or running for 30-40 minutes, or until exhaustion). Insulin secretion and sensitivity were estimated using OGTT-derived indices. During exercise, all subjects wore a metabolic holter to assess energy expenditure.

**Results:** Based on the energy expenditure during work-out, subjects were divided (the median in the cohort [7 METs] was used as cut-off value) into: non-intense (<7 METs) or intense group (>7 METs). In both groups, a significant improvement in insulin sensitivity (p<0.04 Quicki) was observed. After exercise, 25(OH)D levels increased in the intense group and decreased in the non-intense group (p=NS for both). Furthermore, 25(OH)D levels, as well as the disposition index, were significantly greater in the intense group after physical activity (p<0.02 and p<0.03, respectively), as compared with the non-intense group. The improvement in the disposition index was correlated with the change from baseline in 25(OH)D in the intense group (r=0.4, p<0.05).

**Conclusion:** These data indicate that a single session of aerobic exercise might improve beta cell secretory performance and this improvement is closely related with the increase in the levels of 25(OH)D after strenuous physical activity.

## 620

### Metabolic effects of interval training exercise in patients with type 2 diabetes

C.M.A. Cefalo<sup>1</sup>, C. Saponara<sup>2</sup>, C. Conte<sup>1</sup>, V.A. Sun<sup>1</sup>, G.P. Sorice<sup>1</sup>, T. Mezza<sup>1</sup>, C. Policola<sup>1</sup>, S. Moffa<sup>1</sup>, M. Broccatelli<sup>1</sup>, I. Romito<sup>1</sup>, A. Sgadari<sup>1</sup>, A. Giaccari<sup>1</sup>;

<sup>1</sup>Catholic University of the Sacred Heart,

<sup>2</sup>Centro Diabetologico ACISMOM Camillo Negro, Rome, Italy.

**Background and aims:** Major guidelines on the management of type 2 diabetes mellitus (T2DM) recommend performing at least 150 min/week of moderate-intensity aerobic physical activity. Nevertheless, the most effective type of exercise for glycaemic control has not been established. The aim of the present study was to compare the effects of interval training exercise, which pairs high-intensity exercise phases with low-intensity exercise recovery phases, with those of a conventional, constant-load aerobic exercise on glycaemic control (HbA1c), lipid profile and body composition in patients with T2DM.

**Materials and methods:** Thirty sedentary patients (17/13 M/F; age [mean±SD] 63.0±8.0 yrs; BMI 29.0±3.9 kg/m<sup>2</sup>; HbA1c% [median (1<sup>o</sup>-3<sup>o</sup> quartile)] 6.6 (6.5-7.1) with a diagnosis of T2DM ≥5 years and treated with oral hypoglycaemic agents and/or basal insulin were randomized into 3 groups: constant-load aerobic exercise (CL), interval training aerobic exer-

cise (IT) for 10 weeks (a 2-week conditioning phase + 8-week exercise programme, 3 times/week) or no activity (SED) for the same time period. Fasting plasma glucose, insulin, HbA1c, triglycerides (TG), total cholesterol, HDL and LDL cholesterol and body composition (DXA) were measured at baseline and at study end.

**Results:** Baseline characteristics of the 3 groups were comparable. After 10 weeks, there were no significant differences from baseline in HbA1c% [pre vs. post: 6.7 (6.5–7.1) vs. 6.6 (6.5–6.9); 6.6 (6.5–7.0) vs. 6.5 (6.5–6.6); 6.7 (6.1–7.5) vs. 6.6 (6.4–7.2) in the CL, IT and SED groups, respectively; *p* for time and interaction=ns) or cholesterol levels. Significant improvements in fasting plasma glucose (*p*=0.03), TG (*p*=0.02) and insulin resistance estimated with the HOMA-IR index (*p*=0.04) were observed in the IT group only, despite similar and significant changes in total body composition in both exercise groups (fat mass: -4.3% and -4.9%, fat free mass +1.5% and +1.7% in the CL and IT groups, respectively; both *p*<0.05 vs. baseline; CL vs. IT: *p*=ns).

**Conclusion:** Interval training exercise might have specific effects on segmental body composition and/or lead to different adaptive changes in skeletal muscle as compared with constant load aerobic exercise. Such changes might be responsible for the observed benefits on fasting plasma glucose, TG and HOMA-IR. The lack of significant effects on HbA1c might be due to the good glycaemic control at baseline.

## 621

### Investigation of glycaemic control in elite and recreationally-active individuals with and without type 1 diabetes mellitus during multi-day ultra-distance exercise: 2014 mHealth grand tour

M.D. Campbell<sup>1</sup>, D.J. West<sup>1</sup>, P. Simpson<sup>2</sup>, M.I. Trenell<sup>3</sup>;

<sup>1</sup>Department of Sport, Exercise and Rehabilitation, Northumbria University, Newcastle upon Tyne, UK, <sup>2</sup>DexCom Inc, San Diego, USA, <sup>3</sup>Institute of Cellular Medicine, Newcastle University, Newcastle upon Tyne, UK.

**Background and aims:** Despite improvements in cardiovascular health and wellbeing, fear of exercise-induced hypoglycaemia and a paucity of evidence-based advice on how to manage diabetes during / after exercise remain significant barriers to exercise participation to people with Type 1 diabetes (T1DM). How professional athletes with T1DM manage their diabetes may provide an insight into optimising diabetes control around exercise. The present study examined glucose control in elite and recreational cyclists with and without T1DM during participation in the 2014 mHealth grand tour cycle ride from Brussels to Barcelona (EASD).

**Materials and methods:** Interstitial glucose (IG) concentrations were captured using continuous glucose monitoring (Dexcom G4<sup>®</sup>, INC, CA, USA) over a period of six consecutive days during a long-distance, multi-stage endurance cycling event in three groups of individuals: 10 recreationally-active type 1 diabetes individuals (T1rec), 8 elite cyclists with T1DM (T1pro), and 10 recreationally-active individuals without diabetes (CON). Each individual completed all 6 days of road cycling in full, covering a total distance of 1044km (174km av/day). Data (mean±SD) were analysed using a one-way ANOVA and independent student *t* tests.

**Results:** There was no change in glycaemic control over the course of the six days in any group, with similar mean, mean peak and mean nadir IG during ride time, daytime and night time periods (*p*>0.05). During the ride, mean IG was significantly greater in T1rec and significantly lower in T1pro compared to CON (7.6±2.8 vs. 5.2±2.7 vs. 6.3±0.1 mmol.l<sup>-1</sup>; *p*<0.05). During the ride, time spent in hypo- and hyperglycaemia were similar between T1rec and T1pro (hypo: 209±49 vs. 207±57min; *p*=0.332; hyper 240±5 vs. 244±10min; *p*>0.05). During recovery time before sleep T1pro displayed similar mean IG to CON (6.4±2.8 vs. 6.6±0.9 vs. mmol.l<sup>-1</sup>; *p*=0.553), which was significantly less than T1rec (9.3±1.7 mmol.l<sup>-1</sup>; *p*=0.013). Similar patterns were observed during sleep, whereby T1pro displayed similar mean IG to CON (T1pro 6.7±3.4, CON 6.1±0.9 mmol.l<sup>-1</sup>; *p*=0.412), which were both significantly less than T1rec (8.7±2.6 mmol.l<sup>-1</sup>; *p*<0.05). However, more T1rec individuals experienced nocturnal hypoglycaemia compared to T1pro (T1rec 66% vs. T1pro 13% patients) with more time spent hypoglycaemic (T1rec 402±62, T1pro 223±51 minutes; *p*=0.018) and lower mean IG nadir under T1rec (T1rec 2.6±1.3, T1pro 4.3±2.5, CON 4.4±0.7 mmol.l<sup>-1</sup>; *p*<0.05) during this time.

**Conclusion:** Recreational cyclists with T1DM had higher IG levels during exercise, in recovery and during sleep, and experienced more hypoglycaemic events than elite athletes with T1DM. Elite athletes with T1DM displayed IG comparable to people without diabetes during exercise, in recovery and during sleep. Glycaemic stability in elite athletes with T1DM provides a valuable insight to strategies that can be used to optimise glycaemic control during exercise in the wider T1DM patient population.

### The effect of basal insulin dose reduction during exercise in adolescents with type 1 diabetes mellitus

J. Sendela, A. Szypowska, K. Piechowiak, K. Dzygala, A. Kowalska; Pediatrics, Medical University of Warsaw, Poland.

**Background and aims:** Physical activity helps improve metabolic control and reduces insulin requirement in type 1 diabetic children (T1DM). There is no consensus regarding the guidelines for administration of insulin in patients treated with continuous subcutaneous insulin infusion during physical activity. The aim of the study was to assess the impact of basal insulin reduction on the risk of hypoglycaemia in T1DM children treated with insulin pump.

**Materials and methods:** We performed a non-randomized, open-labeled, two-way crossover study. There were 50 patients included, 28 (58%) boys and 22 (42%) girls, aged 14.5 ± 2.3 years (range 10–18) with mean diabetes duration 7.1 ± 3.1 years, mean HbA1c 8.89 ± 1.4 % mean BMI 21.19 ± 3.4kg/m<sup>2</sup> and mean basal insulin 36% of total insulin dose. Subjects were allocated to one of two groups regarding on basal rate reduction 90 minutes prior to physical activity (group A - 50% and group B - 0% of basal dose). Patients performed 45 minutes exercise on the cycle ergometer during two subsequent days. Primary outcome was the number of hypoglycaemic episodes, defined as blood glucose level below 70 mg/dl. Blood glucose concentrations were recorded with a continuous glucose monitoring system and with multiple blood glucose self-tests for 90 minutes prior to the study and 20, 45, 105 minutes after the beginning of the study. Other data were collected such as: height, weight, glycated haemoglobin, daily insulin dose.

**Results:** During the 45 minutes of exercise more hypoglycaemia episodes were noted in the group A (16%) than in the group B (4%), the difference was close to statistical significance *p*=0.051. Most hypoglycaemia episodes were noted in the 20th min. of the study. There was no statistically significant difference in blood glucose levels between both groups in each time-interval. Mean glycaemia in the group A vs. group B: at the start was 118 vs 108 (*p*=0.148); 20 min 127 vs 106 (*p*=0.012); 45 min 123 vs 116 (*p*=0.115); 60 min. after finishing the study 145 vs 129 (*p*=0.144). There was no between groups difference in the number of subjects with hyperglycaemia defined as blood glucose >160mg/dl 60 min. after finishing the study, OR 0.5 95%CI [0.2 to 1.2]; *p*=0.186. We did not find any correlation between basal insulin calculated as percentage of total insulin dose and blood glucose level during the study.

**Conclusion:** During prolonged exercise basal insulin dose reduction by 50% compared to the total cessation of insulin infusion was associated with a 4 fold higher risk of hypoglycaemia. Therefore we recommend more than 50% reduction in basal rate during prolonged exercise. The degree of basal insulin reduction should be individually determined for each child.

### An acute bout of exercise is not able to lower liver fat content in overweight middle-aged men

B. Brouwers<sup>1</sup>, L. Bilet<sup>1</sup>, P.A. van Ewijk<sup>1</sup>, M.K.C. Hesselink<sup>2</sup>, M.E. Kooi<sup>3</sup>, P. Schrauwen<sup>1</sup>, V.B. Schrauwen-Hinderling<sup>3</sup>, NUTRIM, School of Nutrition, Toxicology and Metabolism;

<sup>1</sup>Human Biology, <sup>2</sup>Human Movement Sciences, <sup>3</sup>Radiology, Maastricht University, Netherlands.

**Background and aims:** Elevated hepatic lipid content (IntraHepatic Lipid, IHL) markedly increases the risk of metabolic complications, including insulin resistance and cardiovascular events. Although prolonged exercise training has been shown to lower IHL, it is unknown if acute exercise has the same effect. Next to IHL, hepatic ATP content may be related to insulin resistance and IHL. Therefore, we aimed to investigate if acute exercise leads to changes in IHL and if these changes are accompanied by changes in hepatic ATP content.

**Materials and methods:** IHL content was determined by proton magnetic resonance spectroscopy (MRS) at baseline, directly after 2h of exercise (50 % of the maximal output) and again 4h post-exercise and expressed as percentage of the water resonance. Hepatic ATP content was measured by phosphorus MRS at baseline and 4h post-exercise in 8 subjects and is given relative to the total phosphorus signal. Blood was sampled and substrate oxidation was measured by indirect calorimetry. Since exercise leads to an increase in plasma FFA that may affect liver fat content, subjects performed the study not only in the fasted condition, but also while ingesting glucose.

**Results:** Twenty-one overweight middle-aged men with a wide range of IHL, including nonalcoholic fatty liver disease (age 54.8±7.2 years, BMI 29.7±2.2 kg/m<sup>2</sup>) participated in this study. IHL was unchanged directly after exercise (8.27±1.80 to 8.34±1.85 %). Similar effects were observed when exercising with glucose supplementation (IHL: 8.26±1.88 to 8.40±1.89 %). 4h after exercise, IHL was elevated compared to baseline in the fasted condition (from 8.3±1.8 to 8.7±1.8 %; p=0.010), while it did not change when glucose was supplemented (from 8.3±1.9 to 8.3±1.9 %; p=0.789). Hepatic ATP content tended to decrease post-recovery in the fasted condition compared to baseline values (0.164±0.009 vs. 0.146±0.009 γ-ATP/total phosphorus; p=0.086), whereas it did not change when glucose supplementation was given (0.168±0.008 vs. 0.163±0.005 γ-ATP/total phosphorus; p=0.582). Plasma FFA concentrations increased with time during exercise and recovery in the fasted condition (p<0.0001), but this effect was blunted in the glucose-fed condition. Respiratory quotient was significantly higher at all time points, except for baseline, in the glucose-fed state compared to fasted (p<0.01). Plasma glucose concentrations were comparable at baseline in both conditions (GLU:5.26±0.11 vs. FASTED:5.23±0.11 mmol/l), but increased after 2h of exercise and post-recovery in the glucose-supplemented state compared to the fasted condition (7.12±0.31 vs. 5.01±0.12 mmol/l, 6.51±0.26 vs. 4.49±0.11 mmol/l; p<0.0001). Moreover, plasma glucose increased with time during exercise and recovery in the glucose-supplemented condition (p<0.0001).

**Conclusion:** This data shows that an acute bout of exercise is not able to lower IHL, neither in a fasted nor in a glucose-supplemented condition, in overweight middle-aged men with a wide range of liver fat content. These results are in contrast to previous results on prolonged exercise training and demonstrate that the long term effects of training cannot simply be explained by an additive effect of acute exercise bouts.

### Carbohydrate doses before a 10 km competition in type 1 diabetes athletes

S. Murillo<sup>1</sup>, L. Brugnara<sup>1</sup>, E. del Campo<sup>2</sup>, I. Yagüe<sup>3</sup>, B. Dueñas<sup>4</sup>, A. Novials<sup>1</sup>;

<sup>1</sup>CIBERDEM - IDIBAPS, Hospital Clínic, Barcelona,

<sup>2</sup>Asociación de Diabéticos de Madrid, <sup>3</sup>Hospital de Fuenlabrada,

<sup>4</sup>Fundacion para la Diabetes, Madrid, Spain.

**Background and aims:** Clinical guidelines recommend increasing the intake of carbohydrates (CH) to maintain glycaemic levels and avoid hypoglycaemia during exercise in type 1 diabetes (T1D) patients. Previous data indicate that the amount of CH recommended is higher than those actually consumed

by patients in competitions. The aim of this study was to identify the real consumption of CH during a 10Km competitive run and to compare these quantities with those recommended by current guidelines.

**Materials and methods:** Athletes with T1D, older than 18 years and treated with multiple insulin doses or an insulin pump participated in two different protocols. Protocol 1: Observational study including 31 athletes with T1D, collecting data of dietary records of CH intake before, during and after a 10Km competitive run. Data obtained were compared with those of a control group of 127 athletes without diabetes. Protocol 2: Single blind randomized trial in athletes with T1D, testing two different doses of pre-exercise CH supplements: a recommended dose of 0.7g CH/body weight (n=10) and a real dose (obtained after analyses from protocol 1) of 0.35g CH/body weight (n=8). This supplement was taken in the form of an isotonic beverage with a concentration of 6.5g of sucrose per 100ml. Capillary blood glucose was self-determined in all cases, before taking the supplement and at the end of competition.

**Results:** In the observational study, baseline characteristics were similar in both groups of individuals (table 1). Athletes with T1D consumed a lower quantity of CH at breakfast on a typical day and during the meal <1 hour after the competition. We did not find significant differences between groups in CH intake at breakfast or in the supplement before the competition. In T1D athletes, this supplement prior to the competition contains 25.0±11.3g of CH (0.33g CH/body weight). In the randomized study, athletes consuming the dose of 0.7g CH/body weight increased glycaemic levels significantly, from 144.3±88.6mg/dl starting to 211.1±100.1mg/dl (p<0.05) finishing the competition, while athletes taking 0.35g CH/body weight maintained glycaemic levels, from 197.5 ±38.9mg/dl before to 162.5±56.8mg/dl (p=0.5) after the competition.

**Conclusion:** On competition day, athletes with T1D seem to increase CH intake prior to the competition, both at breakfast and just before exercise, consuming similar amounts to those athletes without diabetes. In both cases, athletes with and without diabetes consume quantities of CH smaller than those recommended. A pre-exercise supplement with moderate-carbohydrate content (0.35g CH/body weight) appears to induce a more stable glycaemic response in comparison with a supplement with high-carbohydrate content in this group of athletes.

### Exercise induces an anti-inflammatory response and positive effects on the metabolic status in a Non-Obese Diabetic (NOD) mouse model

R. Codella<sup>1,2</sup>, G. Lanzoni<sup>3</sup>, A. Zoso<sup>3</sup>, A. Montesano<sup>1</sup>, I. Terruzzi<sup>4</sup>,

A. Caumo<sup>1,2</sup>, L. Luzi<sup>1,2</sup>, L. Inverardi<sup>3</sup>;

<sup>1</sup>Department of Biomedical Sciences for Health, Università degli Studi di Milano, <sup>2</sup>Metabolism Research Centre, IRCCS Policlinico San Donato Milanese, Italy, <sup>3</sup>Diabetes Research Institute, Miami, USA, <sup>4</sup>San Raffaele Scientific Institute, Milan, Italy.

**Background and aims:** The Non-Obese Diabetic (NOD) mouse represents a well-established experimental model analogous to human type 1 diabetes mellitus (T1DM) as it is characterized by a progressive autoimmune destruction of pancreatic β-cells. NOD mouse might provide a useful model for the study of exercise in T1DM. Experiments were designed to investigate the impact of moderate-intensity training on T1DM immune modulation.

**Materials and methods:** Under a chronic exercise regime, NOD mice (n=20; ♀; 8-wk old) were trained on a treadmill for 12 weeks (12m/min for 30min,

5d/wk) while same number, age-matched, control animals were sedentary. Prior and upon completion of the training period, fed plasma glucose and immunological soluble factors were monitored.

**Results:** After 12 weeks of training, control mice were all diabetic (n=5) whereas only 2 out of 5 mice on-exercise became diabetic. An exercise-induced weight loss (-9%, p<0.05) was detected in the trained mice with respect to the controls. As to the cytokines results, while control mice did not show any changes in the inflammatory factors at end of the training program with respect to baseline, we observed a slight but significant decrease of MIP-1 $\beta$  (-1%), IFN- $\gamma$  (-2%), IL-10 (-2%), IL-2 (-1%) IL-13 (-2%), GM-CSF (-2%), and a substantial increase in G-CSF (+27%) in the trained animals compared to their pre-training values (p<0.05). Preliminary data from a morphometric analysis of pancreata indicated the presence of larger infiltrates along with increased  $\alpha$ -cells areas in the control mice.

**Conclusion:** In summary, moderate-intensity exercise induced an anti-inflammatory effect in the trained mice paralleled by a greater amount of infiltrates in the disease-related deterioration of the control mice. We speculate that exercise may exert a positive immunomodulation of systemic functions with respect to both T1DM and inflammation.

### Sesamin improves lowered exercise capacity and mitochondrial dysfunction in the skeletal muscle from high fat diet-induced diabetic mice

S. Takada<sup>1,2</sup>, S. Kinugawa<sup>1</sup>, D. Takemoto<sup>3</sup>, T. Kadoguchi<sup>1</sup>, T. Yokota<sup>1</sup>, S. Matsushima<sup>1</sup>, A. Fukushima<sup>1</sup>, Y. Masaki<sup>1</sup>, T. Furihata<sup>4</sup>, T. Suga<sup>5</sup>, W. Mizushima<sup>1</sup>, Y. Ono<sup>3</sup>, H. Shibata<sup>3</sup>, K. Okita<sup>6</sup>, H. Tsutsui<sup>1</sup>;

<sup>1</sup>Department of Cardiovascular Medicine, Hokkaido University Graduate School of Medicine, Sapporo, <sup>2</sup>Research Fellow of the Japan Society for the Promotion of Science, Tokyo, <sup>3</sup>Institute for Health Care Science, Suntory Wellness Limited, Osaka, <sup>4</sup>Department of Cardiovascular Medicine, Hokkaido University Graduate School of Medicine, Sapporo,

<sup>5</sup>Faculty of Sport and Health Science, Ritsumeikan University, Sapporo,

<sup>6</sup>Department of Sport Education, Hokusho University, Sapporo, Japan.

**Background and aims:** We previously reported that high fat diet (HFD)-induced diabetic mice had the reduced exercise capacity and impaired mitochondrial function in the skeletal muscle, which was due to NAD(P)H oxidase-induced oxidative stress. Sesamin is a natural ingredient included in sesame (*Sesamum indicum*) which is a traditional herbal medicine, and has multiple biological functions such as antioxidant activity. We hypothesized that sesamin could ameliorate the reduced exercise capacity in diabetic mice.

**Materials and methods:** C57BL/6J mice were fed on normal diet (ND) or HFD, and each group of mice was treated with or without sesamin (0.2%) in the diet for 8 weeks. Exercise capacity and mitochondrial function in the skeletal muscle were evaluated.

**Results:** HFD significantly increased adipose tissue weight and plasma glucose compared to ND, and sesamin did not affect these parameters in either group (p>0.05). HFD significantly increased body weight and plasma insulin compared to ND (body weight; 43 $\pm$ 1 vs 29 $\pm$ 1 g, insulin; 2.0 $\pm$ 0.3 vs 0.5 $\pm$ 0.1 ng/mL, p<0.05), and these gains were ameliorated in HFD+sesamin (body weight; 37 $\pm$ 1 g, insulin; 0.8 $\pm$ 0.2 ng/mL, p<0.05). The work and peak oxygen uptake determined by treadmill tests were significantly reduced in HFD compared to ND (work; 14 $\pm$ 1 vs 28 $\pm$ 1 J, peak VO<sub>2</sub>; 109 $\pm$ 4 vs 152 $\pm$ 2 mL/kg/min, p<0.05), and these reductions were ameliorated in HFD+sesamin (work; 20 $\pm$ 1 J, peak VO<sub>2</sub>; 129 $\pm$ 2 mL/kg/min, p<0.05). Citrate synthase (CS) activity was significantly decreased, and NAD(P)H oxidase activity and superoxide production by lucigenin chemiluminescence were significantly increased in isolated skeletal muscle from HFD compared to ND (CS activity; 31  $\pm$  3 vs 108  $\pm$  6 nM/min/mg protein, NAD(P)H oxidase activity; 19  $\pm$  1 vs 5  $\pm$  1 RLU/min/mg protein, superoxide anion; 55  $\pm$  9 vs 15  $\pm$  2 RLU/min/mg protein, p<0.05), which were also ameliorated by sesamin (CS activity; 70  $\pm$  8 nM/min/mg protein, NAD(P)H oxidase activity; 8  $\pm$  1 RLU/min/mg protein, superoxide anion; 18  $\pm$  2 RLU/min/mg protein, p<0.05). Additionally, *in vitro* data showed that sesamin and its nomo-catechol metabolite significantly suppressed angiotensin II-induced NAD(P)H oxidase activity in C2C12 myotubes (p<0.05).

**Conclusion:** Sesamin ameliorated the reduced aerobic exercise capacity in HFD-induced diabetic mice via the improvement of impaired mitochondrial function and attenuation of oxidative stress in the skeletal muscle.

### High intensity intermittent exercise reverses abnormal cardiac function in people with type 2 diabetes: an MRI/S study

S.A. Cassidy<sup>1</sup>, C. Thoma<sup>1</sup>, K. Hallsworth<sup>1</sup>, D.G. Jakovljevic<sup>1</sup>, J. Parikh<sup>2</sup>, K.G. Hollingsworth<sup>2</sup>, R. Taylor<sup>2</sup>, M.I. Trenell<sup>1</sup>;

<sup>1</sup>Institute of Cellular Medicine, <sup>2</sup>Newcastle Magnetic Resonance Centre, Newcastle University, Newcastle Upon Tyne, UK.

**Background and aims:** Cardiovascular disease is the leading cause of morbidity and mortality in Type 2 diabetes. Despite the clear individual and societal burden of cardiovascular disease in Type 2 diabetes, evidence based therapies to improve cardiac function are limited. High intensity intermittent exercise is a time efficient strategy for cardiovascular training, but its direct effects on cardiac structure and function in people with Type 2 diabetes are unknown. This study investigated high intensity intermittent exercise as a potential therapeutic tool to moderate cardiac risk in this patient group.

**Materials and methods:** Twenty-three patients with Type 2 diabetes (age 60 $\pm$ 9 years, BMI 31 $\pm$ 5 kg/m<sup>2</sup>, HbA<sub>1c</sub> 55 $\pm$ 8 mmol/mol) were randomised to 12 weeks of high intensity intermittent exercise (treatment, n=12) or standard care (controls, n=11). High intensity intermittent exercise consisted of 5 x 2min intervals at >80% heart rate max using cycle ergometry three times a week (guided by a podcast). Each week the duration of each exercise bout was increased. Cardiac structure, function and energetics were measured respectively by 3.0 T magnetic resonance imaging, 2 dimensional tagging and phosphorus-31 spectroscopy. Liver fat was determined by <sup>1</sup>H-magnetic resonance spectroscopy.

**Results:** Compared to controls, high intensity intermittent exercise improved cardiac structure (Left ventricular Mass-104 $\pm$ 17 to 116 $\pm$ 20 vs. 107 $\pm$ 25 to 105 $\pm$ 25g, p<0.05; End-diastolic blood volume-118 $\pm$ 30 to 126 $\pm$ 30 vs. 129 $\pm$ 28 to 122 $\pm$ 28ml, p<0.05) and cardiac systolic function (stroke volume-76 $\pm$ 16 to 87 $\pm$ 19 vs. 79 $\pm$ 14 to 75 $\pm$ 15ml, p<0.05; Left ventricular ejection fraction-65 $\pm$ 8 to 70 $\pm$ 6 vs. 64 $\pm$ 11 to 63 $\pm$ 10%, p<0.05). Early diastolic filling rates increased (241 $\pm$ 84 to 299 $\pm$ 89 vs. 250 $\pm$ 44 to 251 $\pm$ 47ml/s, p<0.05) and peak torsion decreased (8.1 $\pm$ 1.8 to 6.9 $\pm$ 1.6 vs. 7.1 $\pm$ 2.2 to 7.6 $\pm$ 1.9 $^{\circ}$ , p=0.05) in the treatment group compared to controls. There was no effect on cardiac metabolism determined by magnetic resonance phosphorus-31 spectroscopy. High intensity intermittent exercise also delivered benefits to glucose control (HbA<sub>1c</sub>-55 $\pm$ 11 to 51 $\pm$ 10 vs. 55 $\pm$ 6 to 57 $\pm$ 8 mmol/mol; p<0.05) and liver fat (7 $\pm$ 7 to 4 $\pm$ 4 vs. 7 $\pm$ 7 to 8 $\pm$ 7%; p<0.05).

**Conclusion:** High intensity intermittent exercise has positive effects on cardiac structure and function alongside benefits to glucose control and liver fat. Clinical care teams should consider high intensity intermittent exercise as a therapeutic strategy to moderate cardiac dysfunction in people with Type 2 diabetes.

### Physical activity patterns in a type 2 diabetes population. Relationship with cardiovascular risk factors, diabetes complications and comorbidities

N. Porta<sup>1</sup>, M. Villaró<sup>1</sup>, T. Mur<sup>2</sup>, A. Jaen<sup>3</sup>, Diabetes in primary care Study group MutuaTerrassa;

<sup>1</sup>Primary Care, <sup>2</sup>Primary Care Research,

<sup>3</sup>MutuaTerrassa Foundation, Mutua Terrassa, Spain.

**Background and aims:** The aim of our study is to analyze the physical activity (PA) pattern and risk factors associated with sedentary T2DM population.

**Materials and methods:** Cross-sectional multicenter random study in primary care. Physical Activity (PA) was assessed by Short International PA Questionnaire with 4 categories: Low or Sedentary (<600MET/week), Moderate-medium (600-1499), Moderate-High(1500-2999) and High( $\geq$ 3000). We registered sociodemographic, anthropometric data and cardiovascular (CV) risk factors, disease and risk scores. Yesavage and Mediterranean Diet test and DM complications and comorbidities were also compiled. Analytical data: HbA<sub>1c</sub>, lipid, renal profile and uricaemia. Bivariate and multivariate logistic regression (PA low versus moderate to high) analyses were performed.

**Results:** Of 447 patients, 57.9% were men. Mean age: 67.9 $\pm$ 10.4; mean HbA<sub>1c</sub>: 7.1% $\pm$ 1.2%; 36.6% had overweight and 50.7% obesity I(BMI 30-34); 28.6% and 20.8% had CV and Chronic Renal Disease (CRD), respectively. PA pattern was: 24.4% low, 28.3% moderate-medium, 21.7%moderate-high

and 25.6% high. Low PA was more frequent in: women,  $\geq 75$  years, smokers, hypertensive, patients with higher BMI and waist risk circumference, higher Stroke scores, CRD, depression, and elevated lipid profile. Independent risk factors associated with low PA in the multivariate analysis were (Odds ratios, CI 95%): Hypertension (3.1, 1.5–6.2), CRD (1.8, 1.04–3.2), depression (2.7, 1.2–5.9), longer time of T2DM onset (1.04, 1.0–1.09), higher levels of triglycerides (1.01, 1.0–1.01) and ldl (1.01, 1.0–1.02). By contrast, have a good control of glycaemia (0.5, 0.3–0.8), of blood pressure (0.4, 0.3–0.8) and of triglycerides (0.4, 0.2–1.0) were protective factors for sedentary. Female had a higher risk for sedentary in the limit of the significance (OR: 1.5; CI95%: 0.9–2.5).

**Conclusion:** 24% of our T2DM population was sedentary. PA improves glycaemia control, lipid profile, CV risk factors and CRD, all of them very important to prevention of diabetes morbidity. Inactivity is also related with a risk of depression, probably associated to the quality of life.

## 629

### Lowered muscle endurance in association with neuropathy in patients with type 2 diabetes

T. Gysel<sup>1</sup>, J. Ruige<sup>2</sup>, P. Boon<sup>2</sup>, D. Cambier<sup>1</sup>, P. Calders<sup>1</sup>;

<sup>1</sup>Dept. of Rehabilitation Sciences and Physiotherapy,

<sup>2</sup>Ghent University, Ghent, Belgium.

**Background and aims:** Type 2 diabetes is characterized by a reduced sensitivity of the tissues to insulin (insulin resistance), and a reduced formation of insulin by the pancreas. This is often accompanied by damage to blood vessels and nerves (neuropathy). The treatment of diabetes includes medication, nutritional advice and exercise therapy. Strength training has a positive effect on insulin resistance and muscle function. What kind of strength training is most optimal, remains unknown. To investigate this, first of all, it should be examined to what extent different types of strength (maximal-, explosive-, endurance,  $\bar{x}$ ) are influenced by the severity of diabetes, taking into account additional conditions, such as peripheral neuropathy. Since the negative influence of diabetes and neuropathy on maximal strength has already been investigated, the purpose of this study was to investigate the association between neuropathy and arm/leg muscle endurance.

**Materials and methods:** Data from an isokinetic dynamometer, a clinical neurological examination + quantitative sensory examination and nerve conduction studies were obtained in 35 type 2 diabetic men, with (n=24) and without neuropathy (n=11). Seven patients had small fiber sensory neuropathy, 17 had sensorimotor neuropathy. All men performed 25 elbow- and 30 knee maximal concentric contractions on an isokinetic dynamometer at a given angular velocity of 180°/sec. Elbow- and knee flexor fatigue was measured with the fatigue index, calculated as the ratio of the average peak torque of the last third to the average peak torque of the first third. A neuropathy rank sum score (NRSS) was calculated for each patient to quantify the peripheral nerve function, adding the rank scores for the Michigan Neuropathy Screening Instrument (MNSI) questionnaire, the neuropathy disability score (NDS), the vibration perception thresholds (VPT's), the motor and sensory nerve conduction velocities (MNCV's and SNCV's), as well as the amplitudes of the compound muscle - and sensory nerve action potentials (CMAP's and SNAP's). The VPT's were ranked on the basis of the sum of the two percentiles obtained at right and left great toe. The EMG-parameters (MNCV & CMAP of peroneal, tibial and ulnar nerve, SNCV & SNAP of radial and sural nerve) were ranked for all nerves according to the calculated z-score. In order to calculate these z-scores, MNCV + CMAP and SNCV + SNAP were measured in 16 healthy subjects in an age-matched comparison group. Finally, the mean sum score for the conduction studies was used for the total rank sum score. If no action potential could be obtained, the highest rank score was given. A high NRSS thus reflected severe nerve dysfunction. To estimate the correlations between the neuropathy rank sum score and the fatigue indices, pearson correlation analysis was used.

**Results:** A significant negative correlation was indicated between the isokinetic fatigue index of knee flexors and the NRSS ( $r = -0.356$ ,  $p = 0.036$ ). For elbow flexors there was also a tendency towards a negative correlation with the NRSS ( $r = -0.318$ ,  $p = 0.062$ ).

**Conclusion:** This finding suggests that not only maximal strength, but also endurance in diabetic people with neuropathy is worse than in diabetics without neuropathy.

## 630

### Characteristics of patients with type 2 diabetes who achieved better glycaemic control through resistance training: a meta-analysis

H. Ishiguro<sup>1</sup>, S. Kodama<sup>2</sup>, S. Matsunaga<sup>3</sup>, C. Horikawa<sup>3</sup>, Y. Heianza<sup>3</sup>, N. Ohara<sup>4</sup>, T. Yamada<sup>3</sup>, A. Suzuki<sup>3</sup>, O. Hanyu<sup>3</sup>, H. Sone<sup>3</sup>;

<sup>1</sup>Tsugawa Hospital, Niigata prefecture, <sup>2</sup>Mito kyodo Hospital, Ibaraki prefecture, <sup>3</sup>Niigata University Faculty of Medicine,

<sup>4</sup>Nagaoka Red Cross Hospital, Niigata prefecture, Japan.

**Background and aims:** Recently, an increasing number of studies have suggested that resistance training (RT) has been effective in improving glycaemic control (GC) in patients with type 2 diabetes (T2D). Our aim of this meta-analysis is to determine the antihyperglycemic effect of RT and analyze characteristics of patients for whom RT could be especially indicated for improvement in GC.

**Materials and methods:** Electronic-based literature search was conducted for intervention studies examining the metabolic effect of RT in T2D patients using MEDLINE and EMBASE. Studies were included if 1) both an RT-exercise group and non-RT control group were examined and 2) the net change in hemoglobin A<sub>1c</sub> (A1C) (i.e., difference in mean change in A1C from before to after the study between RT and non-RT groups) and its corresponding standard error as a study weight could be estimated. We included studies that described other interventions such as aerobic training if those other interventions were similar between the RT and non-RT groups.

**Results:** Twenty-seven studies were eligible. Net change in A1C (95% confidence interval [CI]) was  $-0.3$  [ $-0.46$ – $-0.14$ ]. A significantly larger reduction in A1C was observed in studies of subjects with the following characteristics: 1) short duration of T2D ( $\geq 6$  years vs.  $< 6$  years,  $P = 0.03$ ), 2) women-dominant ( $< 50\%$  vs.  $\geq 50\%$  proportion of men,  $P = 0.006$ ) and 3) high A1C values at baseline ( $\geq 7.5\%$  vs.  $< 7.5\%$ ,  $P = 0.006$ ). There was a linear relationship between baseline body mass index and the net effect on A1C ( $R$ -squared=0.42,  $P < 0.001$ ), predicting that a 1 kg/m<sup>2</sup> leaner subject would achieve a 0.09% larger reduction in A1C after RT (Figure). The training protocol such as intensity, interval between sets, frequency, and intervention periods did not significantly modify study results.

**Conclusion:** This meta-analysis produced useful suggestions regarding the characteristics of patients with T2D for whom clinicians should especially prescribe RT to achieve improved GC.

Relationship between mean body mass index (BMI) and the effect of resistance training (RT) on glycemic control. Net change in hemoglobin A1C (A1C) (i.e., change in A1C in RT group minus that in non-RT group from before to after the intervention study) was plotted against mean BMI in study subjects. The area of circles is proportional to study weight (i.e., inverse of square of standard error of the net effect in A1C)

## PS 042 Consequences of hypoglycaemia

631

### Severe hypoglycaemia requiring medical assistance in patients with diabetes is associated with simultaneous prolongation of QTc interval

M. Mylona<sup>1</sup>, G. Anastasiadis<sup>2</sup>, K. Zerva<sup>2</sup>, V. Vasgiourakis<sup>2</sup>, C. Liaskos<sup>1</sup>, S. Liatis<sup>1</sup>;<sup>1</sup>Diabetes Center, First Department of Internal Medicine,<sup>2</sup>Department of Cardiology, Laiko Hospital, Athens, Greece.

**Background and aims:** It has been shown that hypoglycemia induces multiple pre-arrhythmic changes, mainly increase pre-existent QT prolongation, produce intracellular Ca<sup>2+</sup> overload, and decrease serum K<sup>+</sup>. As a consequence, hypoglycemia is considered a state that may lead to sudden death, as a result of cardiac arrhythmia. Few data, however, directly link episodes of severe hypoglycemia with pre-arrhythmic conditions, such as QT prolongation. Aim of the present study is to explore the association between severe hypoglycemic events requiring medical assistance and QT interval, in patients with diabetes.

**Materials and methods:** Eight hospitals (nine clinics), in five cities of Greece, participated in a 16-month prospective survey of documented iatrogenic hypoglycemia at the emergency departments (ED). According to the protocol, a 12-lead ECG was obtained simultaneously or immediately after the management of hypoglycemia and no later than 30 minutes after the administration of glucose. The ECGs obtained from hypoglycemic patients were compared to those from a control group consisted of patients with diabetes, matched for age and gender, visiting the outpatient diabetes clinics of the same hospitals, during the same time period. QT and RR intervals were measured blindly by three independent cardiologists. QTc was calculated according to the Bazett formula:  $QTc = QT \text{ interval} / \text{square root of the R-R interval}$ . QTc measurements of  $\geq 440$  msec were considered abnormally prolonged and those of  $\geq 500$  msec as highly prolonged. Patients receiving medications possibly affecting the QTc interval and those with hypokalaemia (serum potassium  $< 3.5$  mEq/l) were excluded from the analysis.

**Results:** During a median follow-up of 16 months, 295 episodes of iatrogenic hypoglycemia in 294 patients with diabetes were identified and 223 ECGs were obtained according to the pre-specified criteria. However, 46 ECGs were excluded from the analysis, due to the presence of the above mentioned criteria. Finally, 177 ECGs from hypoglycemic patients were analyzed (mean age  $72.7 \pm 15.7$  years, 48.6% women, 9% with type 1 diabetes) and compared to 91 age and gender matched controls. Mean QTc interval was significantly prolonged in patients compared to controls ( $440.4 \pm 45.1$  msec vs.  $413.9 \pm 32.5$  msec,  $p < 0.001$ ). In addition, a significantly higher proportion of hypoglycemic patients had an abnormally prolonged QTc ( $\geq 440$  msec) compared to controls (49.7% vs. 24.2%,  $p < 0.001$ ), while 14 hypoglycemic patients (7.9%) had a highly prolonged QTc ( $\geq 500$  msec) compared to none in controls.

**Conclusion:** In patients with diabetes, severe iatrogenic hypoglycemia requiring medical assistance is associated with a both statistically and clinically significant prolongation of QTc interval.

632

### Facial skin temperature measured by infrared thermography during hypoglycaemia in patients with longstanding type 1 diabetes

A.-S. Sejling<sup>1,2</sup>, K.H.W. Lange<sup>1</sup>, C.S.S. Frandsen<sup>3</sup>, S.S. Diemar<sup>4</sup>, L. Tarnow<sup>1,5</sup>, J. Faber<sup>6</sup>, T.W. Kjær<sup>7</sup>, C.B. Juhl<sup>8,2</sup>, B. Thorsteinsson<sup>1,4</sup>, U. Pedersen-Bjergaard<sup>1,4</sup>;<sup>1</sup>Nordsjællands Hospital, Hillerød, <sup>2</sup>Faculty of Health Sciences, University of Southern Denmark, Odense, <sup>3</sup>Hvidovre Hospital, <sup>4</sup>Faculty of Health and Medical Sciences, University of Copenhagen, <sup>5</sup>Aarhus University, <sup>6</sup>Herlev Hospital, <sup>7</sup>Roskilde Hospital, Roskilde, <sup>8</sup>Sydvestjysk Sygehus, Esbjerg, Denmark.

**Background and aims:** Hypoglycaemia is associated with increased activity in the autonomic nervous system resulting in increased sweat production and changes in peripheral blood flow. Since peripheral blood flow influences overlying skin temperature (Ts), hypoglycaemia may cause changes in skin temperature. The aim of this study was to investigate changes in Ts during induced hypoglycaemia in patients with long standing type 1 diabetes. We hypothesized that hypoglycaemia results in decreased Ts.

**Materials and methods:** Twenty-four patients with type 1 diabetes participated in the study (14 men, age  $54 \pm 12$  years (mean  $\pm$  SD), duration of diabetes  $28 \pm 11$  years, HbA1c  $8.0 \pm 1.0$  %). Fourteen patients had hypoglycaemia unawareness and 10 patients had normal hypoglycaemia awareness. The patients were studied during euglycaemia ( $5.4 \pm 0.6$  mmol/L) and hypoglycaemia ( $2.4 \pm 0.2$  mmol/L) by a hyperinsulinaemic glucose clamp technique. During each phase of one hour, Ts was measured by infrared thermographic imaging in two pre-defined facial areas of approximately 2 cm<sup>2</sup> size on the forehead just above the bony nose and on the tip of the nose. Autonomic symptoms of hypoglycaemia were recorded and venous blood was sampled.

**Results:** During hypoglycaemia Ts decreased on the forehead ( $\Delta Ts = -0.86 \pm 0.99^\circ\text{C}$ ,  $p=0.001$ ) and on the nose ( $\Delta Ts = -1.75 \pm 2.1^\circ\text{C}$ ,  $p=0.002$ ). There was a difference in Ts changes on the forehead between the two groups ( $\Delta Ts = -1.4 \pm 0.29^\circ\text{C}$  in aware patients vs  $\Delta Ts = -0.4 \pm 0.23^\circ\text{C}$  in unaware patients,  $p=0.01$ ) (Figure). Epinephrine concentrations increased during hypoglycaemia compared to euglycaemia ( $0.49 \pm 0.42$  ng/mL vs  $0.07 \pm 0.05$  ng/mL,  $p < 0.001$ ) with no significant difference in rise of epinephrine between aware and unaware patients ( $0.54 \pm 0.52$  ng/mL vs  $0.34 \pm 0.31$  ng/mL,  $p=0.19$ ). Autonomic symptom scores increased during hypoglycaemia ( $10 \pm 6$  points vs  $5.5 \pm 1.8$  points,  $p=0.001$ ). The aware group reported 2.5 times higher symptom scores during hypoglycaemia than the unaware group ( $15 \pm 5.9$  points vs  $6.5 \pm 2.6$  points,  $p < 0.01$ ).

**Conclusion:** Hypoglycaemia-associated changes in facial skin temperature can be quantified by infrared thermography in patients with type 1 diabetes. Patients with normal awareness had a larger Ts decrease on the forehead compared to patients with hypoglycaemia unawareness and more autonomic symptoms during hypoglycaemia despite no significant difference in blood epinephrine concentrations between the two groups.

#### Skin temperature on the forehead during hypoglycaemia

Figure: Temperature changes on the forehead during hypoglycaemia. Measurements were performed 15 and 55 min into the normoglycaemic, hypoglycaemic and recovery phases. \*  $p=0.03$ , \*\*  $p < 0.001$  when compared to normoglycaemia.

### Cardiac autonomic regulation during acute experimental hypoglycaemia in type 2 diabetes

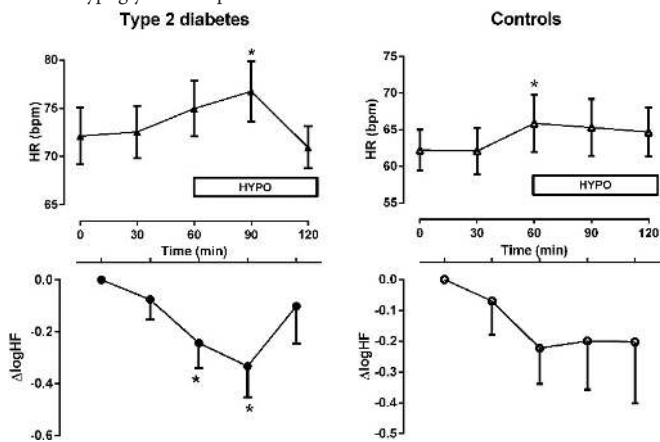

E. Chow<sup>1</sup>, A. Bernjak<sup>2</sup>, P.J. Sheridan<sup>1</sup>, S.R. Heller<sup>2</sup>;<sup>1</sup>Cardiovascular Sciences, <sup>2</sup>Human Metabolism, University of Sheffield, UK.

**Background and aims:** Hypoglycaemia is associated with increased cardiovascular mortality in trials of intensive therapy in type 2 diabetes. In recent clinical studies involving type 2 diabetes patients, we reported a higher incidence of ventricular ectopics and bradyarrhythmias during spontaneous prolonged hypoglycaemia, which we attributed to differential changes in autonomic tone. In this study our aim was to examine changes in cardiac autonomic function in more detail during sustained experimental hypoglycaemia.

**Materials and methods:** Twelve type 2 diabetes subjects with normal cardiac autonomic function tests and eleven age, BMI-matched nondiabetic controls underwent paired hyperinsulinaemic clamps separated by 4 weeks. In the euglycaemic arm, glucose was maintained at 6.0 mmol/L for 2h while during hypoglycaemia, glucose was lowered to 2.5 mmol/L over 1 hour and maintained for a further hour. Heart rate (HR), blood pressure and heart rate variability (HRV) were assessed at 30 min intervals. Spectral power of HRV was calculated within low frequency (LF: 0.04-0.15 Hz) and high frequency (HF: 0.15-0.4 Hz) intervals.

**Results:** In the diabetic group, HR increased maximally from  $72 \pm 10$  to  $77 \pm 10$  bpm ( $p=0.04$ ) after 30 minutes of hypoglycaemia (T90), but fell to  $71 \pm 8$  bpm despite maintained hypoglycaemia (T120) (see Fig). High frequency HRV decreased up to T90 ( $\log_{\text{HF}} 1.89 \pm 0.61$  vs  $1.61 \pm 0.63$ ,  $p=0.02$ ), indicating acute vagal withdrawal, but returned towards baseline at T120. There was a rise in normalised low frequency power indicating increased sympathetic contribution. In the control group, the maximal increase in HR occurred earlier at T60 during hypoglycaemia (from  $62 \pm 9$  to  $66 \pm 13$  bpm,  $p=0.04$ ) but HR remained elevated at  $65 \pm 11$  bpm after hypoglycaemia for 1 hour. HF power decreased from baseline ( $\log_{\text{HF}} 2.36 \pm 0.44$  to  $2.14 \pm 0.59$ ,  $p=0.05$ ) and remained unchanged despite continued hypoglycaemia, indicating inhibition of vagal tone throughout. No significant changes in HRV occurred in either group during euglycaemic clamps.

**Conclusion:** Cardiac autonomic regulation during hypoglycaemia appears time-dependent and differs between patients with type 2 diabetes and non-diabetic individuals. In type 2 diabetes, the initial heart rate increment to hypoglycaemia is delayed. Following early vagal withdrawal, there is reactivation of vagal activity during more sustained hypoglycaemia which did not occur in nondiabetic individuals. These mechanisms may relate to autonomic dysfunction and could contribute to tachy- and bradyarrhythmias during clinical hypoglycaemic episodes.

## 634

### Survey of outpatients with type 2 diabetes among older adults in Japan

M. Fukuda, K. Doi, M. Sugawara, Y. Naka, K. Mochizuki;  
Japan Physicians Association, Tokyo, Japan.

**Background and aims:** The number of older adults with Type II diabetes (T2DM) is continuously increasing in Japan, and care needs to be provided according to the individual needs of these patients, which require more urgent attention in Japan than in the West. Despite this situation, few studies have investigated the prevalence of hypoglycemia among older T2DM in Japan. This study describes the results of a survey conducted by the Japan Physicians Association (JPA) to elucidate the prevalence of hypoglycemia among older T2DM in Japan. The survey collected data on patient knowledge about hypoglycemic symptoms as well as their clinical background.

**Materials and methods:** A total of 15,892 older adults aged  $\geq 65$  years (8319 men and 7516 women) who were undergoing regular outpatient treatment for their diabetic conditions were included in this study. The survey included questions pertaining to 28 items concerning hypoglycemic symptoms and age-related syndromes experienced in the last month. The JPA also collected patients' medical records from their doctors.

**Results:** The average age of patients was 74.2 years (men, 73.6 years; women, 75.0 years), the mean disease duration was 12.8 years (men, 13.1 years; women, 12.5 years), and the mean body mass index (BMI) was 24.1 (men, 24.0; women, 24.2). Medications used for diabetes treatment, including concomitant prescriptions, were as follows: DPP-4 inhibitors, 53.3%; SU, 39.4%;  $\alpha$ -GI, 23.4%; metformin, 22.8%; pioglitazone, 14.0%; glinide, 4.4% and insulin, 17%. Although the incidence of hypoglycemic symptoms as estimated by the doctors on the basis of their diagnoses in the previous month was 7.8%, the actual incidence indicated by the patient responses was 10.4%. The responses indicated that the incidence of hypoglycemia among patients treated with either SU or insulin was 20.9%, whereas that among patients treated

without neither drugs was lower at 2.5%. Tiredness/feeling languid (32.8%), loss of balance/dizziness (32.4%), cold sweats (30.4%), and eye blink (24.8%) were the most frequently experienced hypoglycemic symptoms. Among the patients who used SU or insulin, 80.1% were aware of their hypoglycemic symptoms and 64.4% knew how to treat these symptoms. However, only 38.1% patients who were aware of their hypoglycemia always carried some form of glucose with them.

**Conclusion:** The results of our survey indicated that the symptoms of hypoglycemia were atypical and vague in older T2DM patients, and the actual incidence of hypoglycemia among the patients was considerably higher than that estimated by the doctors on the basis of their diagnoses. Although there was satisfactory awareness of hypoglycemia among the older adults, two-thirds of them did not always carry some form of glucose with them. Therefore, more careful treatment of T2DM and more positive measures to promote the awareness of hypoglycemia are required for older adults with T2DM.

## 635

### Impaired awareness of hypoglycaemia in insulin-treated patients with type 2 diabetes mellitus

N. Sakane, K. Kotani, K. Tsuzaki, K. Takahashi, Y. Sano;  
Kyoto Medical Center, Japan.

**Background and aims:** Severe hypoglycemia (SH) is associated with a higher risk of cardiovascular disease-related mortality and mortality. Impaired awareness of hypoglycemia (IAH) in insulin-treated patients with type 2 diabetes mellitus (T2DM) has been reported to be associated with the presence of SH. However, little is known regarding the actual states of hypoglycemia, including IAH, in Japan. The aim of the study was therefore to survey the states of hypoglycemia and patient-physician communication among insulin-treated patients with T2DM.

**Materials and methods:** A questionnaire survey on hypoglycemia and patient-physician communication was conducted in 331 patients with insulin-treated T2DM patients at 16 hospitals and clinics. Inclusion criteria were: 1) over 20 years, 2) T2DM, 3) insulin treatment, 4) patients regularly attended the surveyed hospitals and clinics. Exclusion criteria were: 1) children and young patients under 20 years old, and 2) type 1 diabetes mellitus. Clinical data such as the insulin regimen and diabetic complications were collected from their physicians. Hypoglycemia was defined as blood sugar  $\leq 50$  mg/dL (2.8 mmol/L) or symptoms of dizziness, blurry vision, confusion, and/or sweating that the patient was able to resolve without assistance. Similar symptoms that required external assistance were defined as SH. Favorable glycemic control to prevent diabetic complications was defined as HbA1c  $< 7\%$  according to "Kumamoto declaration 2013". Patient-physician communication regarding hypoglycemia and strategies to avoid it was based on the answer categories "never" and "seldom" as poor communication, and "sometimes" and "often" as favorable communication, in response to "how often do you talk about hypoglycemia and strategies to avoid it with your physician?"

**Results:** The rate of IAH was 22.1%. There were no significant differences in clinical characteristics, such as the age, diabetes duration, prevalence of hypoglycemia, insulin regimen, and diabetic complications, between patients with and without IAH. The rates of alcohol drinking and smoking in males were significantly higher than in females (22.5 vs. 1.4%;  $p < 0.01$ , and 30.9 vs. 12.2%;  $P < 0.01$ , respectively). A stepwise logistic regression analysis revealed that glycemic control at an HbA1c level  $< 7.0\%$  was a significant risk factor of IAH (odds ratio [OR]: 2.12; 95% confidence interval [CI]: 1.22-3.68;  $P=0.01$ ), along with a male sex (OR: 1.89; 95% CI: 1.06-3.38;  $P=0.03$ ) and a BMI level (OR: 0.89; 95% CI: 0.82-0.97;  $P=0.01$ ). Concerning talking about hypoglycemia with physicians, patients with IAH showed a similar frequency of talking with physicians as patients without IAH (76.1 vs. 71.4%;  $P=0.44$ , respectively), while patients with SH communicated more frequently than those without SH (90.9 vs. 70.3%;  $P=0.01$ , respectively).

**Conclusion:** The current survey found that IAH was not uncommon among insulin-treated patients with T2DM in Japan. Aging, a lower BMI, and lower HbA1c levels were significantly correlated with IAH. The patients with SH talked less about hypoglycemia with their physicians. To improve the actual states of hypoglycemia, physicians should be conscious of the factors associated with IAH, and should talk more about hypoglycemia to insulin-treated patients with T2DM in Japan.

**Hypoglycaemia unawareness in emerging adults transferred from a paediatric to an adult diabetes unit**M.C. Careaga<sup>1</sup>, M. Vidal<sup>1</sup>, M. Jansa<sup>1</sup>, C. Yoldi<sup>2</sup>, R. Cardona<sup>2</sup>, A. Gomez<sup>2</sup>, M. Gimenez<sup>1</sup>, E. Esmatjes<sup>1</sup>, I. Conget<sup>1</sup>;<sup>1</sup>Diabetes Unit, Endocrinology and Nutrition Department, Hospital Clinic and University of Barcelona,<sup>2</sup>Pediatric Endocrinology, Hospital Sant Joan de Deu, Barcelona, Spain.

**Background and aims:** Repeated hypoglycemia and the syndrome of hypoglycemia unawareness (HU) are major barriers to achieving normoglycemia over a lifetime of using intensive insulin therapy and thus precludes euglycemia's long-term benefits. Type 1 Diabetes (T1D) management in young patients is troublesome specially when they are transferred to adult Diabetes Units. The aim of our study was to evaluate the impact of the presence of HU on the results of a transition therapeutic education program (TEP) specifically addressed to the transfer T1D patients from a pediatric to an adult diabetes Unit.

**Materials and methods:** We included 56 patients with T1D (age 18.0 ± 0.3 years, 26 girls, disease duration 8.0 ± 4.0 years, HbA1c 8.0 ± 1.2%) consecutively transferred (2009-2011). The TEP included a co-ordinated transfer between the Units, individual visits and group sessions. At baseline, we registered data on BMI, insulin dose, HbA1c and the frequency of hypoglycemia. For evaluation of the quality of life (QoL) and knowledge in T1D management, self-report questionnaires were assessed. Mother tongue (spanish and catalan versions) validated Clarke's test was used to evaluate HU. After 12-months, all subjects were re-evaluated.

**Results:** Nine out of 56 patients had HU (16%). Age, gender, duration of disease, type of treatment, HbA1c, the different aspects of QoL and the degree of knowledge of the disease were not different in those subjects affected by HU in comparison to the unaffected group. Only the number of severe hypoglycemia episodes was significantly different between groups (0.33±0.50 vs. 0.09±0.28, episodes-subject-year with and without HU respectively, p 5 non severe episodes/week was close to significantly different (66 vs 34 %, p=0.13). After 12 months, in the group with HU, 4 patients improved awareness, there was a reduction in the number of non severe hypoglycemia episodes/ week, but this was not the case of severe episodes. The HbA1c was not significantly different between the two groups (8.2 ± 1.1 vs. 7.6 ± 0.9% with and without HU, respectively)

**Conclusion:** The presence of HU is far from uncommon when emerging adults with T1D are transferred from a pediatric to an adult diabetes unit. While the use of a specific TEP improves metabolic prognosis in the mid-term, the reduction of hypoglycemia episodes, specially severe, remains an elusive issue

## 637

**Timing of hypoglycaemia is associated with increased mortality and length of stay among patients with diabetes admitted to internal medicine departments**J. Wainstein<sup>1</sup>, M. Boaz<sup>2,3</sup>, E. Leibovitz<sup>4,5</sup>;<sup>1</sup>Diabetes clinic, Wolfson Medical Center, <sup>2</sup>Research and Epidemiology, Wolfson Medical Center, Holon, <sup>3</sup>Epidemiology, Tel Aviv University,<sup>4</sup>Internal Medicine E, Wolfson Medical Center, Holon,<sup>5</sup>Sackler school of Medicine, Tel Aviv University, Israel.

**Background and aims:** Hypoglycemia among hospitalized patients with diabetes is associated with poor hospital prognosis. The aim of the study was to examine the effect of hypoglycemia timing on hospital prognosis

**Materials and methods:** In this retrospective analysis of electronic medical records, we included all 3941 patients with diabetes (Mean age 71.7±12.9 years, 49.3% males) discharged from internal medicine departments during 2009. All glucose measurements were computerized using an institutional glucometer. Patients were categorized into 3 groups according to hypoglycemia timing: Group 1, no hypoglycemia, Group 2, hypoglycemia only upon admission and Group 3, hypoglycemia during hospital stay.

**Results:** Included in the analysis were 3413 (86.4%) patients with diabetes who had glucose measurements performed during hospitalization. A total of 157 patients (4.6%) had at least 1 hypoglycemia event during the hospital stay (42 patients upon admission and 115 patients during hospitalization). Patients in Group 3 had significantly increased in-hospital mortality and length of hospital stay (27.0%, 18.4±24.7 days), compared to Groups 1 (3.4% mortality, 5.1±8.8 hospital days) and Group 2 (4.7% mortality, 3.2±3.3 hos-

pital days). Mortality rates were associated with the severity and number of hypoglycemia events. Patients in Group 3 had higher creatinine and lower albumin levels compared to Groups 1 and 2.

**Conclusion:** Hypoglycemia during hospitalization is associated with increased rates of in-hospital mortality and prolonged hospital stay among diabetic patients admitted to internal medicine departments. Poor hospital outcome was associated with timing of hypoglycemia, as well as the number and severity of the events.

## 638

**Baseline insulin deficiency is associated with increased mortality and severe hypoglycaemia in the ACCORD study**E.R. Seaquist<sup>1</sup>, H. Chen<sup>2</sup>, M. Miller<sup>2</sup>, L. Chow<sup>1</sup>;<sup>1</sup>Medicine, University of Minnesota,<sup>2</sup>Biostatistics, Wake Forest School of Medicine, Winston Salem, USA.

**Background and aims:** Intensive glycemic control is associated with increased mortality, but the role of hypoglycemia remains unclear. Hypoglycemia is associated with insulin deficiency. Whether insulin deficiency and/or islet autoimmunity may affect mortality in patients with type 2 diabetes remains unknown. Using the ACCORD (Action to Control Cardiovascular Risk in Diabetes) cohort, we tested the hypothesis that baseline insulin deficiency and islet autoimmunity in type 2 diabetes would be associated with severe hypoglycemia and mortality.

**Materials and methods:** A nested case-control study (86 cases, 344 controls) was used. A participant who died during ACCORD with at least 1 episode of severe hypoglycemia, defined as hypoglycemia requiring assistance, was classified as a case. Participants who did not die during ACCORD and did not have severe hypoglycemia were classified as controls. Each case was matched to 4 controls [age (+/- 5 yrs), BMI (+/- 2.5), glycemic intervention arm, race]. Insulin deficiency was defined as fasting C-peptide < 0.45 nmol/L. Islet autoimmunity was determined by antibodies against glutamic acid decarboxylase (GAD), tyrosine phosphatase-related islet antigen 2 (IA-2A), insulin (IAA), and zinc transporter (Zn-T8). Conditional logistic regression was used.

**Results:** Death during ACCORD with at least 1 episode of severe hypoglycemia was associated with baseline insulin deficiency (OR 4.8, 95% CI 2.1-11.1, p<0.01) and GAD antibodies (OR 2.3, 95% CI 1.1-5.1, p=0.04). These associations remained after adjusting for age and BMI (insulin deficiency: OR 6.5, 95% CI 2.6-16.4, p<0.01; GAD antibodies: OR 2.4, 95% CI 1.0-5.4, p=0.04). Other baseline antibodies (IA2, IAA, Zn-T8) had no association. GAD antibodies were more common in insulin deficient (54.6%) than non-insulin deficient (4.9%) participants.

**Conclusion:** In patients with type 2 diabetes, insulin deficiency, possibly due to islet cell autoimmunity, is associated with death and a history of severe hypoglycemia. Whether treatments to preserve insulin secretion in type 2 diabetes may reduce mortality remains an intriguing area for further study.

## 639

**Is hypoglycaemia an increasing barrier to achieving HbA1c target for NPH insulin than insulin glargine?**Q. Zhang<sup>1</sup>, E. Chou<sup>1</sup>, H.-W. Chung<sup>2</sup>, H. Wang<sup>1</sup>;<sup>1</sup>R&D, Sanofi, Bridgewater, <sup>2</sup>TechData, King of Prussia, USA.

**Background and aims:** Hypoglycemia is a common side effect of insulin therapy and may impede the outcomes of glycemic control. This study was to assess risk of hypoglycemia at each level of achieved A1C between patients initiating NPH insulin (NPH) and insulin glargine (GLA) as add-on to oral anti-diabetic drugs (OAD) from a US managed care database.

**Materials and methods:** Patients with T2DM who initiated NPH or GLA between January 2006 and December 2012 were identified from Clinformatics™ DataMart Multiplan. All patients had a minimum of 1-year continuous health coverage prior to and after basal insulin initialization. Baseline comorbidity was measured by Charlson Comorbidity Index (CCI) with a higher number corresponding to increased burden of comorbidity. Number of hypoglycemic events was evaluated against achieved level of A1C and tested at each A1C level with adjustment of baseline patient characteristics.

**Results:** NPH (n=864) had mean age of 47 years with average baseline A1C of 7.5% and CCI of 2.38 relative to GLA (n=10,843) with mean age of 55 years, baseline A1C of 8.6% and CCI of 2.55. Both groups had about 46% female.

During the year following basal insulin initiation, unadjusted achieved A1C decreased -1.0% from baseline in NPH and -1.2% in GLA. Mean number of hypoglycemic events in the year was 0.74 in NPH and 0.50 in GLA after adjustment of baseline characteristics. Overall, number of hypoglycemic events increased as achieved A1C during the year approached the target ( $\leq 7\%$ ) and remained higher in NPH relative to GLA ( $p < 0.01$ ). In particular when achieved A1C was at 7%, number of hypoglycemia events was estimated at 29.1/100 patient-years in NPH and 16.3/100 patient-years in GLA (Fig 1).

**Conclusion:** Consistent with previous research, this study shows an elevated hypoglycemia risk in NPH relative to GLA in the US managed care database. Furthermore, the risk of hypoglycemia rises as A1C approaches 7%, suggesting hypoglycemia as an increasing barrier for more intensive glycemc control in patients with T2DM initiating basal insulin from the clinical practice setting.

**Fig 1. Number of hypoglycemic events over achieved A1C in the year following the initiation of basal insulin initiation**

## 640

### Is the fear of hypoglycaemia associated with glycaemic imbalance?

A. Avignon<sup>1</sup>, M. Lièvre<sup>2</sup>, A. Penfornis<sup>3</sup>, B. Cariou<sup>4</sup>, N. Jeandidier<sup>5</sup>, S. Lavigne<sup>6</sup>, L. Vaur<sup>7</sup>;

<sup>1</sup>Montpellier University Hospital, <sup>2</sup>Laennec University of Medicine, Lyon, <sup>3</sup>Besançon University Hospital, <sup>4</sup>Nantes University Hospital, <sup>5</sup>Strasbourg University Hospital, <sup>6</sup>ITEC Services, Cenon, <sup>7</sup>Novo Nordisk, Paris, France.

**Background and aims:** The fear of hypoglycemia in clinical practice is important, but few practical tools exist to evaluate it. The HFS-II (Hypoglycemia Fear Survey-II) is a validated questionnaire measuring fear of the risk of hypoglycemia in patients with diabetes. It evaluates behaviors to avoid hypoglycemia and its consequences as well as degree of worry related to hypoglycemia. The objective of this analysis is to estimate the clinical correlations of a high HFS score ( $> +1SD$ ) on high HbA1c value ( $\geq 7\%$ ) and occurrence of severe hypoglycemia within 30 days.

**Materials and methods:** Data from 1927 French patients with insulin-treated diabetes (1008 patients with type 1 diabetes mellitus [T1DM] and 919 with type 2 diabetes mellitus [T2DM]) completing the HFS-II questionnaire in the DIALOG observational prospective study was used. The correlated factors were analyzed using a multivariate logistic regression model.

**Results:** Factors that were correlated to a HbA1c  $\geq 7\%$  were separately investigated in patients with T1DM and T2DM. For patients with T1DM, the main factors contributing to an HbA1c  $\geq 7\%$  were the HFS class  $> +1SD$  (odds ratio [OR] 3.5; 95% confidence interval [95CI] 1.9-6.4) and the class between -1 and +1SD (OR 2.8; 95CI 1.7-4.7) versus the lowest class ( $< -1SD$ ), as well as the insulin therapy duration  $> 10$  years (OR 1.8; 95CI 1.3-2.5). In patients with T2DM, the HFS score was no longer significant in the multivariate model. On the other hand, the main associated factors contributing to occurrence of a severe hypoglycemic event in both T1DM and T2DM patients were history of hypoglycemia (OR 3.8; 95CI 1.4-10.6), T1DM (OR 1.8; 95CI 1.3-2.5) and an HFS score  $> +1SD$  versus  $< -1SD$  (OR 7.1; 95CI 3.2-16.1) or between -1SD and +1SD versus  $< -1SD$  (OR 3.4; 95CI 1.6-7.5).

**Conclusion:** The fear of hypoglycemia is correlated with high HbA1c values in patients with T1DM and also with the occurrence of severe hypoglycemia in both T1DM and T2DM.

## PS 043 Nocturnal and drug-induced hypoglycaemia

#### Predisposing factors for hypoglycaemia: analysis from the SAVOR-TIMI 53 trial

I. Raz<sup>1</sup>, A. Cahn<sup>1</sup>, B.M. Scirica<sup>2</sup>, K.K. Ray<sup>3</sup>, F. Goldberg Eliashewitz<sup>4</sup>, R.G. Moses<sup>5</sup>, B. Hirshberg<sup>6</sup>, M. Sjöstrand<sup>7</sup>, N. Iqbal<sup>8</sup>, O. Mosenzon<sup>1</sup>, B.S. Lewis<sup>9</sup>, D.L. Bhatt<sup>2</sup>;

<sup>1</sup>The Diabetes Unit, Hadassah Hebrew University - Medical Center, Jerusalem, Israel, <sup>2</sup>Brigham and Women's Hospital, Harvard Medical School, Boston, USA, <sup>3</sup>St. Georges University of London, UK, <sup>4</sup>Clinical Research Center, São Paulo, Brazil, <sup>5</sup>Illawarra and Shoalhaven Local Health District, Wollongong West, Australia, <sup>6</sup>AstraZeneca, Wilmington, USA, <sup>7</sup>Clinical Development, AstraZeneca R&D, Mölndal, Sweden, <sup>8</sup>BMS, Princeton, USA, <sup>9</sup>Lady Davis Carmel Medical Center, Haifa, Israel.

**Background and aims:** Hypoglycemia is a significant barrier to treatment escalation by patients (pts) and physicians. Predisposing factors to hypoglycemia in the SAVOR TIMI 53 trial were studied.

**Materials and methods:** In the SAVOR TIMI 53 trial, 16,492 patients (pts) with type 2 diabetes (T2D) were randomized to receive either saxagliptin (SAXA) or placebo. Conventional therapy was adjusted by investigators to achieve HbA1c (A1c) target. Pts were followed for a median of 2.1 years. Patients were requested to record hypoglycemic episodes based on symptoms suggestive of hypoglycemia that recovered by carbohydrate ingestion and/or documentation of low blood glucose  $< 54$  mg/dl (minor) or the need for assistance from another person (major).

**Results:** 2,722 individuals (16.5% of trial participants) experienced at least one hypoglycemic episode and 312 (1.9%) experienced at least one major hypoglycemic episode. Hypoglycemic risk increased with age, disease duration, reduced GFR and increased albuminuria ( $p < 0.01$ ). Incidence of hypoglycemic events changed with baseline A1c: 12.8% at A1c  $< 7\%$ , 17.4% at A1c 7-8%, 20.5% at A1c 8-9% and 16.3% at A1c  $> 9\%$ . Pts on sulfonylurea (SU), long acting insulin (glargine or detemir), intermediate acting insulin, or short acting insulin in different combinations experienced increased hypoglycemic rates (14.9%, 20.2%, 23.9% and 29.3% respectively). Pts assigned to SAXA vs. placebo reported more hypoglycemic events (17.6% vs. 15.4%,  $p < 0.001$ ), including major hypoglycemic events (2.1% vs. 1.7%,  $p = 0.05$ ). Hypoglycemia requiring hospitalization was similar between groups (0.6% vs. 0.5%,  $p = 0.3$ ). Higher rates of hypoglycemia in SAXA vs. placebo arm were observed in SU treated pts (alone or in combination with other oral anti diabetic drugs) (17.2% vs. 12.5%,  $p < 0.001$ ), but not in insulin treated pts (27.1% vs. 26.7%,  $p = 0.8$ ). Patients treated with SU and baseline A1c  $< 7\%$  in SAXA arm had increased rates of major hypoglycemia (3.6% vs. 1.6%,  $p = 0.02$ ). Addition of SAXA vs. placebo to metformin alone, insulin alone or to SU in combination with insulin and/or metformin, resulted in more pts achieving A1c  $< 7\%$  at 1 year without experiencing hypoglycemia (figure).

**Conclusion:** The SAVOR TIMI 53 trial enables us to characterize the main predictors for development of hypoglycemia in T2D pts at high cardiovascular risk. Adding SAXA to metformin alone, insulin alone or to SU in combination, increases the likelihood of attaining a glycemc target of A1c  $< 7\%$  without excess hypoglycemic risk.

## 642

**A simple algorithm to predict the risk of hypoglycaemia in case of physical activity (PA) in patients with type 1 diabetes under pump therapy**G. Charpentier<sup>1</sup>, J. Boudoux<sup>2</sup>, M.-H. Petit<sup>3</sup>, A. Douidi<sup>3,1</sup>, C. Simon<sup>4</sup>, A. Pochat<sup>3,5</sup>, H. Laroye<sup>3</sup>, N. Brunel<sup>3</sup>, S. Franc<sup>3</sup>;<sup>1</sup>CHSE, Corbeil, France, <sup>2</sup>ENSIIE, <sup>3</sup>CERITD, Evry, <sup>4</sup>CHU of Lyon, <sup>5</sup>CHSE, Evry, France.

**Background and aims:** The aim of our study was to develop a model to predict the occurrence of hypoglycemic events from data of Continuous Monitoring Systems (CGMs), collected during physical activity (PA) sessions, in patients with type 1 diabetes (T1D), under pump therapy.

**Materials and methods:** Twenty adult patients with type 1 diabetes (11 males, mean age 45.3±11.9 yrs, HbA1c 7.9±0.9%, VO2max 33±10 ml/kg/min) performed 5 basal sessions (i.e. 3 hours after lunch) in a random order: 4 PA sessions (30-min cycling sessions on a constant-power electronic cycle ergometer) at 2 levels of PA and with 2 kinds of adjustment of the basal rate (BR) of their pump (50% VO2max with a BR reduction of 50 or 80%, 75% VO2max with again a BR reduction of 80 or 100%) and 1 rest session. Patients wore a CGMs from the beginning of each session and until the next morning. Classification methods were used, based on the patients' profile and the kind of sessions, to classify patients according to the occurrence or not of hypoglycemia. Several models of prediction were then elaborated. A number of explanatory variables had been previously selected and were used to compare the effectiveness of each model to predict the risk of hypoglycemia.

**Results:** From one model to another, variables that proved not to be essential or that were not available for the patient in a realistic context, were progressively removed. Finally, we considered variables available during the first ten minutes of a PA: weight, age, gender, VO2max, BR reduction, glucose level at the beginning of PA, glycemic gradient during the first 10 min of PA. Among these variables, we used statistical model selection methods in order to select the most relevant variables for the prediction of hypoglycemic events which were weight, and glycemic gradient during the first 10 min of PA reported to the initial glucose level (GG10). The value of the Area Under the Curve (AUC) of the ROC curve based on these variables was 0.74 which means a rather acceptable prediction but that can still be improved. We used a logistic regression for modeling the probability *p* of occurrence of hypoglycemic events and the estimated model is:  $\text{logit}(p) = -4.13 - 438.7 \times \text{GG10} + 0.5 \text{ weight (kg)}$ , where  $\text{logit}(p) = \log(p/(1-p))$  is an increasing function of *p*. The model, based on these 3 variables easy to collect in clinical practice, provides a prediction rate exceeding 80% (concordance between the predicted and the actual situation) with less than 20% of mismatch data.

**Conclusion:** A simple model of prediction mainly based on the CGM gradient of the first 10 min of a 30-min physical activity session, allows to predict the occurrence of hypoglycemia with a relative good efficiency. This kind of model that we can imagine coupled with CGMs to predict the risk of hypoglycemic event in clinical practice, (open-loop system), may, in an improved version, reveal to be of particular interest in the development of closed-loop systems.

**The early warning indicators for nocturnal hypoglycaemia in type 2 diabetes**

Y. Wang, H. Su, Y.M. Xue;

Department of Endocrine and Metabolism,

The First People's Hospital of Yunnan Province, Kunming City, China.

**Background and aims:** The existing research on hypoglycaemia is largely done in special environments such as use of a specific medicine or focusing on a certain age period, its practicality in broad clinical contexts is thus limited. Moreover, most causes of hypoglycaemia like endogenous insulin inadequacy and the diabetic process cannot be altered. This study is to explore quantitative indicators warning of nocturnal hypoglycaemia by using Continuing Glucose Monitoring System (CGMS) on a large sample in routine clinical environments to seek some basis for preventing hypoglycaemia in clinics.

**Materials and methods:** First, 1147 patients (male 723 and female 424) of type 2 diabetes were sampled, whose ages being 59.21±11.31(14~91 years old) and Mean Blood Glucose (MBG) being 7.41±2.98 mmol/L. Those

whose BGs turned stable after treatment, except those who took medicine like hypnotics or sedative before sleep, were monitored for 65 to 82 hours by CGMS. Second, another 479 patients whose BG 3 hours after supper was ≤ 4.7mmol/L were sampled and randomly divided into the intervention group and the non-intervention group, measures like insulin dosage reduction before sleep and/or eating some 50 to 100 grams of protein or carbohydrate were adopted for the intervention group. Statistical analyses were made by correlation regression (with *r* below representing correlation coefficient), relative risk (RR) calculation and Chi-square test whereas comparison between the two groups was made by *t* test.

**Results:** The occurrence rate of hypoglycaemia, asymptomatic hypoglycaemia and nocturnal hypoglycaemia is respectively 37.23% or 427 cases, 22.75% or 261 cases, and 18.31% or 210 cases. Among 965 person-times showing hypoglycaemia, 60.8% or 697 person-times were asymptomatic whereas 49.2% or 470 person-times showed nocturnal hypoglycaemia. 1. MBGs are correlated negatively with incidence rates of hypoglycemia on an exponential curve ( $r = -0.995$ ,  $Y_e = 10^{2.550 - 0.139X}$ ) and negatively with incidence rates of nocturnal hypoglycaemia ( $r = -0.953$ ,  $Y_e = 10^{4.135 - 3.445 \lg X}$ ) and of asymptomatic hypoglycaemia ( $r = -0.963$ ,  $P < 0.01$ ,  $Y_e = 10^{3.663 - 2.718 \lg X}$ ) on a hyperbolic curve. 2. The risk occurrence of nocturnal hypoglycaemia during 22:00~2:00 is 1.72 times that during 2:00~6:00 (RR=1.72,  $\chi^2 = 31.667$ ,  $P < 0.01$ ). 3. BGs 3 hours after supper are negatively correlated with incidence rates of nocturnal hypoglycaemia on an exponential curve ( $r = -0.955$ ,  $Y_e = 10^{3.450 - 2.627 \lg X}$ ), with the limit value of BGs 3 hours after supper for 50% of nocturnal hypoglycaemia incidence rates being 4.7mmol/L. 4. For the 479 patients, no significant difference is found between MBGs of the two groups (8.29±1.98 vs 8.53±2.24,  $t = 1.182$ ,  $P > 0.05$ ). The incidence rate of the intervention group is significantly reduced in contrast to that of the non-intervention group (9.67% vs 16.76%,  $\chi^2 = 8.79$ ,  $P < 0.01$ ), with RR=1.7, relative efficiency= 42.43%,  $\chi^2 = 6.16$ ,  $P < 0.05$ .

**Conclusion:** 1. Occurrence rates of nocturnal hypoglycaemia in routine clinical environments are high. 2. 22:00~2:00 is the peak period when nocturnal hypoglycaemia occurs. 3. The BG 3 hours after supper being ≤ 4.7mmol/L can be used as a quantitative indicator warning of the occurrence of nocturnal hypoglycaemia. 4. The occurrence of hypoglycaemia in the non-intervention group was 1.7 times that in the intervention group; with interventions to patients whose BG 3 hours after supper were ≤ 4.7mmol/L, 40% of them were protected from nocturnal hypoglycaemia.

## 644

**The impact of nocturnal hypoglycaemia on sleep in subjects with type 2 diabetes**S. Madsbad<sup>1</sup>, N.R. Jørgensen<sup>2</sup>, R. Rabøl<sup>3</sup>, P.-L. Chu<sup>4</sup>, K. Stender-Petersen<sup>3</sup>, P. Jennum<sup>5</sup>;<sup>1</sup>Department of Endocrinology, Hvidovre Hospital, <sup>2</sup>Department of Diagnostics, Copenhagen University Hospital Glostrup, <sup>3</sup>Novo Nordisk A/S, Søborg, Denmark, <sup>4</sup>Novo Nordisk Inc., Plainsboro, USA, <sup>5</sup>Danish Center for Sleep Medicine, Copenhagen University Hospital Glostrup, Denmark.

**Background and aims:** Nocturnal hypoglycaemia is a major barrier in achieving optimal glycaemic control in patients with diabetes. Knowledge about the consequences of nocturnal hypoglycaemia on sleep is limited. The aim of the present trial was to investigate the impact of nocturnal hypoglycaemia on sleep pattern.

**Materials and methods:** In this randomised, single-blinded, two-period, cross-over trial, 26 subjects with type 2 diabetes attended two experimental night visits (one normoglycaemic and one hypoglycaemic) in randomised order to assess the impact of nocturnal hypoglycaemia on sleep (using polysomnography) and on hormonal responses. Plasma glucose (PG) levels were controlled on the experimental nights by hyperinsulinaemic glucose clamping. On the hypoglycaemic night, hypoglycaemia was induced when subjects had reached sleep stage N2 or deeper by turning off the glucose infusion (PG target: 2.7-2.8 mmol/L) for approximately 15 min, after which subjects were brought back to normoglycaemia. On the normoglycaemic night, PG was maintained at 5-7 mmol/L throughout the night.

**Results:** There was no difference between the hypoglycaemic night and the normoglycaemic night, in either the number of EEG-identified arousals or awakenings in the first 4 hours of sleep (0-4h after reaching sleep stage N2). During the last 4 hours (4-8h) and during the entire night (0-8h), the number of awakenings was significantly lower ( $p < 0.05$ ) on the hypoglycaemic night than on the normoglycaemic night (observed geometric means 4-8 h: 10 vs. 14 awakenings and 0-8h: 25 vs. 30 awakenings). Total sleep time tended to be longer on the hypoglycaemic night (observed means: 366 vs. 349 min,  $p = \text{NS}$ ).

Statistically significantly higher hormonal counter-regulatory responses (adrenaline, growth hormone and cortisol) to hypoglycaemia were observed as compared with normoglycaemic night.

**Conclusion:** Nocturnal hypoglycaemia in patients with type 2 diabetes caused a decrease in awakening response following the event. These findings underscore the risks associated with nocturnal hypoglycaemia since these events potentially affect the subject's ability to wake up and respond adequately to hypoglycaemia.

## 645

### Impact of nocturnal hypoglycaemia on the risk of hypoglycaemia the next day

G. Reihill, L. Green, S.A. Amiel, P. Choudhary;  
Diabetes Research Group, King's College London, UK.

**Background and aims:** In people with type 1 diabetes [T1D], nocturnal hypoglycaemia (NH) is reported to occur on about 30% of nights. Fear of [NH] can lead to suboptimal glucose control. Antecedent hypoglycaemia, including specifically at night, blunts symptomatic and hormonal responses to subsequent hypoglycaemia, which may lead to a vicious cycle of recurrent hypoglycaemia, ultimately in some patients leading to impaired awareness of hypoglycaemia [IAH]. We aimed to study the impact of biochemical NH on the risk of subsequent daytime hypoglycaemia [DH], and conversely also the impact of antecedent DH on the risk of subsequent NH in adults with T1D using continuous glucose monitoring [CGM].

**Materials and methods:** 172 consecutive CGM traces obtained using Medtronic iPRO2 met the following criteria: 48 hours of CGM data starting from midnight,  $\geq 3$  valid calibrations/24 hours, mean absolute error  $< 1.8$ . Patient inclusion criteria included: clinical diagnosis of T1D and not pregnant. We defined moderate CGM hypoglycaemia as sensor glucose  $< 3.9$  mM and severe CGM hypo as sensor glucose  $\leq 2.2$  mM for at least 20 minutes. Nocturnal was defined as 24:00–06:00 hrs.

**Results:** The cohort providing data was 40% male, mean age 44.75 ( $\pm 14.54$ ) yrs; duration of T1D 18.95 ( $\pm 13.821$ ) yrs, mean HbA1c 8.1% ( $\pm 1.30$ ) [ $65 \pm 10.2$  mmol/mol]. 29.8% used continuous subcutaneous insulin infusion [CSII]; 41.0% had IAH. 20.9% of traces had at least one episode of NH  $< 3.9$  mM and 4.7% had at least one episode of NH  $\leq 2.2$  mM in the 48 hrs. Risk of mild DH  $< 3.9$  mM following NH  $< 3.9$  mM was 48.7% compared to 43% after no NH  $< 3.9$  mM [ $\chi^2 0.537$ ] giving a relative risk [RR] of 1.13 [95%CI 0.77–1.66;  $p=0.124$ ]. However, 25% of those with severe NH  $\leq 2.2$  mM had a subsequent DH  $\leq 2.2$  mM, compared to 6.7% risk of severe DH  $\leq 2.2$  mM after no NH  $\leq 2.2$  mM [ $\chi^2 0.056$ ] giving a RR of 3.72 [CI 0.99–14.08;  $p=0.052$ ]. Conversely, risk of mild NH  $< 3.9$  mM after DH  $< 3.9$  mM was 30.3% vs. 12.5% if no DH  $< 3.9$  mM [ $\chi^2 0.004$ ] giving a relative risk of 2.42 [95%CI 1.29–4.54;  $p=0.006$ ]. Risk of severe NH  $\leq 2.2$  mM after DH  $\leq 2.2$  mM was 6.6% vs. 1.8% if no DH [ $\chi^2 0.001$ ] giving a RR of 7.34 [CI 1.97–27.33;  $p=0.003$ ]. Frequency of mild NH  $< 3.9$  mM was significantly lower in CSII vs. MDI (10% vs. 25%,  $p=0.047$ ), with less time hypo [14 vs. 52 mins/night];  $p=0.035$  mins]. There were no significant differences between number or duration of mild DH episodes between MDI and CSII, or in number or duration of severe DH or NH  $\leq 2.2$  mM. Frequency of NH was not significantly different between normal awareness and IAH [NH  $< 3.9$  mM 0.29 vs. 0.25  $p=0.620$ ; NH  $\leq 2.2$  mM [0.05 vs. 0.06  $p=0.824$ ]. Duration of NH was also not significantly different; NH  $< 3.9$  mM [52 vs. 40 mins;  $p=0.504$ ], NH  $\leq 2.2$  mM [5 vs. 5 mins;  $p=0.936$ ].

**Conclusion:** Mild NH does not increase the risk of mild hypoglycaemia the following day, with a trend to increased risk of DH after more severe NH. However, both mild and severe DH significantly increases the risk of NH. The lack of difference in hypoglycaemia rate using CGM between those with impaired awareness and normal awareness needs further research. Our data also added to the body of evidence that CSII use is associated with significantly reduced frequency and duration of NH. Meanwhile, patients can be advised to reduce overnight insulin following episodes of daytime hypoglycaemia.

## 646

### Severe hypoglycemia during therapy with sulfonylurea in patients with type 2 diabetes (T2D) in Germany/Austria: event rate and identification of patients at risk

N. Schloot<sup>1,2</sup>, A. Haupt<sup>3</sup>, M. Schütt<sup>3</sup>, K. Badenhoop<sup>4</sup>, C. Nicolay<sup>5</sup>, M. Reaney<sup>6,7</sup>, K. Fink<sup>8</sup>, R. Holl<sup>8</sup>, for the German BMBF Competence Net Diabetes Mellitus;

<sup>1</sup>Medical BU Diabetes, Lilly Deutschland GmbH, Bad Homburg, <sup>2</sup>Institute for Clinical Diabetology, German Diabetes Center, Heinrich Heine University, Düsseldorf, <sup>3</sup>Department of Internal Medicine <sup>1</sup>, University of Lübeck, <sup>4</sup>Internal Medicine <sup>1</sup>, Division of Endocrinology and Metabolism, Goethe University Hospital, Frankfurt am Main, <sup>5</sup>Lilly Deutschland GmbH, Bad Homburg, Germany, <sup>6</sup>Lilly Research Centre, Earl Wood Manor, Windlesham, Surrey, <sup>7</sup>eResearchTechnology Limited (ERT), Peterborough, UK, <sup>8</sup>Institute for Epidemiology and Medical Biometry, Ulm University, Germany.

**Background and aims:** We investigated the rate of severe hypoglycemia and confounding factors in T2D patients treated with sulfonylurea (SU) in the German/Austrian DPV-Wiss-database cohort.

**Materials and methods:** Data from 29,485 SU-treated patients were analyzed (mean (SD) age 69.5(11.5) years, diabetes duration 9.7 (7.6) years, with/without antidiabetic co-medication). Primary objective was to estimate the event rate of severe hypoglycemia (defined as requirement for help +/- coma, or emergency hospitalization due to hypoglycemia). Secondary objective was the identification of confounding risk factors for hypoglycemia through group comparison and hierarchical negative binomial regression.

**Results:** Severe hypoglycemic events were reported in 826 (2.8%) of all SU-treated patients;  $n=531$  (1.8%) suffered from coma,  $n=501$  (1.7%) were hospitalized at least once. Event rates/year [95%CI] were 0.039 [0.037;0.042], 0.019 [0.018;0.021] and 0.016 [0.015;0.018]. Unadjusted severe hypoglycemia rates for different treatment groups were 0.074 (SU + insulin), 0.038 (SU + insulin + other oral antidiabetic agents [OaD]), 0.027 (SU + other OAD), 0.042 (SU only). Patients with severe hypoglycemia were older ( $p<0.0001$ ) and had longer diabetes duration ( $p=0.0195$ ). In regression analysis, severe hypoglycemia was associated with lower HbA1c and with the frequency of mild hypoglycemic events (all  $p<0.0001$ ). Lower eGFR was associated with an increased rate of severe hypoglycemia ( $>60$  ml/min: 3.9% of all patients with SU; 30–60 ml/min: 4.8%;  $\leq 30$  ml/min: 7.7%). Indirect measures of insulin resistance such as increased BMI, plasma triglycerides and participation in educational diabetes program were associated with less frequent severe hypoglycemia (all  $p\leq 0.0002$ ).

**Conclusion:** Our analysis of real-life data showed a higher risk for severe hypoglycemia in older patients, in patients reporting more non-severe hypoglycemia and in patients with decreased eGFR, suggesting that treatment with SU in those patients should be considered with caution.

## 647

### High prevalence of silent hypoglycaemic episodes among patients with well-controlled type 2 diabetes mellitus treated by sulfonylureas

G. Simonyi<sup>1</sup>, R. Gasparics<sup>1</sup>, Á. Hegedűs<sup>1</sup>, G. Csitári<sup>1</sup>, R. Kollár<sup>1</sup>, P. Kempler<sup>2</sup>;  
<sup>1</sup>Metabolic Center, St Imre Teaching Hospital, <sup>2</sup>1st Department of Internal Medicine, Semmelweis University, Budapest, Hungary.

**Background and aims:** Hypoglycaemia is a well known cardiovascular risk factor. The aim of this study was to determine the prevalence of silent hypoglycaemic episodes among patients with well-controlled type 2 diabetes treated with sulfonylurea.

**Materials and methods:** 10 type 2 diabetic patients (7 men, 3 women) with HbA1c  $\leq 7\%$  treated with sulfonylurea and/or metformin without symptoms of hypoglycaemia during the past two years were included in the study (mean age:  $71 \pm 10$ , mean duration of diabetes mellitus  $11 \pm 9$  years, mean HbA1c:  $4.9 \pm 0.9\%$ ). A 120-h long (5 days) glucose monitoring was performed using a Continuous Glucose Monitor System (CGMS) device (Medtronic iPro2<sup>®</sup>). Moreover, patients were asked to record four self-monitored capillary blood glucose levels each day for calibration of the monitor and also to record meal times, exercise and symptoms of hypoglycaemias. According to EASD/ADA recommendation a glucose concentration of  $\leq 3.9$  mmol/l can be used as a cut-off value in the classification of hypoglycaemia. The number of hypoglycaemic events  $\leq 3.9$  mmol/l and, additionally, the number of hypoglycaemic

events <3.1 mmol/l were determined. An event was defined as a glucose value that persisted for at least 15 minutes with or without symptoms.

**Results:** Ten patients were each monitored for an average of  $5757.0 \pm 1192$  min. The mean interstitial glucose (IG) concentration was  $6.10 \pm 0.56$  mmol/l. The minimum IG was 2.2 mmol/l and maximal IG concentration was 13.3 mmol/l. 7/10 patients had a total number of 30 silent hypoglycaemic episodes (interstitial glucose  $\leq 3.9$  mmol/l), mean:  $4.6 \pm 2.6$  episodes per patients. The total duration of these hypoglycemic episodes was  $374.5 \pm 462.97$  min. 5/10 patients had hypoglycaemic episodes of interstitial glucose  $\leq 3.1$  mmol/l. The numbers of episodes were  $2.0 \pm 0.7$  per patient. The total number of episodes was 9. The total duration of hypoglycemic episodes with glucose values  $\leq 3.1$  mmol/l was  $96.0 \pm 156.55$  min. No symptoms of hypoglycemia were recorded by any patient in their daily diaries. CGMS measurements were generally well tolerated.

**Conclusion:** Our data suggest that silent hypoglycemia is quite common in well-controlled patients with type 2 diabetes treated with a sulfonylurea with or without metformin. It should be noted that glycemic control of our patients was overly normal. Nonetheless, as a key finding, in our small cohort of patients all episodes of hypoglycaemia were silent. CGMS might serve as a useful clinical tool to discover silent hypoglycemia.

## 648

**In case of physical activity performed just after lunch, what is the best option to reduce the risk of hypoglycaemia in case of pump therapy: basal rate or bolus reduction?**

S. Franc<sup>1</sup>, M.-H. Petit<sup>2</sup>, A. Daoudi<sup>2,1</sup>, A. Pochat<sup>2,1</sup>, C. Simon<sup>3</sup>, H. Laroye<sup>2</sup>, L. Boursiquot<sup>4</sup>, E. Pussard<sup>4</sup>, C. Petit<sup>2</sup>, P. Dupont<sup>4</sup>, F. Koukoui<sup>1</sup>, G. Charpentier<sup>1</sup>;

<sup>1</sup>CHSF, Corbeil, <sup>2</sup>CERITD, Evry, <sup>3</sup>CHU of Lyon,

<sup>4</sup>CHU of Bicêtre, Kremlin-Bicêtre, France.

**Background and aims:** In T1 diabetic subjects on pump therapy, there is no consensus regarding the adjustment of insulin doses in the event of physical activity (PA) just after a meal. The aim of our study was to determine what was the best attitude in such a situation between reducing the basal rate (BR) of the pump (BRR) or the prandial bolus (PBR) to limit the risk of hypoglycemia.

**Materials and methods:** 20 patients (11 men, BMI  $24 \pm 5$  kg/m<sup>2</sup>, age  $45 \pm 12$  yrs, HbA1c  $7.9 \pm 0.7\%$ , diabetes duration  $17.6 \pm 10$  yrs, on pump therapy for 5 yrs, practicing 4.3 hrs/wk of PA) performed 2 physical activity sessions (30-min cycling sessions) 90 min after lunch in a random order, at 50%VO<sub>2</sub>max, one with bolus reduction (PBR) of 30/50%, the other one with basal rate (BRR) reduction of 50/80% (during PA+2hrs). Blood glucose (BG) levels were measured during the exercise period and over the following 2hrs. Patients wore an iPro2 device from lunchtime until breakfast the next day. We focused on the occurrence of hypoglycemic events recorded on the CGM system.

**Results:** CGM level at lunchtime did not differ between both groups but was higher after lunch, in case of PBR vs BRR, as was glucose level just before exercising [ $221 \pm 62$  vs  $171 \pm 59$  mg/dl]. The mean decrease in glucose value was similar in PBR vs BRR (BG =  $-71$  vs  $-77$  mg/dl, CGM =  $42.1$  vs  $34.4$ ). After the initial drop, the average glucose level remained stable during the afternoon, at a higher level in case of PBR vs BRR. Total glucose AUC and time spent in  $[70;180$  mg/dl] did not significantly differ in both cases but less time was spent  $>180$  mg/dL ( $p=0.057$ ) in case of PBR compared to BRR. Only 1 hypoglycemia occurred during PA (BRR). During the afternoon, there was a trend towards less hypoglycemic events in case of PBR vs BRR (3 events in 3 patients vs 10 in 6,  $p=0.07$ ) with a mean number of events 3.5 times lower ( $0.16 \pm 0.37$  vs  $0.56 \pm 0.92$ ). There was no significant hyperglycemic rebound before dinner in both cases and no significant difference in the CGM level at bedtime ( $176 \pm 79$  mg/dl vs  $160 \pm 85$ ,  $p=NS$ ). The average glucose level remained stable and at a similar level at night in both cases. There was no difference in the timing and in the level of nocturnal nadir between PBR and BRR [ $77 \pm 35$  vs  $77 \pm 34$  mg/dL,  $p=NS$ ]; no differences were observed in the total AUC, the time spent in or out the range  $[70;180]$  or  $[80;140]$ . At night, the number of hypoglycemic events did not differ in case of PBR vs BRR (7 events in 5 patients vs 10 events in 7 patients,  $p=0.39$ ) and the mean number did not significantly differ ( $0.37 \pm 0.68$  vs  $0.56 \pm 0.86$ ). There was no hyperglycemic rebound the next morning, even in case of hypoglycemia at night.

**Conclusion:** In case of PA 90 min after a meal, PBR led to a higher sustainable glucose level in the afternoon than in case of BRR, limiting therefore the risk of hypoglycemia. PBR can thus be considered as the security option while BRR would lead to a lower glucose level and potentially to an increased

risk of hypoglycemia. However, in both cases the practice of PA will first lead to an initial drop in glucose level of around 70 mg/dL. If a BRR strategy is chosen, then the BRR should be anticipated at least 30 min earlier to limit the risk of hypoglycemia.

**Effects of automatic insulin pump interruption and bedtime glucose levels on nocturnal hypoglycaemic events in the ASPIRE In-Home Study**  
D. Klonoff<sup>1</sup>, A. Ahmann<sup>2</sup>, S. Garg<sup>3</sup>, R. Slover<sup>3</sup>, T. Bailey<sup>4</sup>, B. Bode<sup>5</sup>, J. Thrasher<sup>6</sup>, R. Brazg<sup>7</sup>, F. Schwartz<sup>8</sup>, M. Mao<sup>9</sup>, R. Weiss<sup>10</sup>, ASPIRE In-Home Study Group;

<sup>1</sup>Mills-Peninsula Health Services, San Mateo, <sup>2</sup>Oregon Health and Sciences University, Portland, <sup>3</sup>University of Colorado Denver, Aurora, <sup>4</sup>AMCR Institute, Inc., Escondido, <sup>5</sup>Atlanta Diabetes Associates, <sup>6</sup>Arkansas Diabetes and Endocrinology Center, Little Rock, <sup>7</sup>Rainier Clinical Research Center, Renton, <sup>8</sup>Ohio University, Athens, <sup>9</sup>Medtronic Diabetes, Northridge, USA, <sup>10</sup>Human Metabolism and Nutrition, Hebrew University, Jerusalem, Israel.

**Background and aims:** The ASPIRE In-Home Study was designed to evaluate the Threshold Suspend (TS) feature of sensor-augmented pump (SAP) therapy, which automatically interrupts insulin delivery at a pre-set sensor glucose (SG) threshold. We evaluated the risk of nocturnal hypoglycemia (NH) with regard to bedtime sensor glucose (SG) values and use of the TS feature.

**Materials and methods:** Nocturnal hypoglycemia (NH) was defined as an event lasting  $>20$  min with SG values  $\leq 65$  mg/dL that started between 10:00 PM and 8:00 AM. Subjects with type 1 diabetes with  $\geq 2$  NH episodes during a 2-week run-in phase were eligible. A total of 247 patients were randomized to SAP therapy with the TS feature (TS group,  $n=121$ ) or without the TS feature (Control group,  $n=126$ ). During the 6-month study phase, each patient-night was classified according to the patient's treatment group assignment and the 10:00 PM ("bedtime") SG value. Four categories of bedtime SG values were defined as  $<100$  mg/dL, 100-150 mg/dL, 150-200 mg/dL, and  $>200$  mg/dL. The percentage of nights with a NH event was calculated for the TS and Control groups within each bedtime SG value category.

**Results:** The figure shows the percentage of nights with a NH event according to treatment group and bedtime SG value, and the number of patient-nights in each SG category. Higher bedtime SG values tended to decrease the risk of NH in the Control group ( $p<0.001$  for trend) and in the TS group ( $p=0.01$  for trend). Subjects in the TS group who had bedtime SG values  $<100$  mg/dL, 100-150 mg/dL, or 150-200 mg/dL were significantly less likely to experience a hypoglycemic event later that night than subjects in the Control group with similar bedtime SG values ( $p<0.001$  for bedtime SG values  $<150$  mg/dL;  $p=0.02$  for bedtime SG values 150-200 mg/dL). For bedtime SG values  $<100$  mg/dL, the TS group's percentage of nights with a hypoglycemic event was 31% less than in the Control group, and 25% less for bedtime SG values of 100-150 mg/dL. When the bedtime SG value was  $>200$  mg/dL, the difference between the groups was not significant.

**Conclusion:** In subjects with type 1 diabetes and bedtime SG values <200 mg/dL, use of the TS feature was associated with a lower risk of nocturnal hypoglycemic events.

### Association of low normal TSH levels and increment of TSH levels with the development of metabolic syndrome; a 6-year retrospective, longitudinal study

S. Oh, J. Jun, S.-M. Jin, M.-K. Lee, M.-S. Lee, J. Kim, K. Hur; Samsung Medical Center, Seoul, Republic of Korea.

**Background and aims:** Many cross-sectional studies have showed an increased association with metabolic syndrome (MetS) in the subjects with higher TSH levels in subjects with euthyroid (0.3-6.5mU/l) and subclinical hypothyroid (6.5-10mU/l). However, little is known about the relationships between TSH levels and development of MetS in a longitudinal study. We investigated the associations of baseline TSH levels or increment of TSH levels with new-onset MetS in subjects with euthyroid and subclinical hypothyroid.

**Materials and methods:** We retrospectively analyzed the medical records of 23717 subjects (13989 men and 9728 women, age 18 to 89 years) who underwent health screening annually or biennially from 2006 to 2012 at our Medical Center (Seoul, Republic of Korea). After exclusion of the subjects with abnormal value of T4 or FT4 and subjects with MetS at baseline, we selected 19823 subjects (13989 men and 9728 women). We divided the subjects into 3 groups by baseline TSH levels as follows; low-normal TSH group (0.3-2.5mU/l), high-normal TSH group (2.5-6.5mU/l) and subclinical hypothyroid TSH group (6.5-10mU/l). We also divided the subjects into two groups by changing TSH levels from baseline to last visit (increasing TSH group; the ratio of last TSH/initial TSH  $\geq$  1, decreasing TSH group; the ratio of last TSH/initial TSH < 1).

**Results:** By using a Cox proportional hazard models, the groups by baseline TSH level and the groups by a change of TSH levels, were analyzed for time to the development of MetS after adjustment of age, smoking, body mass index, systolic and diastolic blood pressure, lipid profile, fasting blood glucose and hemoglobin A1c. Compared to high-normal TSH group and subclinical hypothyroid group, the prevalence of new-onset MetS was higher among subjects with low-normal TSH group after adjustment ( $p < 0.001$ ) in men, but not women. Compared to decreasing TSH group, increasing TSH group had an increased hazard ratio of 1.26 (95% confidence interval, 1.19-1.35,  $p < 0.001$ ) in men and 1.23 (95% confidence interval, 1.09-1.37,  $p < 0.001$ ) in women.

**Conclusion:** In contrast to the cross section study, the low-normal TSH levels (0.3-2.5mU/l) may be a risk for development of MetS in men, and increment of TSH levels also could be an independent risk for new-onset MetS in men and women.

### Glucose intolerance and diabetes in patients with new onset Graves' hyperthyroidism

X. Li, Y. Ling, Z. Lu, X. Gao;

Department of Endocrinology and Metabolism, Zhongshan Hospital, Fudan University, Shanghai, China.

**Background and aims:** Overt thyrotoxicosis is associated with reduced insulin sensitivity (IS) and beta cell function, the prevalence and characteristics of diabetes and impaired glucose regulation (IGR) in patients with Graves' hyperthyroidism is still unknown in Chinese. This study is to evaluate the glucose homeostasis in patients with Graves' hyperthyroidism and the associations with thyrotropin levels.

**Materials and methods:** From 2012 to 2014, a total of 278 patients with new onset Graves' hyperthyroidism without anti-thyroid therapy were enrolled from the department of endocrinology of our university. The oral glucose tolerance test (OGTT) was performed to measure the levels of fasting and 2-hour postprandial blood glucose (FBG and 2hPG) levels. In addition, the glycosylated hemoglobin (HbA1c) and thyroid hormones levels were also measured. Analyses were performed with SPSS software version 13.0.

**Results:** Among the 278 patients with Graves' hyperthyroidism, 82 cases is male (29.5%), and 196 cases were female (70.5%), with an average age of 45.4 years. There were 148 cases (53.2%) with normal glucose tolerance (NGT), 88 cases (31.7%) with IGR and 42 cases (15.1%) with diabetes. The T3(P < 0.05) and FT3(P < 0.01) levels were significantly higher in patients with diabetes than with NGT, after adjusting for sex, age and BMI. By the tertile groups

of fT3, the levels of FBG ( $P < 0.05$ ), 2hPG ( $P < 0.01$ ), HbA1c ( $P < 0.05$ ) in the 3rd tertile group were significantly higher than the 1st tertile group, after sex, age and BMI were adjusted. The levels of FBG ( $r = 0.24, P = 0.05$ ) were positively correlated with serum fT3 levels, and 2hPG were positively correlated with serum T3, T4, fT3 levels ( $r = 0.30, P = 0.01$ ;  $r = 0.28, P = 0.02$ ;  $r = 0.30, P = 0.02$ , respectively). Multivariate linear regression model showed that only BMI was independently associated with FBG, but BMI and fT3 were both independently associated with 2hPG in these patients. Logistic regression model showed that BMI (OR = 1.26, 95% CI 1.00–1.60,  $P = 0.05$ ), fT3 (OR = 1.53, 95% CI 1.06–2.21,  $P = 0.03$ ) were the independent risk factor of diabetes in patients with Graves' hyperthyroidism.

**Conclusion:** The patients with Graves' hyperthyroidism had a high percentage of abnormal glucose homeostasis, including IGR and diabetes. Thyroid hormone was closely related to glucose homeostasis, BMI and fT3 were the independent risk factor for 2hPG and diabetes in the patients with Graves' hyperthyroidism.

## 652

### Association between lower normal free thyroxine concentrations and obesity phenotype in healthy euthyroid subjects

E. Mo, E. Kim, J. Shin, S. Moon, J.-H. Han, Y.-B. Ahn, H.-S. Son; The Catholic University of Korea, Seoul, Republic of Korea.

**Background and aims:** We investigated whether thyroid function could identify obesity phenotype in euthyroid subjects.

**Materials and methods:** A cross-sectional analysis was performed among non-diabetic, euthyroid subjects. We stratified subjects into four groups by BMI and insulin resistance (IR), defined by a HOMA-IR in the top quartile.

**Results:** Of 6241 subjects, 33.8% were overweight or obese (OW/OB) and 66.2% were normal weight (NW). Free thyroxine (FT4) levels were negatively associated with body mass index, waist circumference, triglyceride, c-reactive protein and HOMA-IR and positively with high-density lipoprotein cholesterol in both genders. In multivariate regression analysis, FT4 level, a continuous measurement, was negatively correlated with HOMA-IR ( $\beta = -0.155$ ,  $P < 0.001$  in men;  $\beta = -0.175$ ,  $P < 0.001$  in women). After adjustment for age, sex, metabolic and life style factors, subjects in the lowest FT4 quartile had an odds ratio (OR) for IR of 1.99 (95% confidence interval 1.61–2.46), as compared to those in the highest quartile. The association between low FT4 and IR remained significant in both NW and OW/OB subgroups.

**Conclusion:** Low normal FT4 levels were independently related to IR in NW and OW/OB euthyroid subjects. Further studies are needed to investigate the mechanisms by which low FT4 levels are linked to high IR in euthyroid ranges.

## 653

### Exogenous glucagon decreases IGF-I bioactivity in humans, independently of insulin levels, by modulating its binding proteins

Z. Sarem<sup>1,2</sup>, C. Bumke-Vogt<sup>2</sup>, B. Assefa<sup>1,3</sup>, M.O. Weickert<sup>4,5</sup>, A. Adamidou<sup>1</sup>, V. Bähr<sup>1</sup>, J. Frystyk<sup>6</sup>, M. Möhlig<sup>1</sup>, J. Spranger<sup>1,3</sup>, A.F.H. Pfeiffer<sup>1,2</sup>, A.M. Arafat<sup>1,2</sup>;

<sup>1</sup>Department of Endocrinology, Diabetes and Nutrition, Charité-University Medicine Berlin, <sup>2</sup>Department of Clinical Nutrition, German Institute of Human Nutrition, Potsdam-Rehbruecke, Nuthetal, <sup>3</sup>Department of Endocrinology, Diabetes and Nutrition at the Center for Cardiovascular Research (CCR), Charité-University Medicine Berlin, Germany,

<sup>4</sup>Warwickshire Institute for the Study of Diabetes, Endocrinology and Metabolism, University Hospitals Coventry and Warwickshire NHS Trust, Coventry, <sup>5</sup>Division of Metabolic & vascular Health, Warwick Medical School, University of Warwick, Coventry, UK, <sup>6</sup>Medical Research Laboratory, Institute of Clinical Medicine, Faculty of Health, Aarhus University, Denmark.

**Background and aims:** The mechanisms underlying glucagon-induced growth hormone (GH) release are unclear. Our goal was to identify the role of glucagon-induced changes in IGF-I bioactivity as a possible mechanism, excluding changes in insulin as known major confounder.

**Materials and methods:** In our double-blind placebo-controlled study, we investigated changes in GH, IGF binding proteins (IGFBPs) and IGF-I bioactivity, determined using the cell-based KIRA-method, after intramuscular glucagon administration in 13 patients with type-1 diabetes mellitus (T1DM; 6 males; [BMI]:  $24.8 \pm 0.95$  kg/m<sup>2</sup>), 11 obese participants (OP; 5/6;  $34.4 \pm 1.7$

kg/m<sup>2</sup>), and 13 healthy lean participants (LP; 6/7;  $21.7 \pm 0.6$  kg/m<sup>2</sup>). In vitro, the impact of glucagon on forkhead box transcription factor O1 (FOXO1), an important modulator of IGFBP-1, was further investigated using human osteosarcoma cells (U-2OS) that were transfected with pEGFP-FOXO1 and visualized by fluorescence microscopy.

**Results:** Glucagon significantly decreased IGF-I bioactivity in all groups ( $P < 0.01$ ), despite unchanged total IGF-I and IGFBP-3 levels, whereas significant increases in IGFBP-1 and IGFBP-2 were observed ( $P < 0.01$ ). In contrast to the transient increase in insulin levels in OP and LP, no change was observed in T1DM. As expected, glucagon induced a surge in GH in all subjects. In vitro, significant nuclear FOXO1 translocation was induced dose-dependently by glucagon.

**Conclusion:** Glucagon decreased IGF-I bioactivity in humans independently of endogenous insulin levels, likely through modulation of IGFBP-1 and-2 levels. The increased FOXO1 nuclear translocation may explain glucagon-mediated up-regulation of IGFBP-1. The glucagon-induced reduction in IGF-I bioactivity may represent a novel mechanism, underlying the impact of glucagon on GH secretion.

### Elevated level of serum leptin is associated with reduced insulin secretion in Bangladeshi impaired fasting glucose subjects

M. Hasan, I.A. Hossain, L. Ali; Biochemistry and Cell Biology, Bangladesh University of Health Sciences (BUHS), Dhaka, Bangladesh.

**Background and aims:** Leptin is an important adipose tissue-derived hormone that has been shown to be involved in pathophysiological mechanisms related to cardiovascular disease and diabetes. However, few studies have examined the association between serum leptin and reduced insulin secretion in IFG subjects. Therefore, we explored the association of serum leptin with beta cell dysfunction in IFG subjects.

**Materials and methods:** Under a cross-sectional analytical design a total of 65 participants, aged 35–68 years consisting of 47.7% ( $n = 31$ ) IFG (21 male & 10 female) and 52.3% ( $n = 34$ ) healthy Controls (19 male & 15 female) were recruited for the study. Each participant underwent an oral glucose tolerance test and completed a questionnaire. Anthropometric indices were recorded and serum samples were collected for measurement. Serum leptin and insulin were measured by enzyme immunoassay. Insulin secretory function (HOMA%B) and insulin sensitivity (HOMA%S) were calculated from fasting serum glucose and fasting serum insulin values by Homeostasis Model Assessment (HOMA) using HOMA-CIGMA software.

**Results:** Serum leptin levels [Median (range) 16.43 (2.66–42.17) vs. 6.39 (3.03–29.54) (ng/ml),  $p < 0.001$ ] was significantly higher in IFG group compared to the Control. HOMA%B [97 (51–163) vs. 142 (61–375),  $p < 0.001$ ] was significantly lower in IFG group compared to the Control. On Pearson correlation analysis leptin showed significant positive correlation with gender ( $r = 0.417$ ,  $p = 0.019$ ) and significant negative correlation with age ( $r = -0.545$ ,  $p = 0.002$ ) and HOMA%B ( $r = -0.359$ ,  $p = 0.048$ ) in IFG subjects. In multiple linear regression analysis leptin showed significant positive association with gender ( $\beta = 0.396$ ,  $p < 0.001$ ) and IFG group ( $\beta = 0.418$ ,  $p = 0.010$ ) however it showed significant negative association with age ( $\beta = -0.157$ ,  $p = 0.022$ ) and HOMA%B ( $\beta = -0.104$ ,  $p = 0.049$ ) after adjusting the major confounders (BMI and HOMA-IR). In binary logistic regression analysis age, gender, leptin and HOMA%B are independent determinants of IFG [age OR (95% CI): 1.14 (1.01–1.29),  $p = 0.032$ , gender OR (95% CI): 0.061 (0.006–0.654),  $p = 0.021$ , leptin OR (95% CI): 1.33 (1.13–1.58),  $p = 0.001$  and HOMA%B OR (95% CI): 0.93 (0.90–0.97),  $p = 0.001$ ] after adjustment of BMI.

**Conclusion:** Higher serum leptin levels are independently associated with insulin secretory dysfunction in IFG subjects. Thus, leptin may represent useful biomarkers for predicting the onset of glucose intolerance in Bangladeshi adults.

## 655

**The relationship between vitamin D and hypogonadism in patients with type 2 diabetes mellitus**H. Dogan<sup>1</sup>, G. Sargin<sup>2</sup>, E. Harman<sup>3</sup>;<sup>1</sup>Department of Internal Medicine, Bozyaka Training and Research Hospital, Izmir, <sup>2</sup>Department of Internal Medicine, Canakkale State Hospital, Canakkale, <sup>3</sup>Division of Endocrinology and Metabolism, Yesilyurt Training and Research Hospital, Izmir, Turkey.

**Background and aims:** Association has been reported between abnormal glucose metabolism, serum vitamin D levels and gonadal dysfunction. 25 (OH) D levels are lower in patients with Type 2 diabetic male patients compared with non-diabetic male patients. Type 2 diabetic patients were separated into three groups according to vitamin D levels (<20 ng / ml, 20–29.9 ng / ml and ≥ 30 ng / ml) and the relationship between vitamin D levels and insulin, c-peptide, fasting blood glucose, postprandial blood glucose, HOMA-IR, HbA1c, body mass index, FSH, LH, total testosterone levels were investigated.

**Materials and methods:** Fasting and postprandial blood glucose values were analyzed by enzymatic colorimetric method with Roche cobas 8000 brand device. HbA1c levels were analyzed by HPLC affinity boranate method with Premier Hb9210 trinity BioTec. And, insulin, C-peptide, FSH, LH, total testosterone, vitamin D levels were determined by kemiluninessans method with Beckman Coulter DXi 800. Kruskal Wallis H and Mann Whitney U tests used for statistical analysis, and <0.05 was considered as statistically significant.

**Results:** There is statistically significant difference between HbA1c groups and the distribution of BMI, HOMA-IR, vitamin D, fasting and postprandial blood glucose, C-peptide values ( $p < 0.05$ ). Total testosterone levels were found statistical significantly lower in the patients with vitamin D level <20 ng/ml than vitamin D level 20–29.9 ng/ml and ≥30 ng/ml (Table 1) ( $p < 0.05$ ). There is positive correlation between the level of vitamin D and total testosterone, and negative correlation between the level of FSH, LH and total testosterone. Vitamin D values were statistical significantly lower in the patients with HbA1c ≥10% than HbA1c: <6.5%, 6.5–8% and 8–10% ( $p < 0.05$ ).

**Conclusion:** 25 (OH) D levels should be evaluated in the patients with type 2 diabetes mellitus associated with hypogonadism. Also, it is emphasized possible detection of vitamin D deficiency and replacement simultaneously.

**Table 1: Distribution of laboratory values according to Vitamin D groups**

**Betatrophin, a novel potential biomarker of beta cell function in diabetes R. Lupi<sup>1</sup>, S. Del Guerra<sup>2</sup>, P. Ursoleo<sup>2</sup>, C. Bianchi<sup>1</sup>, S. Del Prato<sup>2</sup>;**<sup>1</sup>Medical Area, <sup>2</sup>Clinical and Experimental Medicine, Metabolic Unit, Pisa, Italy.

**Background and aims:** Betatrophin was recently described as a potent stimulator of beta cell proliferation in mice. However, information is scanty with respect to the behavior of this hormone in metabolic disorders in human beings. Therefore, we have measured serum betatrophin levels in non-diabetic (ND), type 1 (T1DM), transplanted T1DM (TX) and type 2 (T2DM) diabetic patients. Moreover, since betatrophin is located in the corresponding intron of DOCK6, we have explored associations with the DOCK6 single nucleotide polymorphisms rs1541922 (SNP, C/T).

**Materials and methods:** We recruited 18 ND (49±18 yrs; 8M/10F; BMI 25.4±0.7 kg/m<sup>2</sup>), 17 T1DM (47±9 yrs; 7M/10F; BMI 24.2±1.4 kg/m<sup>2</sup>), 14 TX

(44±3 yrs; 5M/9F; BMI 21.2±2.2 kg/m<sup>2</sup>) and 33 T2DM (63±15 yrs; 18M/15F; BMI 28.5±4.7 kg/m<sup>2</sup>). Betatrophin levels were determined by an ELISA technique, C-peptide by an IRMA method, and DOCK6 SNP was genotyped using TaqMan Allelic Discrimination Assays on DNA from circulating blood cells.

**Results:** In the population as a whole, betatrophin levels were inversely associated with age ( $p=0.0009$ ,  $r=0.612$ ), triglyceride ( $p=0.032$ ,  $r=0.418$ ) and total cholesterol ( $p=0.049$ ,  $r=0.378$ ) concentrations, while a direct correlation was apparent with HDL levels ( $p=0.0035$ ,  $r=0.542$ ). When T1DM subjects were excluded from the analysis, betatrophin correlated with C-peptide concentration ( $p=0.026$ ,  $r=0.421$ ). Betatrophin was significantly higher in T1DM (892.7±84.59 pg/ml) and significantly reduced in T2DM (153.54±21.32 pg/ml) as compared to ND (440.7±46.46, pg/ml; all  $p < 0.05$ , Bonferroni's test). In TX, betatrophin concentration returned to levels similar to those of ND (533.65±44.03 pg/ml). In the whole study population CC, CT and TT genotype frequency was 0%, 53% and 47%, respectively. Interestingly, with the exception of T2DM, the presence of the C allele in single copy was associated with a marked increase in betatrophin concentration (ND TT=268.9±11.6 and CT=386.15±47.13; T1DM TT=818.14±9.9 and CT=1043.33±89.33; TX TT=449.73±46.95 and CT=785.4±9.23; all  $p < 0.05$  or less).

**Conclusion:** The correlation between betatrophin levels and C-peptide concentrations, together with normalization of betatrophin in TX patients, supports a role of the hormone in the maintenance of beta-cell function. Whether betatrophin may provide a useful biomarker of beta cell function (or mass), however, will require further investigation. Also, a potential modulating effect of DOCK6 genotype remains to be fully explored.

## 657

**Hypothalamic-pituitary-adrenal axis dysfunction in streptozotocin(STZ)-diabetic rats: effect of lipoic acid and α-tocopherol treatment**P. Arias<sup>1</sup>, E.M. Repetto<sup>2</sup>, A.L. Bonelli<sup>2</sup>, S. Rocío<sup>2</sup>, M.E. Mercat<sup>2</sup>, C.B. Cymeryng<sup>2</sup>;<sup>1</sup>Chair of Human Physiology, University of Rosario Medical School,<sup>2</sup>Department of Biochemistry, University of Buenos Aires Medical School-CEFYO-CONICET, Argentina.

**Background and aims:** Glucocorticoid release is involved in glucose counter-regulation, and a diminished or absent adrenocortical function renders non-diabetic as well as insulin-treated diabetic subjects prone to hypoglycemia. We previously demonstrated that STZ-diabetic rats show increased basal, but markedly reduced ACTH-stimulated corticosterone (CS) levels. Present experiments, performed in STZ-diabetic rats receiving lipoic acid (LA) or α-tocopherol (aT) treatment, were designed 1) to evaluate the effect of these treatments on oxidative stress parameters, on nitric oxide synthase (NOS) activity, and on steroidogenic function of the adrenal cortex of STZ-treated rats, and 2) to test the hypothesis that STZ-induced oxidative stress might modify CS release by affecting pituitary ACTH secretion.

**Materials and methods:** Male Wistar rats (220–240g) were randomly assigned to the following groups: CON (control), STZ (2 injections of 40 mg/kg STZ separated by 48 h), LA (90 mg/kg ip every 48 h), aT (200 mg/kg/d po), STZ-LA or STZ-aT. LA, aT or vehicle were initiated immediately after the confirmation of hyperglycemia. After 4 weeks, all animals were sacrificed. Oxidative stress parameters and NOS activity, as well as the expression levels of CYP11A1, a key steroidogenic enzyme, and of the ACTH receptor MC2R were evaluated by RT-qPCR in the adrenal cortex. Plasma ACTH and serum CS levels (basal and ACTH-stimulated) were measured by RIA. After normality testing a one-way ANOVA was used for statistical evaluation.

**Results:** STZ rats displayed elevated basal CS levels, and a diminished CS response to ACTH injection. Antioxidants decreased CS levels to those observed in controls (CON:  $7.3 \pm 2.5^*$ , STZ:  $71.7 \pm 9.2$ , STZ aT:  $5.8 \pm 3.4^*$ , STZ-LA:  $19.1 \pm 5.5^*$  ng/ml;  $*p < 0.001$  vs STZ), and restored the defective response to ACTH. Lower basal ACTH levels were detected in STZ animals; neither LA nor aT had an impact on these changes. At the adrenal level, both drugs precluded the increase in TBARS and carbonyl content, and in the expression levels of catalase and heme oxygenase-1 detected in STZ rats. Both antioxidants also prevented the increase in NOS activity detected in diabetic animals (CON:  $88.5 \pm 0.5^*$ , STZ:  $216.7 \pm 9.2$ , STZ-aT:  $108.6 \pm 7.4^*$  and STZ-LA:  $117.4 \pm 16.8^*$  pmol/min/mg protein;  $*p < 0.01$  vs STZ), and corrected the down-regulation of MC2R expression observed in the STZ group. CYP11A1 mRNA levels were not affected by any of these treatments.

**Conclusion:** Our results show that, in STZ-diabetic rats, generation of oxidative stress is associated with an increased activity of the adrenocortical

NO generating system, a known negative modulator of CS release. Systemic antioxidant treatment not only normalized oxidative stress parameters and NOS activity, but also corrected the observed effects of STZ-induced diabetes on CS levels. Compared to control animals, STZ-diabetic rats showed lower baseline circulating levels of ACTH, probably resulting from exaggerated basal CS output. Antioxidant therapy restored basal and ACTH-induced glucocorticoid release without modifying plasma ACTH levels, further supporting the role of local regulatory signals, such as NO, in the dysregulation of adrenal steroidogenesis observed in this animal model of diabetes.

### Progressive reduction in beta cell mitochondrial function leads to diabetes

S. Weksler-Zangen<sup>1</sup>, G. Aharon-Hananel<sup>1</sup>, A. Kogot-Levin<sup>1</sup>, A. Saada<sup>2</sup>, I. Raz<sup>1</sup>;

<sup>1</sup>Department of Internal Medicine, Diabetes Unit,

<sup>2</sup>Department of Human Genetics and Metabolic Diseases, Hadassah University Hospital, Jerusalem, Israel.

**Background and aims:** Pancreatic  $\beta$ -cells couple glucose stimulated insulin secretion (GSIS) with oxidative phosphorylation via the mitochondrial respiratory enzyme, cytochrome *c* oxidase (COX). Emerging evidence suggests interplay between mitochondrial dysfunction and the development of diabetes. We investigated the relation between COX activity and GSIS in isolated pancreatic islets of Cohen diabetes sensitive rats and the role it plays in diabetes development

**Materials and methods:** Cohen diabetic sensitive and Cohen diabetic resistant rats were maintained on a diabetogenic-diet for periods of 4, 11, 20 and 30 days. Blood glucose and insulin concentrations were measured before and during OGTT performed at different time periods on the diabetogenic-diet. Islet-COX activity was determined spectrophotometrically and normalized to citrate-synthase (a ubiquitous mitochondrial matrix enzyme).

**Results:** Islets of normoglycemic Cohen diabetic sensitive rats had 50% of COX activity and GSIS compared to islets of Cohen diabetic resistant rats supporting the existence of a congenital COX impairment. Following exposure to a diabetogenic-diet, Cohen diabetic sensitive rats exhibited a progressive increase in blood glucose levels and decrease in GSIS, developing overt hyperglycemia within 20 days. The decline in GSIS coincided with a significant decrease in islets-COX activity. The reduction in islet-COX activity positively correlated ( $R^2 = 0.9317$ ) with GSIS and inversely correlated ( $R^2 = 0.760$ ) with blood glucose levels. Cohen diabetic resistant rats maintained normoglycemia during the various time periods on diabetogenic-diet and exhibited a partial reduction in GSIS after only 30 days. Islets of Cohen diabetic resistant rats retained more than 50% of their baseline islets-COX activity after 30 days on diabetogenic-diet while in Cohen diabetic sensitive rats less than 20% of islets-COX activity remained.

**Conclusion:** These results show a link between islets COX activity, reduced GSIS and the development of diabetes in the Cohen diabetes sensitive rats. On the diabetogenic-diet, COX activity in islets of normoglycemic-Cohen diabetes resistant rats was reduced by 50%, while in the hyperglycemic-Cohen diabetes sensitive rats the activity was below 20%. Thus, we suggest that COX activity needs to be above a certain threshold to sustain adequate  $\beta$ -cell function and prevent diabetes development.

### Reduced mitochondrial biogenesis in skeletal muscle is associated with obese phenotype in androgen receptor deficient mice (ARKO)

K. Kajita<sup>1</sup>, T. Usui<sup>1</sup>, Y. Kitada<sup>1</sup>, K. Taguchi<sup>1</sup>, I. Mori<sup>1</sup>, T. Ikeda<sup>1</sup>, H. Okada<sup>1</sup>, H. Morita<sup>1</sup>, T. Sasaki<sup>2</sup>, T. Kitamura<sup>2</sup>, T. Sato<sup>2</sup>, T. Ishizuka<sup>1</sup>;

<sup>1</sup>General Internal Medicine, Gifu University Graduate School of Medicine,

<sup>2</sup>Institute for Molecular and Cellular Regulation, Gunma University, Maebashi, Japan.

**Background and aims:** Androgen, including dehydroepiandrosterone (DHEA) and testosterone, reduces adiposity, although the underlying mechanisms are unknown. Here, we examined the effect of androgen on heat production and mitochondrial biogenesis.

**Materials and methods:** C57/Black male mice at 8 w of age were fed CE2 powder with (testosterone group) or without (control group) 0.4% testosterone *ad libitum* for 4wk. In addition, we assessed mitochondrial biogenesis in ARKO at 8wk and 24wk of age. ARKO was provided by Dr. Shigeaki Kato.  $O_2$  consumption,  $CO_2$  production and locomotor activity were measured by indirect calorimetry. The expression levels of PGC1 $\alpha$ , ATP5B and Cox4 protein were measured with western blot. The mRNA expression levels of PGC1 $\alpha$ , nuclear respiratory factor-1 (NRF-1), nuclear respiratory factor-1 (NRF-2), mitochondrial transcription factor A (Tfam) and cytochrome C, and mitochondrial DNA (mitDNA) were evaluated with real time PCR.

**Results:** Testosterone group exhibited weight reduction, decreased fat mass and elevated heat production without reduction of food consumption. Obese phenotype was prominent in ARKO at 24wk, but not 8wk, of age. Serum testosterone level was elevated up to approximately 12-fold, while it was decreased to 10.4% in ARKO. The expression level of PGC1 $\alpha$ , ATP5B and Cox4 protein in skeletal muscle, but not those in brown adipose tissue (BAT) and liver, were elevated in testosterone group, compared with control group, whereas they were suppressed in ARKO at 24wk compared with wild type littermate. Amount of mitDNA and expression level of mRNA involved mitochondrial biogenesis, such as PGC1 $\alpha$ , NRF-1, NRF-2, and Tfam in skeletal muscle were increased in testosterone group. Expression levels of these genes were reduced in skeletal muscle isolated from ARKO at 24wk, however significant reduction was not observed at 8wk, showing that late-onset obesity in ARKO is caused by decreased mitochondrial biogenesis in skeletal muscle. Treatment with 10 nM testosterone significantly increased mRNA levels of PGC1 $\alpha$ , NRF-1, NRF-2, Tfam and cytochrome C in  $C_2C_{12}$  myotubes, which was abolished by flutamide, an AR inhibitor.

**Conclusion:** These results demonstrate that the testosterone-induced increase in energy expenditure is derived from elevated expression level of PGC1 $\alpha$ , and subsequent mitochondrial biogenesis in skeletal muscle, but not BAT. Therefore, skeletal muscle is the major organ contributing to testosterone-induced weight reduction.

### Obese but healthy: Is it really possible?

E. Hamo-Tchatchouang, E. Cosson, S. Chiheb, C. Cussac-Pillegand, I. Banu, M. Nguyen, M. Nguyen, P. Valensi; AP-HP, Jean Verdier Hospital, Bondy, France.

**Background and aims:** Patients displaying the metabolically healthy but obese (MHO) phenotype have an intermediate cardio-metabolic prognosis as compared with normal weight healthy and metabolically unhealthy obese (MUO) patients. We aimed to evaluate the prevalence and characteristics of definite MHO individuals.

**Materials and methods:** Definite MHO phenotype was defined as having none of the International Diabetes Federation metabolic syndrome criteria but waist circumference criterion which is considered as non discriminatory, in 1159 patients including 943 women admitted in stable conditions for obesity (body mass index (BMI)  $38.4 \pm 6.3$  kg/m<sup>2</sup>) without known diabetes. Patients were characterized for cardio-metabolic disorders.

**Results:** The 202 (17.4%) MHO individuals, younger and with lower BMI than the 957 MUO patients in the total cohort, were matched for gender, age and BMI with 404 MUO patients. In addition to the features of metabolic syndrome, the definite MHO patients as compared with the MUO ones were fewer with an homeostasis model assessment of insulin resistance index  $\geq 3$  (23.6 versus 38.9%,  $p < 0.001$ ), with an abnormal oral glucose tolerance test (13.9 versus 23.9%,  $p < 0.001$ ), HbA1c  $\geq 5.7\%$  (43.9 versus 54.2%,  $p < 0.05$ ), pulse pressure  $\geq 60$  mmHg ( $p < 0.001$ ) but did not show significant differences for the prevalence of microalbuminuria (11.1 vs 12.3%), cardiac autonomic dysfunction (45.5 vs 35.3%) and fatty liver index  $\geq 60$  (5.6 vs 10.2%).

**Conclusion:** Our data do not support the characterization of MHO, even definite, as really healthy, as many patients with this phenotype have abnormal cardio-vascular markers and glucose or liver abnormalities.

### Automated quantification of brown and white adipose tissue with x-ray computer tomography (CT) and 18F-deoxyglucose positron emission tomography (FDG/PET)

M.S. Buchsbaum<sup>1</sup>, A. DeCastro<sup>1</sup>, L. Morrow<sup>2</sup>, A. Krentz<sup>3</sup>, G. Peterson<sup>3</sup>, D. Laurent<sup>4</sup>, M. Hompesch<sup>3</sup>;

<sup>1</sup>Psychiatry, University of California, <sup>2</sup>Profil Institute for Clinical Research,

<sup>3</sup>Profil Institute for Clinical Research, San Diego, USA,

<sup>4</sup>Novartis Institutes for Biomedical Research, Basel, Switzerland.

**Background and aims:** Brown and white, adipose tissue in the thorax differ in proportions, locations and their heat generating capability. This study uses voxel-by-voxel analysis of CT and coregistered FDG-PET to assess the volumes, activity, deposit size, and admixture of tissue type in supraclavicular, interscapular, and circumcarotid areas. This novel application of image analysis methods adapted from brain imaging is evaluated for reliability and similarity to imaging fat assessment

**Materials and methods:** We studied 12 insulin resistant subjects and 2 overweight healthy volunteers with FDG-PET/CT of the thorax to assess the glucose metabolic rate (GMR in  $\mu\text{mol glucose}/100\text{g}/\text{min}$  and standard uptake value (SUV) of adipose tissue. Subjects were exposed to a 90-min period of cold (67F) and warm (73 F) temperature on separate days. FDG-PET images were coregistered to a 200 mA CT. Segmented CT masks of 7 Hounsfield unit (HU) bands: -160 to -140, -140 to -120, -120 to -100, -100 to -80, -80 to -60, -60 to -40, and -40 to -20 were evaluated and compared to muscle and skin HU values. CT images had contiguous voxels automatically clustered using Analysis of Functional NeuroImages (AFNI) and the series of narrow HU unit bands as the criterion. In the -140 to -80 range, the largest supraclavicular clusters were 10-20 cm<sup>3</sup>.

**Results:** Greater cold minus warm differences in adipose tissue GMR than in HU defined muscle or skin were confirmed (adipose  $0.06 >$  muscle). Significant areas of thermogenesis in Hounsfield value defined tissue (-120 to -80) were located in 64% of subjects, a percentage similar to that obtained in visual inspection studies and a relatively broad band (-160 to -40) range of mean thermogenesis was observed. Significantly lower metabolic variation (voxel SD within the clusters) was found in supraclavicular clusters at -100 to -80 HU units and a trend observed for the variation to be higher for the cold than warm condition, suggesting a mixture of thermogenic and nonthermogenic

cells being present. Cluster size and thermogenicity were highly correlated ( $r = 0.90$  to  $.98$ ,  $p < 0.001$ ) across the right and left thorax, consistent with reliability of the voxel clustering approach.

**Conclusion:** Automated algorithms based on FDG-PET/CT appear valuable in the anatomical localization, quantification, and characterization of adipose tissue temperature sensitivity. CT/FDG-PET may prove sensitive enough to detect pharmacological therapeutic interventions on different adipose tissue components. This assay complements measurements of weight, BMI, blood insulin measurement and the glucose tolerance test, as well as the sophisticated hyperinsulinemic euglycemic clamp. ### Adipose tissue depot specific promoter methylation of TMEM18

K. Rohde<sup>1,2</sup>, M. Keller<sup>1</sup>, M. Klös<sup>1</sup>, D. Schleinitz<sup>1</sup>, A. Dietrich<sup>3</sup>, M.R. Schön<sup>4</sup>, D. Gärtner<sup>4</sup>, T. Lohmann<sup>5</sup>, M. Dreßler<sup>5</sup>, M. Stumvoll<sup>1,2</sup>, P. Kovacs<sup>1</sup>, M. Blüher<sup>2</sup>, Y. Böttcher<sup>1</sup>;

<sup>1</sup>IFB Adiposity Diseases, <sup>2</sup>Department of Medicine, <sup>3</sup>Department of Surgery, University of Leipzig, <sup>4</sup>Städtisches Klinikum Karlsruhe, Clinic of Visceral Surgery, <sup>5</sup>Municipal Clinic Dresden-Neustadt, Germany.

**Background and aims:** Epigenetic processes such as dynamic promoter methylation may play a role in obesity, fat distribution and its accompanied metabolic alterations. *TMEM18* is a candidate gene for BMI comprising the second largest effect size among all loci identified so far via GWAS. We hypothesized that differential *TMEM18* gene expression in visceral (VAT) and subcutaneous adipose tissue (SAT) may be a consequence of depot specific differential methylation at the *TMEM18* promoter region. Differential methylation levels may confer fat depot specific correlations with measures of obesity and fat distribution.

**Materials and methods:** (i) *TMEM18* mRNA expression was measured in VAT and SAT from 500 subjects. (ii) We investigated 146 Caucasian individuals for differential methylation levels in VAT vs. SAT at three CpG sites. (iii) Subsequently, we tested for potential correlation of methylation levels with anthropometric and metabolic parameters.

**Results:** (i) In 500 individuals, we observed significantly decreased mRNA expression in SAT (paired t-test,  $P < 0.0001$ ) compared to VAT with strongest effects in obese subjects. (ii) We identified significantly higher methylation levels for the entire CpG locus in SAT (paired t-test,  $P = 0.00015$ ). In 146 individuals, we detected positive correlations between CpG methylation levels in SAT with parameters of obesity and fat distribution (e.g. BMI,  $r = 0.173$ ;  $P = 0.036$ ; visceral fat area,  $r = 0.246$ ;  $P = 0.004$ ) and with metabolic traits ( $P \leq 0.05$ ). However, these correlations did not withstand adjustment for covariates. (iii)

**Conclusion:** Our data suggest an adipose tissue depot specific *TMEM18* promoter methylation that may mediate inter-depot specific variance in *TMEM18* mRNA expression.

**A highly potent and specific PPAR alpha agonist, K-877, improves lipid profiles and insulin sensitivity in dyslipidaemia subjects; an integrated analysis of 3 Phase 2/3 trials**E. Araki<sup>1</sup>, S. Ishibashi<sup>2</sup>, S. Yamashita<sup>3</sup>, H. Arai<sup>4</sup>, K. Yokote<sup>5</sup>, H. Suganami<sup>6</sup>, T. Kodama<sup>7</sup>;<sup>1</sup>Department of Metabolic Medicine, Kumamoto University Graduate School of Medicine, <sup>2</sup>Division of Endocrinology and Metabolism, Jichi Medical University, Tochigi, <sup>3</sup>Department of Cardiovascular Medicine, Osaka University Graduate School of Medicine, Suita, <sup>4</sup>Department of Human Health Sciences, Kyoto University Graduate School of Medicine, <sup>5</sup>Department of Clinical Cell Biology and Medicine, Chiba University Graduate School of Medicine, <sup>6</sup>Clinical Data Science Department, Kowa Company, Ltd., Tokyo, <sup>7</sup>Laboratory for Systems Biology and Medicine, The University of Tokyo, Japan.**Background and aims:** K-877 is a specific PPAR alpha agonist with a potentially improved pharmacological profile with respect to efficacy and safety compared with other PPAR alpha agonists. In subjects with atherogenic dyslipidemia, insulin resistance often co-exist, and as such, the treatments which concurrently improve plasma lipoprotein profiles and insulin sensitivity are highly demanded. Therefore, this integrated analysis set out to assess retrospectively the effect of K-877 on efficacy, safety and measures of insulin resistance over 12 weeks in 3 phase 2/3 trials.**Materials and methods:** This is an integrated analysis of two Phase 2 trials (one monotherapy trial and one add-on to stable pitavastatin 2 mg/day therapy) and one Phase 2/3 trial (monotherapy). All subjects had hypertriglyceridemia and low HDL-C and/or high non-HDL-C. All these were 12 weeks, randomized, multicenter, double-blinded, placebo controlled trials. The efficacy and safety of K-877 0.05, 0.1, 0.2 and 0.4 mg/day (twice daily) were examined in all trials.**Results:** A total of 676 subjects (K-877; 37, 0.05 mg/day; 127, 0.1 mg/day; 215, 0.2 mg/day; 172, 0.4 mg/day; placebo; 125) were evaluated in this integrated analysis. The subject baseline characteristics were comparable among all groups. From baseline to Week12, a significant reduction in TG and an increase in HDL-C were observed for K-877 groups (TG; -40.6 to -52.7%, HDL-C; +12.0 to +24.0%,  $p < 0.001$  for all). In K-877 groups, the effects on TG and HDL-C were similar regardless of baseline HOMA-IR. Favorable effects on insulin sensitivity were also observed dose-dependently in K-877 groups [fasting plasma glucose (FPG): K-877; +4.62 to -5.53 mg/dL, placebo; +2.95 mg/dL, fasting plasma insulin (FPI): K-877; -0.87 to -3.36  $\mu\text{U/mL}$ , placebo; -0.28  $\mu\text{U/mL}$ , HOMA-IR: K-877; -0.35 to -1.23, placebo; + 0.01]. The reduction of FPG, FPI and HOMA-IR was greater in the subjects with higher HOMA-IR. The incidence of all adverse drug reactions in K-877 groups were similar to placebo (placebo; 8.0%, 0.05mg/day; 5.4%, 0.1mg/day; 4.7%, 0.2mg/day; 7.9%, 0.4mg/day; 8.1%). Similar results were observed in the incidence of adverse events including abnormal liver function test, increased blood creatine phosphokinase and increased blood creatinine.**Conclusion:** In an integrated analysis, K-877 improved lipid profiles and insulin sensitivity without increasing adverse events. K-877 could be a promising therapy for atherogenic dyslipidemia. The mechanisms how K-877 improve insulin sensitivity should need further investigation.

**Genomic profiling in plasma reveals the effect of a polyunsaturated fatty acid-enriched diet on common microRNAs**J.M. Mercader<sup>1</sup>, F.J. Ortega<sup>2</sup>, M.I. Cardona-Alvarado<sup>3</sup>, J.M. Moreno-Navarrete<sup>2</sup>, M. Moreno<sup>2</sup>, M. Sabater<sup>2</sup>, N. Fuentes-Batllevell<sup>2</sup>, W. Ricart<sup>2</sup>, E.L. Pérez-Luque<sup>2</sup>, J.M. Fernández-Real<sup>2</sup>;<sup>1</sup>Joint IRB-BSC program on Computational Biology, Barcelona, <sup>2</sup>Department of Diabetes, Endocrinology and Nutrition (UDEN), Institut d'Investigació Biomèdica de Girona (IdIBGi), Girona, Spain, <sup>3</sup>Department of Medical Research, Division of Health Sciences, Leon Campus, Mexico.**Background and aims:** Consumption of long-chain polyunsaturated fatty acids (PUFAs) of omega n-3 and n-6 series, which are abundant in seafood and nuts, ameliorate components of the metabolic syndrome, reducing LDL-cholesterol. Mechanisms responsible for diet-induced LDL reduction are likely associated with nutrients provided by these aliments, targeting primary

routes of LDL reduction and regulating enzymes involved in cholesterol synthesis. Circulating microRNAs (miRNAs) have demonstrated to be valuable biomarkers of metabolic diseases. Here, we investigated whether a sustained nuts-enriched diet can lead to changes in circulating miRNAs in parallel to LDL-cholesterol reduction.

**Materials and methods:** The profile of 192 common miRNAs was assessed in plasma from 10 healthy women before and after an 8-week trial with a normocaloric diet enriched in PUFAs (30 g/day of almonds and walnuts). The most relevant miRNAs were validated in an extended sample of 30 participants (8 men and 22 women).**Results:** Concomitantly with decreased body mass index (-3.5%,  $p < 0.0001$ ), circulating LDL (-10%,  $p < 0.001$ ), and increased adiponectin (35%,  $p = 0.017$ ), circulating concentrations of several miRNAs were modified by treatment, including decreased miR 330-3p, miR-328 and miR-221, and increased miR-769-5p, miR-18a, miR-130b, miR-192, miR-19b, and miR-486-5p (all  $p < 0.05$ ). Interestingly, miR-130b ( $r = 0.7$ ,  $p < 0.0001$ ), miR-221 ( $r = 0.44$ ,  $p = 0.03$ ), and miR-409 ( $r = 0.6$ ,  $p = 0.001$ ) variations correlated with changes in circulating C-reactive protein concentrations, while miR-328 ( $r = 0.5$ ,  $p = 0.01$ ) and miR-125b ( $r = 0.63$ ,  $p = 0.002$ ) were associated with adiponectin. Noteworthy, diet-induced changes in circulating miR-486-5p were also associated with dietary fatty acids intake ( $r = 0.44$ ,  $p = 0.02$ ), miR-221 variations were inversely associated with increased dietary omega n-3 ( $r = -0.5$ ,  $p = 0.01$ ), and modifications on circulating miR-192 correlated with dietary omega n-6 ( $r = 0.62$ ,  $p = 0.001$ ). **Conclusion:** This study provides the first evidence that circulating miRNAs may be modified by polyunsaturated fatty acid-enriched diet and reveals their potential relevance in this context.

## 665

**Lysophosphatidylcholines as regulators of gene expression in human skeletal muscle**C. Klingler<sup>1</sup>, M. Wolf<sup>1</sup>, J. Li<sup>2</sup>, S. Chen<sup>2</sup>, X. Zhao<sup>2</sup>, E. Schleicher<sup>3,4</sup>, H.-U. Häring<sup>3,4</sup>, G. Xu<sup>2</sup>, R. Lehmann<sup>3,4</sup>, C. Weigert<sup>3,4</sup>;<sup>1</sup>Department of Internal Medicine IV, University Tuebingen, Germany, <sup>2</sup>Dalian Institute of Chemical Physics, Dalian, China, <sup>3</sup>German Center for Diabetes Research, Tuebingen, <sup>4</sup>Institute for Diabetes Research and Metabolic Diseases of the Helmholtz Center Munich at the University of Tuebingen, Germany.**Background and aims:** Lysophosphatidylcholines (LPC) circulating in the blood stream recently gained attention as biomarkers for insulin resistance and T2DM. It remains to be resolved whether LPC plasma concentrations can contribute to the development of insulin resistance. Skeletal muscle might represent not only a target for LPC but might be a source of circulating LPC.**Materials and methods:** Human Myocytes from biopsies of healthy young volunteers were differentiated to myotubes in AlphaMEM with 2% FBS for 5 days. Myotubes were stimulated for 24 h, 4 h, and 30 min with <sup>13</sup>C-labelled palmitate (0.250 mM). Afterwards LPC biosynthesis and secretion was quantified by isotope-based LPC profiling. Furthermore, myotubes were stimulated with different concentrations of LPC C16:0 and LPC C18:1 followed by transcriptomics analysis, qPCR, siRNA-based knock-down und gel shift assays.**Results:** In primary human myotubes stimulation with palmitate resulted in the synthesis of several LPC species leading to time-dependent intracellular accumulation of LPCs. Moreover newly synthesized LPCs were released into the extracellular compartment. After stimulation of myotubes with 10  $\mu\text{M}$  LPC (16:0) or LPC (18:1) whole genome expression analysis revealed an activation of PPAR $\delta$ -regulated transcripts. qPCR confirmed the induction of the PPAR $\delta$  target genes PDK4 and ANGPTL4 mRNA already at a LPC concentration of 1  $\mu\text{M}$ . This induction was attenuated in the presence of siRNA against PPAR $\delta$ . By gel shift assays we could demonstrate that LPCs regulate DNA binding activity of the PPAR $\delta$ /RXR $\alpha$  complex in a dose-dependent manner.**Conclusion:** Extracellular LPCs can activate PPAR $\delta$ -dependent gene expression in human myotubes as direct ligands of this nuclear receptor. LPCs originating from muscle could act in a paracrine or endocrine fashion on lipid metabolism of different target tissues.

**Lower intensified target LDL-C level of statin therapy results in a higher risk of incident diabetes: a meta-analysis of randomised statin trials**

R. Cai, Y. Yuan, Y. Zhou, W. Xia, P. Wang, H. Sun, Y. Yang, R. Huang, S. Wang;  
Affiliated Zhong Da Hospital of Southeast University, Nanjing, China.

**Background and aims:** A recent meta-analysis has reported that intensive-dose statin drug increases the risk of incident diabetes. However, doubling of the statin dose generates only a further 6% decrease in low-density lipoprotein cholesterol (LDL-c) on average. This study aimed to determine whether statin therapy with lower intensive-target LDL-c level contributes to higher risk of new-onset diabetes.

**Materials and methods:** Medline, Embase, and the Cochrane Central Register of Controlled Trials were searched for randomized controlled endpoint trials of statins conducted from 1966 to 2012. We included trials with more than 1000 participants who were followed up for at least 2 years. The included trials were stratified by the target LDL-c level. I<sup>2</sup> statistic was used to measure heterogeneity between trials. We further calculated risk estimates with random-effect meta-analysis. Meta-regression was used to identify the potential risk factors of statin-induced diabetes.

**Results:** Fourteen trials with a total of 95 102 non-diabetic participants were included. The risks elevated by 33% [odds ratio (OR) = 1.33; 95% confidence interval (CI) 1.14-1.56; I<sup>2</sup> = 7.7%] and 16% (OR = 1.16; 95% CI 1.06-1.28; I<sup>2</sup> = 0.0%) when the intensified target LDL-c levels were ≤1.8 mmol/L and 1.8-2.59 mmol/L, respectively. Incident diabetes did not increase when the target LDL-c level was ≥2.59 mmol/L. Apart from age, female, and baseline level of total cholesterol, meta-regression analysis showed that the target and baseline levels of LDL-c and relative LDL-c reduction were predictors of statin-induced diabetes.

**Conclusion:** A lower intensified target LDL-c level of statin therapy resulted in higher risk of incident diabetes.

**Intensified LDL-C target of statin therapy and cancer risk: a meta-analysis**

S. Haixia, Y. Yuan, P. Wang, Y. Zhou, R. Cai, W. Xia, Y. Yang, R. Huang, S. Wang;  
The Affiliated ZhongDa Hospital of Southeast University, Nanjing, China.

**Background and aims:** Statin therapy and cancer incidence have no relationship according to a recent system review and meta-analysis. However, whether an intensified low-density lipoprotein-cholesterol (LDL-c) target of statin therapy is associated with cancer incidence has been rarely reported.

**Materials and methods:** PUBMED, EMBASE, and Cochrane Central Register of Controlled Trials (CENTRAL) data as of July 2013 were searched for randomized controlled trials (RCTs) on statins. An intensified LDL-c target of <2.59 mmol/L (100 mg/dl) or a relative LDL-c reduction by at least 30% of the baseline was the primary criterion for all the trials that were included in the meta-analysis. The I<sup>2</sup> statistic was used to measure heterogeneity among the trials, and risk estimates were calculated for incident cancer with random-effect meta-analysis.

**Results:** Eleven eligible studies were identified with 70,714 participants, 6,423 of whom (3,231 were given statins and 3,192 were given control treatment) developed cancer during the follow-up period. The intensified LDL-c target of statin therapy showed no effect on cancer incidence (odds ratio [OR] 1.02,

95% CI 0.94–1.11, I<sup>2</sup>=38.2%), including some common types of respiratory and gastrointestinal cancer. However, pravastatin seemed to promote cancer incidence (OR 1.26, 95% CI 1.04–1.53). Meta-regression analysis showed that neither the chemical properties nor the species of the statins accounted for the residual variation in risk.

**Conclusion:** The intensified LDL-c target of statin therapy has no effect on the overall incidence of cancer, including some common types of respiratory and gastrointestinal cancer. Thus, such an intensified statin therapy need not be changed among adult clinical patients.

668

**Age at menarche, glycaemic control, cardiovascular risk factors and chronic complications in women with type 1 diabetes: a nationwide survey in Brazil**

M.B. Gomes<sup>1</sup>, C.A. Negrato<sup>2</sup>;

<sup>1</sup>Internal Medicine, State University of Rio de Janeiro,

<sup>2</sup>Internal Medicine, Associação Médica de Diabetes de Bauru, Brazil.

**Background and aims:** Puberty is an early life event that may have several relations to later life diseases risk and is an event that is usually well recalled by adult women being a reliable measure of pubertal initiation. Earlier age at menarche onset has been associated with several adverse outcomes, such as type 2 diabetes, obesity, cardiovascular diseases, metabolic syndrome and all causes mortality, showing that the timing of pubertal development may have lifelong effects on a woman's health. So far many menstrual irregularities were described in women with type 1 diabetes like early and delayed menarche timing, menstrual cycle irregularities and early menopause. In general a higher age at menarche is observed in women with type 1 diabetes in comparison to controls of the same population, but this difference is not significant. The influence of glycemic control upon age at menarche is still controversial. The aim of this study was to determine the relationship between age at menarche with glycemic control and cardiovascular risk factors in patients with type 1 diabetes in Brazil.

**Materials and methods:** This was a multicenter cross-sectional study conducted between December 2008 and December 2010 in 28 public clinics in 20 cities from the four Brazilian geographic regions. Data were obtained from 1,527 female patients, 59.3% Caucasians, aged 25.1 ± 10.6 years. The diabetes duration was 11.4 ± 8.1 years. Patient information (clinical factors and age at menarche) was obtained through a questionnaire and a chart review. Age at menarche was stratified in four classes: 8 to 11 (class 1, early menarche), 12 (class 2), 13 (class 3) and 14-18 years (class 4, late menarche).

**Results:** The mean age at menarche was 12.7 ± 1.7 years (median 13.0 years) without difference between the geographical regions of the country, economic status, level of care and ethnicity. Patients from class 1 had greater BMI than patients from the other classes, p<0.001, and were more likely to be overweight or obese than patients from the other classes, [169 (31.5%) vs 152 (28.3%), vs 117 (21.8%) vs 99 (18.4%), p <0.001], respectively. BMI had an inverse correlation with age at menarche (r=-0.14, p <0.001). No significant difference was observed among the four classes of age at menarche for blood pressure, lipid profile and diabetes-related chronic complications. More patients from class 1 were using metformin in comparison to patients from class 4, 13.8% vs 7.1 %, p=0.002, respectively. Logistic regression analysis showed that early age at menarche, [(8-11 years, (odds ratio (ORs) 1.77 [1.30-2.41,p<0.001])] and duration of diabetes [ORs 1.01 (1.00-1.03), p=0.02], were related to greater risk of patients' overweight or obesity and adherence to diet [ ORs 0.78 (0.60-0.93), p=0.01], physical activity [ORs 0.75 (0.94-0.94),p=0.01 insulin dose (U/kg) (ORs 0.54 [0.59-0.90,p=0.001])] were related to lower risk for overweight or obesity.

**Conclusion:** Early menarche occurred in 23.4% of Brazilian female with type 1 diabetes and was strongly associated with overweight or obesity in pubertal/adult life which could be minimized with lifestyle changes such as better adherence to diet and physical activity. Further prospective studies must be addressed to establish the relationship between early menarche, glycemic control, cardiovascular risk factors and diabetes-related chronic complications.

### MAPK signalling is required for brain insulin to suppress lipolysis in rodents

T. Scherer<sup>1,2</sup>, E. Zielinski<sup>2</sup>, C. Lindtner<sup>2</sup>, J. O'Hare<sup>2</sup>, C. Buettner<sup>2</sup>;<sup>1</sup>Department of Medicine III, Medical University of Vienna, Austria,<sup>2</sup>Department of Medicine, Mount Sinai School of Medicine New York, USA.

**Background and aims:** Insulin is the major anti-lipolytic hormone and is secreted postprandially. We recently showed that brain insulin action is able to suppress lipolysis by reducing sympathetic nervous system outflow to white adipose tissue. However, the relative importance of brain insulin versus the well-characterized peripheral insulin effects in regulating whole body lipolysis is unknown.

**Materials and methods:** Here, we studied the role of brain insulin versus peripheral insulin action using two inducible insulin receptor knock-out mouse models and their respective controls. The first model lacks the insulin receptor (IR) in the whole body (IR $\Delta$ WB), while the second model lacks the IR in all peripheral tissues (IR $\Delta$ PER) except the brain. All mice were subjected to 2-hour hyperinsulinemic euglycemic clamp studies with stable isotope glycerol tracer to assess whole body lipolysis. To further identify the signal transduction pathway mediating brain insulin's effects on lipolysis, we co-infused insulin with either the PI3K inhibitor LY294002 or the MAPK inhibitor U0126 directly into the mediobasal hypothalamus (MBH) of male Sprague Dawley rats ( $n \geq 4$  per group) using stereotaxically implanted cannulae, and assessed lipolytic flux using the rate of appearance (Ra) of the glycerol tracer.

**Results:** Male IR $\Delta$ PER knock-out mice subjected to a hyperinsulinemic clamp showed a comparable % suppression of Ra glycerol per unit of insulin ( $4.7 \pm 1.7$  vs.  $6.0 \pm 1.4$  %;  $P=0.6$ ) to littermate controls despite being extremely insulin resistant (glucose infusion rate  $21 \pm 5$  vs.  $97 \pm 10$  mg $\cdot$ kg $^{-1}$  $\cdot$ min $^{-1}$ ;  $P = 0.001$ ). In contrast, male IR $\Delta$ WB knock-out mice were unable to adequately suppress lipolytic flux ( $0.4 \pm 0.2$  vs.  $6.9 \pm 2.2$  %,  $P=0.017$ ) compared to control mice when exposed to high doses of insulin during a clamp. MBH insulin co-infusion with LY294002 suppressed Ra glycerol to a similar extent than MBH insulin alone ( $17 \pm 2$  vs.  $15 \pm 6$  vs.  $32 \pm 7$  (controls)  $\mu$ mol $\cdot$ kg $^{-1}$  $\cdot$ min $^{-1}$ ;  $P=0.7$  MBH LY+Insulin vs. MBH Insulin) in rats. However, the co-infusion of the MAPK inhibitor U0126 blocked the ability of insulin to suppress lipolytic flux ( $60 \pm 8$   $\mu$ mol $\cdot$ kg $^{-1}$  $\cdot$ min $^{-1}$ ;  $P=0.006$  vs. MBH LY+Insulin;  $P<0.001$  vs. MBH Insulin).

**Conclusion:** Insulin suppresses lipolysis even after the complete loss of peripheral insulin receptors, provided that functional brain insulin receptors and an intact MAPK pathway are present. Conditions in which brain insulin signaling is impaired, such as high fat feeding and obesity, are likely to compromise the regulation of lipolysis and lead to uncontrolled free fatty acid flux promoting lipotoxicity.

### Alteration of hypothalamic glucose sensing in high fat-high sucrose diet fed rats: early defects linked to mitochondrial dynamics and ROS signalling

L. Desmoulin<sup>1</sup>, S.C. Collins<sup>1</sup>, S. Grall<sup>1</sup>, C. Allard<sup>1</sup>, X. Fioramonti<sup>1</sup>,P.-Y. Risold<sup>2</sup>, L. Pénicaud<sup>2</sup>, C. Leclou<sup>1</sup>;<sup>1</sup>Centre des sciences du gout et de l'alimentation, CNRS UMR 6265 INRAUMR 1324 Université de Bourgogne, Dijon, <sup>2</sup>Laboratoire d'Histologie,

IFR 133, Faculté de Médecine et de Pharmacie, Besançon, France.

**Background and aims:** The hypothalamus participates in the control of energy homeostasis by detecting circulating nutrients, such as glucose. The mediobasal hypothalamus (MBH), in particular, senses hyperglycemia and initiates physiological responses, e.g., insulin secretion (IS) via the autonomous (vagal) nervous system. We have recently demonstrated that glucose sensing (GS) requires mitochondrial reactive oxygen species (mROS) signaling heavily dependant on mitochondrial fusion and fission (dynamics). Recently, genetic models have associated some of these dynamics within the MBH to their obesogenic susceptibility. Using a model that only presents a hypothalamic GS defect, our objectives were thus to determine whether modulating the diet affects 1) mROS signaling, 2) mitochondrial fission and fusion, 3)

respiratory function in the hypothalamus, and how early these defects could be detected during the progression to diabetes.

**Materials and methods:** Male Wistar rats were fed a High Fat-High Sucrose (HFHS) diet during 3 weeks and compared to control rats fed a normal chow. Circulating hormones and metabolites were evaluated as well as glucose tolerance. Hypothalamic glucose-induced IS was studied in response to a carotid glucose injection towards the brain without alteration in peripheral glycemia and compared to islet glucose-induced IS. Hypothalamic ROS production and mitochondrial dynamics (main actors: DRP1 (fission), MFN2(fusion)) were quantified. Efficiency of hypothalamic mitochondrial respiration was evaluated using oxygraphy, as well as the redox status (glutathion red/ox) of MBH explants.

**Results:** A 3 weeks HFHS diet did not significantly alter body weight, despite the caloric intake (STD=72.3 $\pm$ 1,2kcal/j ; HFHS=83,9 $\pm$ 1,8 kcal/j ;  $p<0,001$ ) and the fat mass (STD=11,8 $\pm$ 0,6% ; HFHS=15,1 $\pm$ 0,8% ;  $p=0,007$ ) being increased compared to control rats. HFHS fed rats displayed a glucose intolerance in the first 30 min, an increased fasting glycemia but no modification of fasting insulinemia. Hypothalamic GS induced IS was drastically decreased ( $\Delta$  insulin: STD=86,1 $\pm$ 26,9 $\mu$ U/ml ; HFHS=26,9 $\pm$ 11,4 $\mu$ U/ml ;  $p=0,017$ ) while glucose stimulated IS in isolated islets was not different compared to controls. These defects correlate with a decrease of MBH ROS production (-33%). The fission protein DRP1 exhibited a decreased mitochondrial translocation in the MBH, and no change in MFN2 (fusion) content was observed while controls exhibit an increase. Finally, mitochondrial respiratory deficiencies were present in HFHS fed rats.

**Conclusion:** A hypothalamic alteration of mitochondrial ROS signaling, fission and fusion, and respiration was present in rats exposed to a 3 weeks HFHS diet. Such hypothalamic GS defects are early events preceding those in islets. These results suggest that the glucose intolerance seen in the first 30 min involved the hypothalamo-pancreatic axis rather than the islet GS (the vagal control being of particular importance for this first phase). In conclusion, these early but drastic hypothalamic modifications could participate in a primary nervous defect of the control of insulin secretion, and finally, the establishment of a diabetic phenotype.

### Brain glutamate dehydrogenase (GDH) knockout mice display modified central glucose metabolism reshaping peripheral energy distribution

M. Karaca<sup>1</sup>, F. Frigerio<sup>1</sup>, S. Carrobbio<sup>1</sup>, S. Migrenne<sup>2</sup>, D. Skyt<sup>3</sup>,J. Tamarit-Rodriguez<sup>4</sup>, H. Waagepetersen<sup>3</sup>, C. Magnan<sup>2</sup>, P. Maechler<sup>1</sup>;<sup>1</sup>Dpt of Cell Physiology and Metabolism, University of Geneva, Switzerland,<sup>2</sup>CNRS EAC 4413, BFA, University Paris Diderot, Paris, France,<sup>3</sup>Dpt of Pharmacology and Pharmacotherapy, University of Copenhagen,Denmark, <sup>4</sup>Dpt of Biochemistry, Complutense University, Madrid, Spain.

**Background and aims:** Glucose is the prominent source of energy delivered to the central nervous system (CNS) by the periphery. However, within the brain, oxidative catabolism of the main neurotransmitter glutamate contributes to maintenance of energy homeostasis. Upon glutamatergic transmission, following its uptake by astrocytes, glutamate may be amidated to glutamine and then recycled back to neurons. Alternatively, glutamate may be deaminated to alpha-ketoglutarate by the mitochondrial enzyme glutamate dehydrogenase (GDH, encoded by the Glud1 gene) before further oxidation in the TCA cycle, ultimately producing ATP. We generated brain-specific GDH knockout mice (CnsGlud1 $^{-/-}$ ) to question the importance of GDH as a key enzyme connecting glucose and glutamate metabolism within the CNS.

**Materials and methods:** Mitochondrial oxygen consumption and cytosolic ATP levels were measured in isolated brain tissues and primary astrocytes. Glucose uptake was estimated by incorporation of injected 2-deoxy-D-[14C] glucose. Brain metabolites were measured by NMR in living animals otherwise using commercial kits. Peripheral glucose homeostasis was assessed by ip glucose tolerance tests. Insulin resistance was assessed by hyperinsulinemic-euglycemic clamps.

**Results:** In CnsGlud1 $^{-/-}$  brains lacking GDH, glutamate oxidation was reduced, resulting in elevated glutamate plus glutamine pool and impaired glutamate-induced oxygen consumption and ATP generation in their astrocytes. CnsGlud1 $^{-/-}$  mice compensated for the lack of glutamate usage by increasing brain glucose consumption. This adaptive mechanism was uncovered by the observed lower central glucose concentrations (-47%,  $p<0.05$ ), enhanced brain glucose uptake (+32%,  $p<0.05$ ) and increased glucose-stimulated ATP generation in their astrocytes. Higher brain glucose consumption in Cns-

Glud1<sup>-/-</sup> mice was confirmed by measurements of elevated incorporation of <sup>13</sup>C from [U-<sup>13</sup>C]-glucose into those amino acids representative for oxidative metabolism of glucose products in the TCA cycle (alanine, aspartate, glutamate). CnsGlud1<sup>-/-</sup> mice were glucose intolerant with normal insulin production. However, they displayed increased endogenous glucose production and decreased muscle glucose uptake. Fat turnover was also modified with higher circulating triglycerides and ketone bodies. Furthermore, plasma concentrations of most amino acids were lower in CnsGlud1<sup>-/-</sup> mice in comparison with control mice, suggesting increased mobilization of metabolites in CnsGlud1<sup>-/-</sup> skeletal muscles for provision of brain-specific energy substrates. Lower plasma pancreatic polypeptide and higher catecholamines levels highlighted repressed parasympathetic activity with a concomitant increase in the sympathetic input favouring energy mobilization.

**Conclusion:** Brain-specific GDH deletion induced impairment of glutamate oxidation in the CNS leading to central hypoglycaemia; in turn mobilizing energy substrates from the periphery.

### Acyl ghrelin acts in the brain to control liver function and peripheral glucose homeostasis

R. Stark<sup>1</sup>, A. Reichenbach<sup>1</sup>, S.H. Lockie<sup>1</sup>, C. Pracht<sup>2</sup>, Q. Wu<sup>3</sup>, A. Tups<sup>2</sup>, Z.B. Andrews<sup>1</sup>;

<sup>1</sup>Physiology, Monash University, Melbourne, Australia, <sup>2</sup>Animal Physiology, Philips University, Marburg, Germany, <sup>3</sup>Traditional Chinese Medicine, Peking Union Medical College Hospital, Beijing, China.

**Background and aims:** The gut hormone, ghrelin, acts on neuropeptide Y neurons in the arcuate nucleus of the hypothalamus and stimulates food intake to control energy balance. However, recent evidence suggests that peripheral ghrelin regulates glucose metabolism. Here, we designed experiments to examine how central acyl ghrelin infusion affects peripheral glucose metabolism under pairfed or ad libitum feeding conditions.

**Materials and methods:** Three groups of mice received either ICV infusion of aCSF, ghrelin and allowed to eat ad libitum (Gh-lib) or ghrelin and pairfed to the average of the aCSF group (Gh-pf). Mini pumps delivered acyl ghrelin at a dose of 0.25 µg/hour at 0.5 µl/hour for 7 days.

**Results:** There was no difference in daily fed blood glucose, insulin, glucagon, triglycerides or non-esterified fatty acids between the groups. Body weight gain and food intake was significantly higher in Gh-lib mice compared to aCSF and Gh-pf. However, both Gh-lib and Gh-pf groups exhibited heavier white adipose mass, independent of body weight and food intake. Gh-pf mice exhibited a state of negative energy balance, as hypothalamic NPY and AgRP mRNA expression was increased in Gh-pf mice relative to aCSF or Gh-lib. Gh-pf mice exhibited better glucose tolerance than aCSF or Gh-lib mice during a GTT, although both Gh-lib and Gh-pf increased insulin release during the GTT. Central acyl ghrelin infusion and pairfeeding also increased breakdown of liver glycogen and triglyceride, and regulated genes involved in hepatic lipid and glucose metabolism. Gh-pf mice had an increase in plasma blood glucose during a pyruvate tolerance test in relative to Gh-lib or aCSF mice. Our results suggest that under conditions of negative energy (Gh-pf mice) central acyl ghrelin engages a neural circuit that influences hepatic glucose function.

**Conclusion:** Metabolic status affects the ability of central acyl ghrelin to regulate peripheral glucose homeostasis.

## 673

### Increasing central exposure of an MC4 agonist potentiates food intake and body weight lowering transiently in lean mice

M. Fritsch-Fredin<sup>1</sup>, A. Lindblom<sup>1</sup>, P.R. Ceuppens<sup>2</sup>, E. Lundborg<sup>3</sup>, M. Ahlqvist<sup>3</sup>, M.H. Larsson<sup>1</sup>;

<sup>1</sup>Bioscience, CVMD, AstraZeneca R&D, Mölndal, Sweden,

<sup>2</sup>Discovery Statistics, AstraZeneca, Alderley Park, UK, <sup>3</sup>DMPK & Bioanalytical Chemistry, CVMD, AstraZeneca R&D, Mölndal, Sweden.

**Background and aims:** It is well known that Melanocortin-4 receptors (MC4r) are widely expressed inside (hypothalamus) and outside (circumventricular organs, brain stem) the blood brain barrier (BBB) and that hypothalamus play a central role in regulation of food intake (FI) and body weight (BW). Interestingly, MC4r agonistic peptides which do not penetrate the BBB, decrease FI and BW in rodents both after peripheral and central

administration. This study investigated whether increased CNS penetration potentiates the effects on FI and BW lowering of an orally administered small molecule MC4 agonist, cpd X.

**Materials and methods:** Female wildtype (WT) and Mdr1a/b-Bcrp triple targeted mutation (KO) mice on FVB background were dosed orally twice daily for 10 days with vehicle, or cpd X at 0.5 µmol/kg (only KO) or 15 µmol/kg. Individual FI and BW were recorded daily, including 2 base line days, while plasma and brain PK profiling were performed after 1 and 10 days of dosing. Lean and diet induced obese (DIO) mice on C57Bl/6 background were dosed twice daily with either vehicle or 30 µmol/kg cpd X. Analysis of Covariance, and 5% significance level tests based on Student's t-test were used for statistical validation (n=5-8).

**Results:** Cpd X dosed at 15 µmol/kg resulted in plasma exposure (AUC<sub>0-24h</sub>, day 1) of 5.7 and 3.3 h\*µmol/L in KO and WT mice, respectively, while the unbound brain/plasma ratio was more than 40 times higher in KO compared to WT mice. Cpd X significantly reduced FI and BW over the first 24hr of treatment in WT FVB (15 µmol/kg; FI; -20.2 ± 6.9%, BW; -2.3 ± 1.2%) and KO mice (FI; 0.5 µmol/kg -21.7 ± 6.3% and 15 µmol/kg -48.5 ± 8.9%, BW; 0.5 µmol/kg -0.9 ± 0.8% and 15 µmol/kg -5.1 ± 1.0%) relative to vehicle. The effect on FI was transient and returned towards vehicle levels after 48 hours especially in the KO mice. In contrast, BW lowering was sustained for the remainder of the study, especially for the WT, but also for the high dose KO mice. Cpd X (30 µmol/kg) reduced BW 10.3 ± 1.7% in DIO mice but had no effect in lean C57Bl/6 mice after 10 days treatment.

**Conclusion:** Higher brain exposure of cpd X was associated with greater transient reductions in FI and BW over the first 24 hours only. The initial effects support the hypothesis that CNS penetration of MC4r agonists potentiates FI/BW lowering. The lack of durable efficacy may be due to the FVB genetic background or the fact that the mice used were not obese. The latter is supported by the lack of BW reduction in lean versus DIO mice on C57Bl/6 background. Thus, lean FVB mice are unlikely to be predictive for the long-term effects on FI/ BW lowering in C57Bl/6 DIO mice.

## 674

### Lack of alpha-MSH in POMC neurons controls hepatic glucose production

M. Schneeberger<sup>1,2</sup>, A. Garcia<sup>1,3</sup>, D. Sebastian<sup>4,3</sup>, M. Imbernon<sup>5,6</sup>, C. Castaño<sup>1,3</sup>, Y. Esteban<sup>1,3</sup>, P. Garcia-Roves<sup>1,3</sup>, R. Gomis<sup>1,2</sup>, R. Nogueiras<sup>5,6</sup>, A. Zorzano<sup>4,3</sup>, M. Claret<sup>1,3</sup>;

<sup>1</sup>Laboratory of Diabetes and Obesity, IDIBAPS, Barcelona,

<sup>2</sup>Department of Endocrinology and Nutrition, Universitat de Barcelona,

<sup>3</sup>CIBER de Diabetes y Enfermedades Metabólicas Asociadas (CBIERDEM), Barcelona,

<sup>4</sup>Departament de Bioquímica i Biologia Molecular, IRB

Barcelona, <sup>5</sup>Departamento de Fisiología, Universidad de Santiago de

Compostela, <sup>6</sup>CIBER de la Obesidad y Nutrición (CIBERObn), Santiago de Compostela, Spain.

**Background and aims:** Anorexigenic proopiomelanocortin (POMC)-expressing neurons in the arcuate nucleus of the hypothalamus constitute a fundamental nexus in the neuronal hierarchy controlling whole-body energy balance. In particular, POMC neurons are able to sense and integrate a range of nutrient and hormonal cues informing about the energy status of the organism. Mitochondrial fusion, the merge of two mitochondria into one single compartment, is a key process implicated in mitochondria quality control and also in the bioenergetic adaptations to changes in environmental nutrient availability. A key protein mediating this fusion processes is Mitofusin 2 (Mfn2). We tested the hypothesis that Mfn2 in POMC neurons may be an important component of the sensing machinery implicated in the regulation of systemic glucose homeostasis.

**Materials and methods:** Mice lacking Mfn2 in POMC neurons (POMC-Mfn2KO) were generated and detailed phenotyping performed.

**Results:** Young 6-week old POMC-Mfn2KO mice showed unaltered body weight and adiposity when compared to control counterparts. However, they exhibited mild glucose intolerance and insulin resistance. In vivo glucose-stimulated insulin release and pancreatic morphometric parameters were unaltered in POMC-Mfn2KO mice. Mutant mice showed increased glucose levels in response to pyruvate test and upregulation of key hepatic gluconeogenic genes, enzymatic activity and proteins, consistent with enhanced hepatic glucose production (HGP). POMC-Mfn2KO mice also showed reduced insulin signaling in the liver indicating insulin resistance. These alterations were related to a dramatic reduction in alpha melanocyte stimulating hormone (αMSH), the main anorexigenic peptide released by POMC neurons.

ICV  $\alpha$ MSH administration was able to reverse most of the glucose metabolism alterations observed in POMCMfn2KO mice.

**Conclusion:** Deletion of Mfn2 in POMC neurons leads to defective glucose homeostasis independent of alterations in body weight. Our data indicate that the underlying cause is reduced  $\alpha$ MSH production that eventually leads to enhanced HGP.

### Impaired cognition coexists with hippocampal remodelling obstacles in LDL receptor knock-out mice

Y. Huang<sup>1</sup>, W.-Q. Xia<sup>2</sup>, S.-H. Wang<sup>2</sup>;

<sup>1</sup>Endocrinology, Yancheng First Peoples' Hospital,

<sup>2</sup>Endocrinology, Zhongda Hospital of Southeast University, Nanjing, China.

**Background and aims:** Evidences from clinical studies support that the abnormal cholesterol metabolism in the brain lead to the progress of cognitive dysfunction. Low-density lipoprotein receptor (LDLR) is well known for its role in regulating brain cholesterol homeostasis. We investigated whether LDLR plays roles in cognition and the related potential mechanisms.

**Materials and methods:** Twelve-month-old *Ldlr*<sup>-/-</sup> mice (n = 12) and wild-type littermates C57BL/6J (n = 14) maintained on a standard lab chow diet were subjected to the morris water maze test, sucrose consumption test, and open-field test when they were 4, 7, and 12 month-old, respectively. All animals were killed for the hippocampal remodeling studies, including the hippocampal neural stem cells (NSCs) proliferation, survival and differentiation studies, as well as synapse and apoptosis studies one week after the completion of all behavioral tests.

**Results:** The plasma cholesterol concentrations of *Ldlr*<sup>-/-</sup> mice increased moderately than C57BL/6J ( $P < 0.05$ ). The results of behavioral tests revealed that *Ldlr*<sup>-/-</sup> mice displayed impaired spatial memory, increased anhedonia and hyperactivity (all  $P < 0.05$ ), with decreased hippocampal BrdU<sup>+</sup> cells ( $P < 0.01$ ), BrdU<sup>+</sup>/NeuN<sup>+</sup> and BrdU<sup>+</sup> cells ratio ( $P < 0.05$ ), and reduced expression levels of synaptophysin as well as number of synaptophysin-immunoreactive presynaptic boutons in the hippocampal CA<sub>1</sub> and dentate gyrus areas (all  $P < 0.05$ ). Ultrastructural changes in DG area of the hippocampus were observed by transmission electron microscopy. Furthermore, the apoptosis occurred in the hippocampus of *Ldlr*<sup>-/-</sup> mice was discovered with the elevated Bax/Bcl-2 expression ratio at both mRNA and protein levels ( $P < 0.05$ ;  $P < 0.01$ , respectively), and increased activated-caspase3 level ( $P < 0.05$ ).

**Conclusion:** Deteriorations of brain cholesterol homeostasis induced by LDLR deficiency contributes to impaired spatial cognition, increased anhedonia and hyperactivity, probably via its negative effects on hippocampal remodeling, including reduced hippocampal NSCs proliferation, survival and differentiation as well as increased hippocampal vulnerability to apoptosis and synapse deficits.

### Poorly controlled cholesterol is associated with cognitive impairment in type 2 diabetic patients: a resting state fMRI study

S. Wang, W. Xia, P. Wang, Y. Yang;

Affiliated Zhongda Hospital of Southeast University, Nanjing, China.

**Background and aims:** Debate remains on whether hypercholesterolemia, which often exist in T2DM patients, is etiologically associated with cognitive impairment or dementia. This study aims to investigate whether poor controlled cholesterol impaired functional connectivity among patients with type 2 diabetes mellitus (T2DM).

**Materials and methods:** We used resting-state functional magnetic resonance imaging (fMRI) to investigate the functional connectivity of 25 T2DM patients with poor controlled cholesterol, 22 patients with target cholesterol and 26 well-matched healthy controls. Further correlation analysis was conducted between functional connectivity and clinical data as well as neuropsychological tests.

**Results:** The three groups did not statistically differ in age, sex, education level, BMI, blood pressure, fasting C-peptides, and triglyceride. Compared with target cholesterol patients, patients with poor controlled cholesterol had significantly higher serum cholesterol levels, LDL, LDL/HDL index and worse performance in TMT-B ( $p < 0.05$ ). Apart from these, no other significant

differences were noted between the two groups. Disordered functional connectivity of bilateral hippocampus-middle frontal gyrus (MFG) in the poor controlled group had been consistently shown when compared with the other two groups. Besides, the aberrant functional connectivity was associated with TMT-B scores as well as the LDL/HDL index in T2DM patients with poor controlled cholesterol.

**Conclusion:** T2DM patients with poor controlled cholesterol show impaired attention and executive function. Resting-state connectivity disturbance of the hippocampus-MFG may be involved in this process. Lowering the LDL/HDL ratio might be taken precaution against cognitive decrements.

### Impact of insulin resistance on memory performance, brain morphology and neurochemical profiles of the cortex and hippocampus

J.M.N. Duarte<sup>1</sup>, R. Gruetter<sup>1,2</sup>;

<sup>1</sup>Laboratoire d'imagerie fonctionnelle et métabolique, Ecole Polytechnique Fédérale de Lausanne, <sup>2</sup>Radiology, Universities of Lausanne and Geneva, Switzerland.

**Background and aims:** Insulin signalling is involved in metabolic regulation and synaptic plasticity in the central nervous system. Glucose neurotoxicity and reduced insulin signalling may impair brain structure and function leading to behavioural and cognitive alterations. In the present study we aimed at identifying brain metabolic modifications upon altered insulin signalling, underlying or leading to neurodegeneration and eventual structural and functional anomalies.

**Materials and methods:** Hippocampal-dependent memory of Wistar rats (n=12) and insulin-resistant Goto-Kakizaki rats (GK, n=8) was evaluated by measuring spontaneous alternation in a Y-maze at 2, 4 and 6 months of age. After behavioural testing at each age, magnetic resonance imaging (MRI) and spectroscopy (MRS) were performed under 2% isoflurane anaesthesia in oxygen gas, on a 14.1 T spectrometer using a home-built quadrature surface coil. MRI was performed with fast-spin-echo imaging with 4 s repetition time (TR) and 52 ms echo time (TE) and images were analysed with ImageJ. MRS was performed in hippocampal and cortical areas using Spin Echo, full Intensity Acquired Localized spectroscopy with TE=2.8 ms and TR=4 s. Spectra were analysed with LCmodel to quantify 20 metabolites composing the neurochemical profile. A glucose tolerance test (GTT) was performed by glucose administration (i.p. 2 g/kg) after fasting 18 hours.

**Results:** Fasting glycaemia was 3.4±0.1 and 4.3±0.2 mmol/L, while serum insulin was 4.0±1.1 and 5.9±1.6 mU/L, for Wistar and GK rats respectively. This resulted in a fasting glucose to insulin ratio of 4.8±1.8 for Wistar and 1.0±0.2 mol/U for GK rats, depicting a 79% reduction in insulin sensitivity. The GTT area under the curve was 11.6±1.7 and 42.3±3.4 mmol.h/L for Wistar and GK rats, respectively. At all tested ages, GK rats displayed impaired memory performance, as depicted by reduced Y-maze spontaneous alternation (-14% to -22% relative to controls,  $P < 0.01$ ). The brain of GK rats displayed smaller hippocampal volume (-18% to -20% of controls,  $P < 0.001$ ) and larger volume of lateral and third ventricles (+39% to +84% of controls,  $P < 0.001$ ). Interestingly, glucose intolerance correlated with hippocampal ( $r = -0.86$ ,  $P < 0.001$ ) and ventricular ( $r = 0.57$ ,  $P < 0.01$ ) volumes. Hippocampal volume further correlated with memory performance ( $r = 0.47$ ,  $P < 0.001$ ). The neurochemical profiles were affected by insulin resistance. Most notably, in comparison to controls, GK rats displayed reduced glutamine (-14% to -24%,  $P < 0.001$ ) and choline (-13% to -21%,  $P < 0.001$ ) in both regions. In the hippocampus, GK rats had higher taurine (+8% to +16%,  $P < 0.001$ ) and ascorbate (+38% to 48%,  $P < 0.001$ ) and reduced alanine (-19% to -30%,  $P < 0.01$ ) concentrations relative to controls. Cortical aspartate content was lower in GK relative to controls (-14% to 29%,  $P < 0.01$ ). Memory perfor-

mance was strongly correlated to hippocampal glutamine ( $r=0.62$ ,  $P<0.001$ ) and taurine ( $r=-0.526$ ;  $P<0.001$ ).

**Conclusion:** These data demonstrate that insulin-resistant GK rats are characterised by brain structural deterioration and metabolic modifications. Some metabolites of the measured neurochemical profile were associated to memory performance and therefore constitute non-invasive biomarkers of brain dysfunction in diabetic encephalopathy.

### Weight loss following bariatric surgery recovers decreased brain volumes but not increased fatty acid metabolism in the morbidly obese: a combined PET and VBM study

J.J. Tuulari<sup>1</sup>, H.K. Karlsson<sup>1</sup>, H. Numminen<sup>1</sup>, H. Honka<sup>1</sup>, J. Hirvonen<sup>2</sup>, P. Salminen<sup>3</sup>, M. Soinio<sup>4</sup>, P. Nuutila<sup>1</sup>, L. Nummenmaa<sup>5</sup>;

<sup>1</sup>PET Centre, Turku, <sup>2</sup>Department of Radiology, University of Turku,

<sup>3</sup>Department of Digestive and Acute Surgery, University of Turku and Turku University Hospital, <sup>4</sup>Department of Medicine, Turku University Hospital,

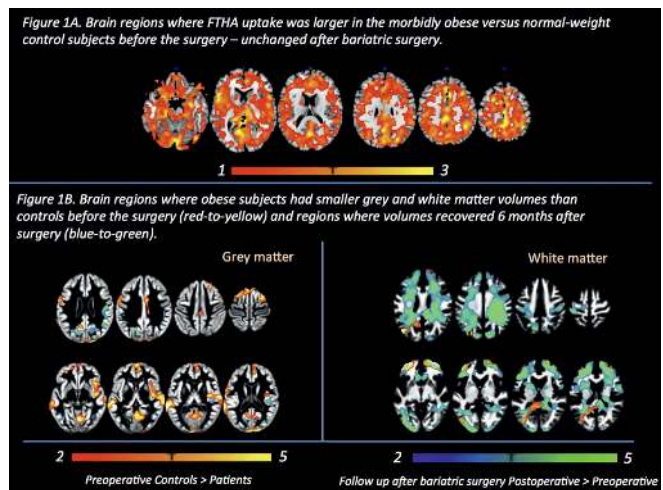

<sup>5</sup>Department of Biomedical Engineering and Computational Science, School of Science, Aalto University, Espoo, Finland.

**Background and aims:** Obese individuals have widespread cortical and sub-cortical atrophy in white (WM) and grey matter (GM). This may be due to metabolic changes that divert brain energy metabolism to abnormally high utilisation of glucose or fatty acids (FA) leading to increased oxidative stress and cellular damage. We studied the effects of weight loss due to bariatric surgery on brain FA uptake and GM / WM densities in obese subjects with and without type 2 diabetes. We hypothesized to find decrease of FA uptake and increase in WM and GM after the surgery.

**Materials and methods:** We studied 20 morbidly obese subjects before (meanBMI 41; SD 3,4) and six months after bariatric surgery (meanBMI 31,8; SD 4,2), and 13 age-matched healthy subjects (meanBMI 22,6; SD 2,8) with palmitate analogue [18F]-FTHA positron emission tomography. Brain fatty acid (FA) uptake was calculated using Gjedde-Patlak analysis. For the voxel-based morphometric analysis the T1-weighted MRI images were segmented into WM and GM using the VBM8 toolbox. Group differences in FA, WM and GM images were compared using independent samples t test in SPM8. Voxelwise associations between FA uptake and WM and GM volumes were analysed using Pearson correlations.

**Results:** Preoperatively, brain FA uptake was higher in morbidly obese versus lean subjects across the whole brain (Figure 1A) and this was not influenced by weight loss following surgery. Preoperatively the morbidly obese subjects had globally lowered grey and white matter density and both recovered following the surgery (Figure 1B). White or grey matter volumes and FA uptake were not associated. The observed differences were independent of diabetic state of the participants.

**Conclusion:** We show here that fatty acid uptake is increased in morbid obesity and that the increase coincides, but is not associated, with adverse structural changes in white matter. Brain atrophy reversed already within 6 months after bariatric surgery whereas no changes occur in brain FA uptake. This suggests that increased FA fluxes do not serve potential reversible causes of brain morphological changes in obesity and diabetes, but could be due to obesity related increased brain insulin sensitivity, which is normalized after bariatric surgery.

### Obesity decreases the expression of sirtuin proteins in adipose tissue of monozygotic twins, independent of genetic factors

J.S. Jukarainen, S. Heinonen, M. Tummers, E. Rappou, J. Rämö, M. Mundiany, A. Hakkarainen, N. Lundbom, J. Kaprio, K. Pietiläinen; University of Helsinki, Finland.

**Background and aims:** Sirtuins 1 and 3 (SIRT1, 3) are reported to be down-regulated in the subcutaneous adipose tissue (SAT) of obese individuals. Some studies associate human SAT SIRT1 and 3 expression with a favorable obesity phenotype. How much all of these associations reflect acquired obesity or are confounded by genetics and other factors is unclear. The objective of this study was to assess the roles of SAT SIRT1, 3 and 5 expression in obesity, insulin resistance and inflammation, controlling for genetic and early environmental factors by studying monozygotic (MZ) twins.

**Materials and methods:** Global gene mRNA expression, body composition and insulin sensitivity were assessed with Affymetrix U133 Plus 2.0 arrays, magnetic resonance imaging (MRI), DEXA scans and 75g oral glucose tolerance tests (OGTT) in healthy MZ twin pairs (N = 40) of which 26 pairs were discordant for BMI (BMI difference > 3 kg/m<sup>2</sup>). For statistical analyses,  $\Delta$ -variables depicting intrapair differences in different traits were calculated by subtracting the value of the leaner co-twin from the value of the heavier co-twin. These  $\Delta$ -variables were used to control for genetic and early environmental factors that the twins share.

**Results:** SIRT1, SIRT3 and SIRT5 were significantly downregulated in the SAT of heavier co-twins of BMI-discordant pairs. Out of adiposity variables,  $\Delta$ intra-abdominal fat volume was the best predictor of  $\Delta$ SIRT1 expression ( $r = -0.81$ ,  $P < 0.001$ ). Where SIRT3 and 5 were correlated with adiposity in the individual level ( $r = -0.30$  to  $-0.55$ ,  $P < 0.007$ ), these associations disappeared in the intrapair differences control setting ( $r = -0.01$  to  $-0.25$ ,  $P > 0.114$ ).  $\Delta$ SIRT1 and 5 expression was associated with insulin sensitivity during OGTT ( $r = -0.32$  to  $-0.47$ ,  $P < 0.047$ ).  $\Delta$ SIRT1 and 5 were significantly correlated with  $\Delta$ CRP levels,  $\Delta$ CD14 expression and various inflammatory gene expression pathways in SAT ( $r = -0.29$  to  $-0.52$ ,  $P < 0.042$ ). Contrary to earlier research,  $\Delta$ SIRT1 mRNA was not correlated with  $\Delta$ adiponectin mRNA ( $r = 0.12$ ,  $P = 0.469$ ).

**Conclusion:** Adiposity (especially IA fat) was strongly related to SAT SIRT1 independent of genetic or early environmental influences, whereas SIRT3 and 5's association with adiposity seems to be confounded by genetic or early environmental factors. SAT SIRT1 and 5 are negatively associated with insulin resistance and adipose tissue inflammation, even after controlling for twin-shared factors.

### Obesity is associated with lower expression of mitochondrial respiratory chain and mitoribosomal transcripts in adipose tissue in monozygotic twins

S. Heinonen<sup>1</sup>, J. Buzkova<sup>2</sup>, R. Kaksonen<sup>1</sup>, A. Hakkarainen<sup>3</sup>, J. Lundbom<sup>3</sup>, N. Lundbom<sup>3</sup>, J. Kaprio<sup>4,5</sup>, A. Rissanen<sup>1</sup>, A. Suomalainen<sup>2</sup>, K. Pietiläinen<sup>1</sup>, University of Helsinki;

<sup>1</sup>Obesity Research Unit, Diabetes and Obesity Research Programs Unit, <sup>2</sup>Research Program of Molecular Neurology and Department of Neurology, <sup>3</sup>Helsinki Medical Imaging Center, <sup>4</sup>FIMM, Institute for Molecular Medicine, <sup>5</sup>Finnish Twin Cohort Study, Department of Public Health, Hjelt Institute, Helsinki, Finland.

**Background and aims:** Low mitochondrial number and activity are suggested to be underlying factors in obesity and metabolic syndrome. However the functions of mitochondrial ribosomes, which are responsible for the synthesis of respiratory chain proteins, in acquired obesity are largely unknown.

**Materials and methods:** Rare young adult MZ twin pairs discordant ( $n = 26$ ,  $\Delta$ BMI > 3 kg/m<sup>2</sup>) and concordant for obesity ( $n = 14$ ,  $\Delta$ BMI < 3 kg/m<sup>2</sup>) identified from ten full birth cohorts of 22-32-year-old Finnish twins were examined. Abdominal body fat distribution was measured by magnetic resonance (MR) imaging, liver fat content by MR spectroscopy and insulin sensitivity

by the oral glucose tolerance test (OGTT). Mitochondrial ribosomal protein (MRP) expression (Affymetrix U133 Plus 2.0) and respiratory chain (RC) protein levels (Western) were quantified from subcutaneous adipose tissue biopsies.

**Results:** The obese (BMI 31.2±1.0kg/m<sup>2</sup>) and lean (25.3±0.9kg/m<sup>2</sup>) co-twins of the discordant pairs had a mean 18±0.5kg,  $p < 0.001$  difference in the body weight. The obese co-twins had significantly more subcutaneous (3810±420 vs. 6360±540cm<sup>3</sup>,  $p < 0.001$ ), intra-abdominal (1640±250 vs. 790±180 cm<sup>3</sup>,  $p < 0.001$ ) and liver fat (4.5±0.9 vs. 1.1±0.3%,  $p < 0.001$ ), and were more insulin resistant (HOMA-index 2.1±0.3 vs. 1.1±0.1,  $p < 0.01$ ), (AUC insulin 130±25 vs. 88±8,  $p = 0.055$ ), (Matsuda-index 5.9±0.7 vs. 8.6±0.9,  $p = 0.02$ ). They also had significantly lower expression levels of mitochondrial ribosome subunits in the adipose tissue, both small (MRPS mean ± SE -0.31±0.1) and large (MRPL 0.26±0.1) than the lean co-twins (MRPS 0.03±0.09,  $p < 0.001$ , MRPL = -0.04±0.1,  $p = 0.0021$ ). MRPS expression in individuals correlated negatively with HOMA-index ( $r = -0.45$ ,  $p < 0.001$ ), AUC insulin during OGTT ( $r = -0.57$ ,  $p < 0.001$ ), fasting triglycerides ( $r = -0.50$ ,  $p < 0.001$ ), and positively with Matsuda-index ( $r = 0.38$ ,  $p = 0.01$ ) and adiponectin ( $r = 0.53$ ,  $p = 0.02$ ). Large subunits (MRPL) correlated with AUC insulin ( $r = -0.45$ ,  $p < 0.001$ ), triglycerides ( $r = -0.41$ ,  $p < 0.001$ ) and adiponectin ( $r = 0.43$ ,  $p = 0.04$ ). The levels of RC complexes that are partly encoded by mitochondrial DNA were significantly reduced in the obese co-twins' fat (RC/ $\beta$ -TUBULIN i.e. RC per cellular proteins: CI  $p = 0.042$ , CIII  $p = 0.015$ , CIV  $p = 0.019$ , CV  $p = 0.036$ ) compared to the lean cotwin. The amount of CI ( $p = 0.050$ ), CIII ( $p = 0.011$ ) and CIV ( $p = 0.037$ ) were reduced also per mitochondria (RC/PORIN) in the obese co-twins. However, CII, which is encoded by nuclear DNA, was not different between the discordant co-twins. No differences were observed between the twins from the concordant pairs.

**Conclusion:** Mitochondrial ribosome protein expression and respiratory chain protein levels in adipose tissue are decreased in acquired obesity, together with a reduction in whole body insulin sensitivity. This suggests that down-regulation of mitochondrial biogenesis in adipose tissue plays a major role in the development of metabolic complications in obesity.

### Knock down of hormone-sensitive lipase in human adipocytes improves glucose metabolism via induction of de novo lipogenesis

M. Houssier<sup>1</sup>, P. Morigny<sup>1</sup>, S. Caspar-Bauguil<sup>1,2</sup>, L. Onfroy<sup>3</sup>, D. Beuzelin<sup>1</sup>, A. Mairal<sup>1</sup>, C. Postic<sup>4,5</sup>, H. Guillou<sup>6</sup>, D. Langin<sup>1,2</sup>;

Institut Cochin, Paris, <sup>6</sup>Toxicologie alimentaire, INRA UR66, Toulouse,

France.

**Background and aims:** We recently showed that partial inhibition of adipose tissue lipolysis improves glucose metabolism and insulin sensitivity in vivo. Adipose tissue de novo lipogenesis (DNL) has recently emerged as a determinant element of whole body insulin sensitivity. DNL enzymes are under the control of the transcription factor carbohydrate-responsive element binding protein (ChREBP). Here, we aimed at understanding the specific role of de novo lipogenesis (DNL) in the improvement of human adipocyte glucose metabolism when hormone-sensitive lipase (HSL) expression is diminished.

**Materials and methods:** Human mesenchymal adipose-derived stem (hMADS) cells were differentiated into adipocytes during 14 days of culture, and then used for metabolic analysis. Knock down was achieved by microporation of small interfering RNA against HSL (siHSL), ChREBP (siChREBP), and as a control green fluorescent protein (siGFP). Gene expression was quantified by RT-qPCR. Radiolabelled 2-deoxy-glucose was used to measure glucose uptake. Glucose oxidation and DNL (glucose carbon incorporation into fatty acids) were evaluated using radiolabelled glucose. Analyses of fatty acid composition in triglycerides and phospholipids were performed using capillary gas chromatography. Cells membranes were separated in 12 different fractions by sucrose gradient, and lipid raft composition was analyzed by Western blot. GM1 ganglioside was detected by Cholera toxin B.

**Results:** Compared to control, glucose transport and oxidation were increased in siHSL adipocytes. This improvement of glucose metabolism was accompanied by an increase of DNL both at the levels of key enzymes gene expression and metabolic flux. Notably, there was a marked induction of ChREBP in siHSL adipocytes. To establish the role of DNL in the improved glucose re-

sponse, ChREBP expression was knocked down. Although siChREBP alone did not affect glucose metabolism, we observed a significant decreased glucose transport, glucose oxidation and DNL in cells exposed to dual inhibition (siHSL/ChREBP) compared to simple inhibition (siHSL), suggesting an involvement of ChREBP in the effects mediated by HSL down regulation. Cellular lipidomic analyses demonstrated a clear qualitative change in fatty acid composition of phospholipids (PL) and triglycerides (TG) between the different siRNA conditions. The knock down of HSL led to an increase proportion of oleate (in PL and TG), in parallel to a decreased proportion of palmitoleate, while the knock down of ChREBP had the opposite. An intermediate profile was observed with dual inhibition (siHSL/ChREBP). These results could partly be explained by the changes in the expression of ELOVL6, an elongase responsible for the shift between C:16 to C:18 series. Interestingly, these changes in PL composition could contribute to the observed changes in lipid rafts associated to insulin signaling.

**Conclusion:** These data concur to a prominent role of DNL in the improved glucose metabolism observed when adipocyte HSL expression is diminished. Supported by: ANR ObeLip

### High fat diet induced adipose tissue inflammation by suppression of anti-inflammatory phospholipids

M.A. Osterhoff<sup>1,2</sup>, T. Frahnow<sup>1</sup>, A.-C. Seltmann<sup>1</sup>, A.S. Mosig<sup>3,4</sup>, K. Neunübel<sup>3</sup>, S. Sales<sup>5</sup>, J.L. Sampaio<sup>5</sup>, S. Hornemann<sup>1</sup>, M. Kruse<sup>1</sup>, A.F.H. Pfeiffer<sup>1,2</sup>;

<sup>1</sup>Clinical Nutrition, German Institute of Human Nutrition, Nuthetal,

<sup>2</sup>Endocrinology, Diabetes and Nutrition, Charité - University Medicine,

Berlin, <sup>3</sup>Molecular Haemostaseology, Jena University Hospital,

<sup>4</sup>Center for Sepsis Control and Care, Jena University Hospital, <sup>5</sup>Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany.

**Background and aims:** Little is known about the interdependency of complex gene-networks regulating the metabolism or signaling function of specific lipids in humans. Lipid metabolism and signaling might be either controlled genetically or by environmental factors. The aim of the study was to correlate lipidomic and genomic data of human subjects to identify specific gene-modules responsible for the regulation or connected with the function of specific lipid metabolites.

**Materials and methods:** In the NUGAT-Study (NUTriGenomic Analysis in Twins) all subjects (monozygous and dizygous twins) first received a carbohydrate-rich low-fat diet for 6 weeks (Clinical Investigation Day 1, CID1 thereafter), immediately followed by a high-fat diet for 1 week (CID2) and additional 5 weeks (CID3). At each CID periumbilical fat biopsies were taken for RNA isolation and Agilent 8x40K gene micro Arrays. Plasma was measured for lipid metabolites and cytokines (ELISA). Weighted gene Co-Expression Network Analysis (WGCNA) was used for identification of co-expressed gene-networks and their correlation with lipidome data. MetaCore was used to find potential roles of identified gene-sets.

**Results:** By analysis of the 5000 strongest regulated genes 10 gene-modules were identified whereof 1 revealed a high correlation ( $p < 0.00001$  to  $0.0006$ ) with CRP ( $r^2 = 0.31$ ), VEGF ( $r^2 = 0.39$ ), IL1ra ( $r^2 = 0.35$ ) and PP ( $r^2 = 0.3$ ). This gene-module contained genes which are known to play a role in processes like phosphatidylethanolamine acyl-chain remodelling, immune response, response to wounding, platelet activation and cytokine production. Furthermore, the gene-module was highly associated ( $r^2 = -0.32$ ,  $p < 0.0004$ ) with a lysophosphatidylethanolamine-metabolite (LPE), a phospholipid which has been previously suspected for its anti-inflammatory/anti-bacterial functions. In almost all volunteers LPE decreased during the high-fat diet (mean:  $-0.50$  /  $-0.70$  mmol/L), as well as IL1ra, while CRP and VEGF increased. Interestingly, the concentration of VEGF was very similar in monozygous twins, the heritability was calculated to approx. 90% during all CIDs.

**Conclusion:** While LPE and IL1ra, which is an anti-inflammatory cytokine, decrease during the high-fat diet, CRP and VEGF, which are markers for inflammation and migration of monocytes/macrophages, increase. Our data show for the first time in humans that high-fat diet induces inflammation by remodeling lipid biosynthetic pathways reducing anti-inflammatory and increasing inflammatory signaling. Specifically we identify downregulation of the anti-inflammatory phospholipid LPE as a mediator of inflammatory processes in the adipose tissue.

## 683

### Adipose tissue as an extrathyroidal source of TSHbeta

M. Moreno, J.M. Moreno-Navarrete, F. Ortega, G. Xifra, W. Ricart, J.M. Fernandez-Real;

Department of Diabetes, Endocrinology and Nutrition, Hospital of Girona, Spain.

**Background and aims:** In addition to the pituitary-thyroid circuit, additional TSH-related circuits may be functioning in extrathyroidal sites, including the immune system as evidenced by the ability of immune cells to produce TSH. A splice variant of TSH $\beta$  has been identified in the pituitary gland, thyroid and peripheral blood leukocytes.

**Materials and methods:** Either total (t-) or variant (v-) TSH $\beta$  gene expression were studied in 40 visceral (VAT) and in 42 subcutaneous adipose tissue (SAT) samples. The expression pattern was also evaluated in adipose tissue fraction cells (mature adipocytes (MA) and stromal vascular fraction (SVF)) and during adipocyte differentiation.

**Results:** Either t- or v-TSH $\beta$  were consistently detected in adipose tissue. t- and v-TSH $\beta$  expression were similar in MAs and SVFs. In SAT, t-TSH $\beta$  decreased during adipocyte differentiation. Perilipin 1, perilipin 2 (ADRP), FSP27 and several lipolytic gene expression (ATGL and MGLL) were negatively associated with t- and v-TSH $\beta$  in both SAT and VAT. Conversely, t- and v-TSH $\beta$  were positively associated with caveolin1 in SAT and VAT. Moreover t- and v-TSH $\beta$  from AT were positively associated with PGC1a and SIRT1 gene expression. Both TSH $\beta$  isoforms in AT were associated with an adverse lipid profile.

**Conclusion:** Current results provide novel evidence of adipose tissue as an extrathyroidal source of TSH $\beta$  in association with genes implicated in lipid droplet formation and lipolysis.

## 684

### Coxsackie and adenovirus receptor: novel depot-specific molecule in human adipose tissue?

G. Xifra<sup>1</sup>, M. Serrano<sup>1</sup>, M. Moreno<sup>1</sup>, J. Bassols<sup>2</sup>, J.M. Moreno-Navarrete<sup>1</sup>, F. Ortega<sup>1</sup>, W. Ricart<sup>1</sup>, J.M. Fernandez-Real<sup>1</sup>;

<sup>1</sup>Department of Diabetes, Endocrinology and Nutrition,

<sup>2</sup>Department of Pediatrics, Hospital of Girona, Spain.

**Background and aims:** The Coxsackie and Adenovirus receptor (CAR) plays a crucial role in both virus-related pathology and adenoviral gene therapy. Recent findings disclose important functional roles in immunity, inflammation, and tissue homeostasis.

**Materials and methods:** CAR gene expression was measured in two-hundred human adipose tissue samples (91 visceral (VAT) and 109 subcutaneous adipose tissue (SAT)). CAR was also studied in human adipose tissue fractions (mature adipocytes (MAs) and stromal vascular fraction (SVF)).

**Results:** CAR expression was 60-fold higher in VAT than in SAT ( $0.036 \pm 0.021$  vs  $0.0006 \pm 0.0005$ ,  $p < 0.0001$ ). In human adipose tissue fractions CAR gene expression in SVF was significantly higher than in MAs, either in SAT ( $0.0016 \pm 0.0002$  vs  $0.00038 \pm 0.00004$ ;  $p = 0.005$ ) or in VAT ( $0.0654 \pm 0.0043$  vs  $0.0249 \pm 0.0040$ ,  $p = 0.028$ ). In SAT, CAR expression was higher in obese than in lean subjects ( $0.00068 \pm 0.00060$  vs  $0.00048 \pm 0.00036$ ,  $p = 0.019$ ), whereas in VAT this pattern was only observed in men ( $0.043 \pm 0.022$  vs  $0.017 \pm 0.022$ ,  $p = 0.031$ ). In SAT, CAR was positively associated with BMI ( $r = 0.258$ ;  $p = 0.008$ ), fat mass ( $r = 0.288$ ;  $p = 0.003$ ), and inversely with the expression of genes such a PPARg ( $r = -0.381$ ;  $p = 0.035$ ), FAS ( $r = -0.333$ ;  $p = 0.011$ ) and Srebp-1c ( $r = -0.357$ ;  $p = 0.019$ ). In VAT, CAR was also positively associated with BMI ( $r = 0.460$ ;  $p = 0.036$ ) only in men, whereas negatively with the expression of the lipogenic gene S14 ( $r = -0.260$ ;  $p = 0.019$ ) and GLUT4 ( $r = -0.531$ ;  $p = 0.001$ ) and FABP5 ( $r = -0.350$ ;  $p = 0.015$ ).

**Conclusion:** The Coxsackie and Adenovirus receptor is detected in both adipose tissue depots, being preferentially expressed by VAT and stromal vascular cells. CAR expression was increased in AT from obese subjects, mainly in SAT, in inverse association with different lipogenic genes.

## 685

**Human adipose tissue microvascular endothelial cells (MVEC) regulate both tissue lipid in-/efflux and adipose cell PPAR $\gamma$  activation**

S. Gogg, U. Smith;

Department of Molecular and Clinical Medicine, University of Gothenburg, Sweden.

**Background and aims:** Animal studies have shown that specific deletion of PPAR $\gamma$  in endothelial cells (EC) leads to dyslipidemia and endothelial dysfunction. We have previously established a method to isolate and culture human primary MVEC from adipose tissue biopsies. We here asked if the MVEC and (pre)adipose cells cross-talk in the regulation of the bidirectional transport of fatty acids between the blood and the adipose cells. We also examined the putative cross-talk between MVEC and PPAR $\gamma$  activation in the adipocytes which, in turn, is required to store excess fat in the adipose cells.

**Materials and methods:** MVEC were extracted from human subcutaneous adipose tissue biopsies using immunomagnetic separation with anti-CD31 Dynabeads. Selected MVEC were cultured and expanded in EC growth medium and the remaining preadipocytes in DMEM-F12 prior to differentiation. Subsequently, these cells were co cultured. To promote lipid accumulation, the MVEC were incubated with 300  $\mu$ M oleic acid (OA) and/or 5  $\mu$ M Rosiglitazone (ROSI) for 48 h. Accumulated lipids in the cells were visualized with the fluorescent long-chain fatty acid analogue BODIPY-500/506 C1 C12 and microphotographs were taken with fluorescence or confocal microscopes. PPAR $\gamma$  activation was identified with the cell-based PPAR $\gamma$  reporter assay-GeneBLazer UAS-bla HEK 293H cells.

**Results:** Both lipid transporters CD36 and FABP4 were highly expressed in MVEC and they were further markedly increased by the addition of the PPAR $\gamma$  agonist ROSI. Interestingly, a similar effect was seen by just adding oleic acid (OA) which in turn, also increased PPAR $\gamma$  gene activation in MVEC and there was no additive effect of combining OA with ROSI. Furthermore, the stimulatory effect of OA was significantly inhibited by the PPAR $\gamma$  inhibitor GW9662, indicating that OA directly activated PPAR $\gamma$  in MVEC. We also examined the cross-talk between MVEC and adipose cells in co-cultures and confirmed the presence of a regulated bidirectional lipid transport (flux and efflux) between these cells. We then investigated the effect of OA in cultured adipocytes and, in contrast to MVEC. OA did not directly increase CD36, FABP4 or PPAR $\gamma$  expression. However, in co-cultures, the addition of the MVEC insert increased the expression of both lipid transporters as well as that of PPAR $\gamma$  suggesting that MVEC secreted a PPAR $\gamma$  agonist to which the adipocytes responded. To further verify this, we incubated the PPAR $\gamma$  reporter cells (reporter assay) with MVEC conditioned media or with equivalent naïve media. Indeed, PPAR $\gamma$  activation was significantly increased when the cells were incubated with MVEC conditioned media as compared with naïve media. This was consistent for both basal culture medium and was further increased by the OA-containing media.

**Conclusion:** These findings support the presence of an intimate cross-talk between adipose cells and MVEC in the regulation of the bidirectional transport of fatty acids. Furthermore, we can here also show for the first time that MVEC secrete a PPAR $\gamma$  ligand targeting both the MVEC and the adipose cells and that this process is further increased in the MVEC by fatty acids.

## 686

**The effect of 2 days very-low calorie diet on cytokines in adipose tissue and in plasma in obese women**

M. Siklova, V. Mayerova, L. Rossmeislova, J. Kracmerova, E. Czudkova, V. Stich;

Department of Sport Medicine, 3rd Faculty of Medicine, Charles University in Prague, Czech Republic.

**Background and aims:** A number of bioactive molecules produced by adipose tissue (AT), such as cytokines, chemokines and acute phase proteins, have been suggested as a possible link between obesity and insulin resistance. It has been shown that circulating adipokines are elevated in obese and diabetic subjects. Very-low-calorie diets (VLCD) are used as dietary intervention to achieve a rapid weight loss in obesity treatment and were shown to improve insulin sensitivity (IS) as soon as after 2 days of intervention. The aim of our study was to investigate the response of pro- and anti-inflammatory cytokines in AT and plasma after 2 and 28 days of VLCD and its possible relationship to IS improvement.

**Materials and methods:** 16 obese pre-menopausal women (BMI 32.5  $\pm$  3.6 kg/m<sup>2</sup>) followed 800 kcal/d VLCD for 28 days. Anthropometric measurements, blood sampling and biopsy of subcutaneous abdominal AT were performed before diet and at the day 2 and 28 of VLCD. To evaluate insulin sensitivity, euglycemic-hyperinsulinemic clamp was performed at each phase and Homeostatic model assessment of insulin resistance (HOMA-IR) was calculated. IL-6, IL-1 $\beta$ , IL-8, IL-10, MCP-1, and TNF $\alpha$ , were analyzed in plasma and in conditioned media of AT explants using multiplex immunoassay at Luminex 100. AT mRNA expressions of cytokines and lipogenic genes DGAT2, SDC, and FASN were analyzed.

**Results:** At day 2 IS increased as evaluated by HOMA-IR but not by glucose disposal rate. At day 28 both indices of IS increased. Fat mass was not changed at day 2, while it decreased at day 28 (38 $\pm$ 8.5 kg vs. 32 $\pm$ 7 kg). At day 2, levels of IL-1 $\beta$ , IL-6 and IL-10 were increased in plasma, while the secretion and mRNA expression of all cytokines in AT was unchanged. In contrast, at day 28, secretion and mRNA expression of all cytokines in AT was increased, while their plasma levels were not different from the pre-diet condition. Expression of lipogenic genes DGAT2, SCD and FASN decreased at day 2 (DGAT2, p=0.04; SCD, p=0.005; FASN, p=0.05) and their decrease was further enhanced at day 28 (p=0.001 for all genes).

**Conclusion:** Improvement of IS after 2 days of VLCD was not associated with changes in expression and secretion of cytokines in AT. The concomitant increase in plasma cytokines suggests a contribution of non-adipose tissues. The lipogenesis in AT was down-regulated at the early phase of the diet.

**The number of microRNA target sites identifies those transcripts that will experience the most dramatic downregulation in adipose tissue from obese subjects after weight loss**E.J. Ortega<sup>1</sup>, J.M. Mercader<sup>2</sup>, J.M. Moreno-Navarrete<sup>1</sup>, L. Nonell<sup>3</sup>, E. Puigdecant<sup>3</sup>, G. Xifra<sup>1</sup>, M. Sabater<sup>1</sup>, M. Moreno<sup>1</sup>, N. Fuentes-Batllevell<sup>1</sup>, D. Mayas<sup>4</sup>, N. Moreno-Castellanos<sup>5</sup>, W. Ricart<sup>1</sup>, F.J. Tinahones<sup>4</sup>, M. Malagón<sup>5</sup>, J.M. Fernández-Real<sup>1</sup>;<sup>1</sup>Department of Diabetes, Endocrinology and Nutrition (UDEN), Institut d'Investigació Biomèdica de Girona (IdIBGi), <sup>2</sup>Joint IRB-BSC program on Computational Biology, Barcelona, <sup>3</sup>Institut Hospital del Mar d'Investigacions Mèdiques (IMIM), Barcelona, <sup>4</sup>Service of Endocrinology and Nutrition, Hospital Clínico Universitario Virgen de Victoria de Malaga, <sup>5</sup>Department of Cell Biology, Physiology and Immunology, Instituto Maimonides de Investigaciones Biomedicas de Cordoba (IMIBIC)/Reina Sofia University Hospital, University of Cordoba, Spain.

**Background and aims:** Bariatric surgery is an excellent therapeutic approach to elucidate the pathophysiology of obesity-associated metabolic disturbances. The identification of abnormal function and gene expression patterns regulated by multiple microRNAs (miRNAs) may be useful in this context. In this study we aimed to identify changes in the genome wide adipose tissue (AT) transcriptome linked to the miRNA profile after surgery-induced weight loss.

**Materials and methods:** Whole genome and miRNA expression patterns were assessed in subcutaneous AT of 16 morbidly obese women before and after surgery-induced weight loss. Validation of both genome wide and miRNA microarrays was made by quantitative real-time PCR using both longitudinal and cross-sectional cohorts. Three alternative datasets were downloaded from public repositories and analyzed to check for reproducibility. Analyses in macrophages and differentiated human adipocytes were performed in vitro to try to comprehend the associations found in human AT. **Results:** Five thousand and eighteen different probe sets identified significant variations in gene expression. Only 15 miRNAs differed in the comparison before-after surgery-induced weight loss. Functional analysis revealed significant changes in cell cycle, development and proliferation, in lipid metabolism, and the inflammatory response, as further confirmed by in vitro results. Interestingly, when transcriptomes were analyzed taking into account the presence of miRNA target sites, the mRNAs that experienced the most dramatic changes were precisely those with more miRNA target sites (p=10-195), being significantly down-regulated after surgery-induced weight loss.

**Conclusion:** Current findings suggest that surgery-induced weight loss is associated with an improvement in post-transcriptional modulation by miRNAs, in parallel to changes in inflammatory status and lipid metabolism of obese AT.

**Relationship between muscle/adipose tissue morphology, insulin sensitivity and beta cell function in diabetic and nondiabetic obese patients: effects of bariatric surgery**

S. Camastra<sup>1</sup>, A. Vitali<sup>2</sup>, M. Anselmino<sup>3</sup>, A. Gastaldelli<sup>4</sup>, R. Bellini<sup>3</sup>, R. Berta<sup>3</sup>, S. Baldi<sup>1</sup>, B. Astiarraga<sup>1</sup>, E. Barsotti<sup>1</sup>, M.C. Zingaretti<sup>2</sup>, S. Cinti<sup>2</sup>, E. Ferrannini<sup>1</sup>;

<sup>1</sup>Dept. Clinical & Experimental Med., University of Pisa,

<sup>2</sup>Univ Politecnica Marche, Ancona, <sup>3</sup>Bariatric Surg. Unit, AOUP, Pisa,

<sup>4</sup>Inst Cl Phys, CNR, Pisa, Italy.

**Background and aims:** Obesity is associated with low-grade inflammation in adipose tissue (AT), high lipolytic activity, ectopic fat deposition and insulin-resistance (IR). Bariatric surgery leads to major fat mass loss and improvements in IR and  $\beta$ -cell function ( $\beta$ -GS). Aim of this study was to relate the improved metabolic status after Roux-en-Y gastric bypass (RYGB) to the morphological changes of subcutaneous (SAT) and visceral AT (VAT) and skeletal muscle.

**Materials and methods:** 14 non-diabetic (ND) and 14 type 2 diabetic (T2D) obese patients (BMI =  $50 \pm 2$  and  $52 \pm 2$  kg/m<sup>2</sup>) received a euglycaemic clamp study (to measure IR) with 2H5-glycerol infusion (to measure lipolysis) and a mixed meal test (to measure insulin secretion and  $\beta$ -GS) before and one year after RYGB. During RYGB, VAT (omental), SAT and rectus abdominis samples were excised for light (LM) and electron microscopy (EM) analysis.

**Results:** Before surgery, both T2D and ND patients showed marked IR and enhanced lipolysis, T2D also had impaired  $\beta$ -GS. On LM, perivascular and interfibrillar muscle fat content was similar in ND and T2D; intramyocellular fat was more abundant in T2D than ND patients (1.0 [1.5] vs 0.1 [0.5] units,  $p=0.008$ ). In SAT, adipocyte area and density of crown-like structures (CLS) were similarly increased in T2D and ND. In VAT, adipocyte area (5806 [1793] vs 5056 [1320],  $p=0.01$ ) and CLS density (3.60 [7.31] vs 0.00 [1.75],  $p=0.0002$ ) were higher in T2D than ND.  $\beta$ -GS was inversely related to VAT adipocyte area ( $r = -0.58$ ,  $p=0.004$ ) and CLS density ( $r = -0.50$ ,  $p=0.02$ ). On EM, SAT and VAT adipocytes showed necrotic material, fibrosis, thickened capillary basal membrane, degenerating adipocytes with thin cytoplasm with extrusion of free lipids in interstitium and small mitochondria. In T2D patients, VAT and SAT blood capillaries contained neutrophils. After RYGB (33% weight loss), IR and lipolysis were markedly improved, equally in ND and T2D ( $p<0.003$  for all). In T2D,  $\beta$ -GS was improved ( $p=0.04$ ) but not normalized. By LM, in both ND and T2D fat deposits were reduced in all muscle locations ( $p<0.03$ ) as were adipocyte area and CLS density in SAT ( $p<0.0001$ ). By EM, SAT adipocytes were generally smaller, in advanced state of delipidation, with thicker cytoplasm rim and more mitochondria. In T2D, capillaries were free of neutrophils. In the whole dataset, SAT adipocyte area and CLS density were strongly related to BMI, IR and lipolysis ( $r^2$ 's between 0.40 and 0.81, all  $p<0.0001$ ).  $\beta$ -GS was related to SAT CLS density ( $r = 0.46$ ,  $p=0.006$ ) and intramyocellular fat ( $r = 0.53$ ,  $p=0.001$ ); the post-surgery increase in  $\beta$ -GS was related to the concomitant decrease in intramyocellular fat ( $r = -0.79$ ,  $p=0.002$ ).

**Conclusion:** In morbid obesity, fat accumulation results in adipocyte enlargement, lipid extrusion, macrophage infiltration and cell necrosis. In both T2D and ND, these changes correlate with IR and lipolysis; in VAT, histology is worse in T2D than ND and correlates with  $\beta$ -cell dysfunction. After surgically-induced major weight loss, AT/muscle histology and IR improve in parallel; in T2D, however,  $\beta$ -cell glucose sensitivity remains abnormal despite the restoration of tissue morphology, suggesting a different origin for  $\beta$ -cell incompetence.

Tuebingen, Germany, <sup>2</sup>CAS Key Laboratory of Separation Science for

Analytical Chemistry, Dalian Institute of Chemical Physics, Chinese

Academy of Sciences, Dalian, China, <sup>3</sup>German Center for Diabetes Research (DZD), Tuebingen, Germany.

**Background and aims:** Brown adipose tissue (BAT) has a vital function as organ of non-shivering thermogenesis in small mammals and neonates and may also be of relevance in adult humans. Besides the unique expression of uncoupling protein 1, BAT also differs from white adipose tissue (WAT) by containing more mitochondria and multilocular lipid droplets. To obtain a more detailed understanding of the differences between WAT and BAT on the level of lipid metabolism, we performed an extensive lipid profiling of BAT and two different WAT depots, gonadal (GAT) and subcutaneous adipose tissue (SAT).

**Materials and methods:** Interscapular BAT, femorogluteal SAT and GAT were quickly dissected from 12 C57Bl/6N mice (6 female and 6 male, 11 week-old) following anaesthesia and decapitation. For lipid extraction, 10 mg of frozen fat were homogenized in 75% ethanol and further extracted with MTBE. Nontargeted lipidomics analysis was performed on a Waters ACQUITY UPLC system coupled with an ABI Sciex tripleTOFTM 5600 plus mass spectrometer. High resolution tandem MS was utilized to enhance lipid identification. All detected lipids were quantified by normalization to internal standards.

**Results:** In total, 329 lipid species from 15 classes, covering FFA, DG, TAG and several phospho- and sphingolipid classes, could quantitatively be detected. In addition, acyl (alkenyl, alkyl) chains could be assigned to all phospho- and sphingolipids. Overall, WAT contained significantly more TAG while BAT contained more phospholipids and sphingomyelin. Interestingly, 6 of the 11 lipids (9 PE- and 2 PC-species) that showed the highest specificity for BAT contained docosahexaenoic acid. The key differences between the two WAT depots were a higher amount of TAG and lower content of several phospholipid classes in GAT. Interestingly, multivariate PCA analysis led to a clear separation of BAT samples from female and male mice. By analysing the acyl chain composition of the lipids contributing most to this separation, a set of fatty acids including arachidonic and stearic acid was found to occur more frequently in females, while another set including linoleic and palmitic acid was higher in males. Despite the differences between female and male GAT that could be expected in the light of their different anatomical location (ovarial/epididymal), the lipid composition of GAT was less sex-specific than the one of BAT.

**Conclusion:** By MTBE-based extraction followed by high-resolution LC-tandem-MS analysis, we were able to generate detailed lipid patterns of brown and two white adipose tissue depots of female and male mice. When comparing the lipid composition of the different depots, the key findings were, firstly, clear adipose type-specific differences between BAT and WAT, and, secondly, sex-specific differences in phospholipid composition which were most prominent for BAT. By obtaining the composition of all phospho- and sphingolipids, we could identify common FFA residues characterizing the most discriminant lipid species, a prerequisite to explain the metabolic processes underlying the depot- and sex-specific differences observed.

**Peri-droplet mitochondria in brown adipocytes form an exclusive subpopulation of mitochondria**

K. Mahdavian<sup>1</sup>, G. Twig<sup>2</sup>, J.D. Wikstrom<sup>3</sup>, D. Chess<sup>1</sup>, M. Liesa<sup>1</sup>,

K. Trudeau<sup>1</sup>, O. Shirihai<sup>1</sup>;

<sup>1</sup>Boston University School of Medicine, USA, <sup>2</sup>Chaim Sheba Medical Center,

Tel-Hashomer, Israel, <sup>3</sup>Stockholm University, Sweden.

**Background and aims:** Mitochondria play essential roles in brown adipose tissue differentiation and function. We have recently shown that mitochondrial dynamics is a physiological regulator of adrenergically-induced changes in energy expenditure. Moreover, we and others report that changes in mi-

tochondrial architecture may represent adaptive changes to bioenergetics needs. Conditions requiring high mitochondrial ATP synthesis capacity and/or efficiency are associated with mitochondrial elongation. Whereas conditions of excess energy supply and low ATP demand acutely induce mitochondrial fragmentation. However it remains unclear if diversity in subcellular mitochondrial architecture may play a role in generating functional specialization of subpopulations of mitochondria within the cell. We rationalized that the brown adipocyte may shed light on this question as its mitochondria are required for various and competing tasks, such as lipogenesis and beta oxidation as well as ATP synthesis and uncoupling, raising the possibility that the brown adipocyte may harbor a diverse set of mitochondria which are structured to fit different functions.

**Materials and methods:** Brown pre-adipocytes were harvested from 3-week-old male C57BL/6J mice and differentiated in culture. Mitochondrial membrane potential, motility and morphology were measured using TMRE and PAGFP respectively with Zeiss LSM 710 confocal microscope. NADH autofluorescent was used to measure the NADH content of the mitochondria. Protein import and turnover were measured using MitoTimer probe.

**Results:** Mitochondria in brown adipocyte are divided to two different populations, mitochondria with submicron proximity to the lipid droplet or Peridroplet (PD) mitochondria, and mitochondria that are located at least 5µm away from the vicinity of a lipid droplet or Cytoplasmic (C)mitochondria. Photo-conversion of matrix targeted photoactivatable GFP shows that these two populations rarely mix and that mitochondria remain faithful to the lipid droplet they adhere to and do not share their matrix content with other mitochondria, nor do they switch their affiliation from one group to another. These studies also show that PD-mitochondria are more elongated while the C-mitochondria tend to be smaller in size suggesting a more coupled respiratory function and involvement in ATP synthesis. In addition, using TMRE, we found that PD-mitochondria in brown adipocytes but not in other lipid-containing cells are in different energetic state than C-mitochondria. Ratio-metric imaging of membrane potential and NADH/NAD ratio show that PD-Mitochondria have higher NADH/NAD ratio and more polarized membrane potential. Protein import and turnover studies using MitoTimer also indicate that PD-mitochondria have a higher rate of protein import and biogenesis, in agreement with the hyperpolarized state. Altogether these observations support a hypothesis that PD-mitochondria have a higher TCA cycle activity.

**Conclusion:** These data suggests that peridroplet mitochondria represent a functionally exclusive subpopulation of mitochondria in terms of biogenesis and function. This may also demonstrate that the unique architectural characteristics of cells in diverse bioenergetics states may apply subcellularly to a diverse set of mitochondria within the cell, fulfilling different metabolic functions.

## 691

### Diet-induced interleukin-15 promotes obesity by inhibiting adaptive thermogenesis in adipose tissues

S. Ramanathan<sup>1</sup>, G. Lacraz<sup>1</sup>, Y. Cepero-Donates<sup>1</sup>, M. Mayhue<sup>1</sup>, M.-F. Langlois<sup>2</sup>, M. Rola-Pleszczynski<sup>1</sup>, S. Ilangumaran<sup>1</sup>;

<sup>1</sup>Pediatrics, Immunology Division,

<sup>2</sup>Medicine, Endocrinology Division, University of Sherbrooke, Canada.

**Background and aims:** Inflammatory cytokines are implicated in the pathogenesis of obesity. Interleukin-15 (IL-15) is an inflammatory cytokine secreted by many cell types. IL-15 is also produced during physical exercise by skeletal muscle and has been reported to reduce weight gain in mice. Contrarily, our findings on IL-15 knockout (KO) mice indicate that IL-15 promotes obesity. The aim of this study is to investigate the molecular and cellular mechanisms underlying the pro-obesity role of IL-15 in adipose tissues.

**Materials and methods:** C57BL/6 wildtype and IL-15 KO mice were maintained on high fat diet (HFD) or normal control diet. After 16 weeks, body weight, adipose tissue and skeletal mass, serum lipid levels and gene expression in the adipose tissues were evaluated. Primary cultures of brown and white adipocytes were studied using the Seahorse cell metabolism analyzer to evaluate oxygen consumption rates. IL15 gene expression and the expression of inflammation markers were studied in visceral adipose tissues obtained from patients undergoing bariatric surgery.

**Results:** We show that IL-15 deficiency prevents diet-induced weight gain and accumulation of lipids in visceral and subcutaneous white adipose tissues. Circulating levels of cholesterol and non-esterified fatty acids were elevated in wildtype mice but not in IL-15 KO mice. The adipose tissues of IL-15 KO mice showed decreased expression of pro-inflammatory cytokines, chemokines and macrophage markers CD68 and F4/80. Gene expression

analysis also revealed elevated expression of genes associated with adaptive thermogenesis in the brown and subcutaneous adipose tissues of IL-15 KO mice. Accordingly, oxygen consumption was increased in the brown adipocytes from IL-15 KO mice. Adipose tissues from obese diabetic patients showed a tendency towards increase in the expression of IL-15.

**Conclusion:** Our results clearly show that IL-15 plays a pathogenic role in obesity. High fat diet-induced IL-15 promotes accumulation of fat in the white adipose tissues by inhibiting lipid utilization via adaptive thermogenesis. IL-15 also promotes inflammation in adipose tissues that could sustain chronic inflammation leading to obesity-associated metabolic syndrome.

### Effect of the n-3 LC-PUFA EPA on white-to-brown transition of primary human adipose-derived stem cells

M. Elsen<sup>1</sup>, M.H. Schoemaker<sup>2</sup>, E.A.F. van Tol<sup>2</sup>, T. Romacho<sup>1</sup>, J. Eckel<sup>1</sup>;

<sup>1</sup>German Diabetes Center, Duesseldorf, Germany,

<sup>2</sup>Mead Johnson Nutrition, Nijmegen, Netherlands.

**Background and aims:** Promoting the induction of brite adipocytes and thereby increasing energy expenditure may protect against the development of obesity. We have recently shown that both bone morphogenetic protein (BMP)4 and BMP7 induce browning of primary human adipose-derived stem cells (hASCs). Long-chain polyunsaturated fatty acids (LC-PUFAs) and their metabolites are potential PPAR $\gamma$  ligands and chronic activation of PPAR $\gamma$  is known to promote browning of white adipocytes. Furthermore, dietary n-3 LC-PUFAs have been shown to increase oxidative metabolism in white adipose tissue (AT) as well as adaptive thermogenesis in brown AT, suggesting a possible role for n-3 LC-PUFAs in the white-to-brown transition. Therefore, we investigated the direct effects of the n-3 LC-PUFA eicosapentaenoic acid (EPA) on browning of hASCs in comparison to oleic acid (OA) as non-essential fatty acid and BMP4.

**Materials and methods:** Primary hASCs were isolated from the subcutaneous depot of different donors and challenged with EPA (20µM) or OA (20µM) during adipocyte differentiation (12 days). Cells treated with the known inducer of browning BMP4 (50 ng/ml) served as a positive control.

After 12 days of differentiation, lipid accumulation was measured by Oil Red O staining and gene expression was assessed by qRT-PCR.

**Results:** Chronic treatment of hASCs with EPA but not OA increased lipid accumulation to similar extents as BMP4. The BMP4-mediated enhancement of PPAR $\gamma$  and C/EBP $\alpha$  expression was absent in OA-treated hASCs, while the n-3 PUFA EPA slightly increased the expression of PPAR $\gamma$  and C/EBP $\alpha$ . Neither EPA nor OA affected the expression of the white-specific marker Tcf21, which was significantly reduced by BMP4. Remarkably, UCP1 expression was strongly enhanced (7-fold) after EPA exposure, while OA did not induce UCP1 expression. This EPA-mediated effect on UCP1 expression was comparable to that of BMP4.

**Conclusion:** In conclusion, chronic exposure to physiological concentrations of the n-3 LC-PUFA EPA induces browning of hASCs derived from white AT, providing a potential mechanism for the beneficial effects of dietary n-3 LC-PUFAs on metabolism. The non-essential fatty acid OA has no effect on white-to-brown transition. The underlying mechanisms of the effect of the essential n-3 fatty acid EPA on browning will be investigated in future studies. *Supported by: Mead Johnson Nutrition, FP7-EU Marie Curie-IEF (ADDIO-PIEF-2012-328793)*

## 693

### PPAR $\gamma$ and PPAR $\alpha$ agonists induce white-to-brown conversion of human white adipocytes along with a metabolic shift from glucose to fatty acid oxidation

V. Barquissau<sup>1</sup>, D. Beuzelin<sup>1</sup>, M. Giroud<sup>2</sup>, G. Béranger<sup>2</sup>, A. Mairal<sup>1</sup>, B. Roussel<sup>1</sup>, D. Pisani<sup>2</sup>, J.-C. Chambard<sup>2</sup>, E.-Z. Amri<sup>2</sup>, D. Langin<sup>1</sup>;  
<sup>1</sup>UMR1048-I2MC, INSERM Toulouse, <sup>2</sup>CNRS, Nice, France.

**Background and aims:** Since it was demonstrated that adult humans possess active thermogenically-competent brown adipose tissue, fighting obesity and its complications through increasing adipose tissue expenditure has emerged as a putative strategy. “Browning” of white adipose tissue in rodents is suggested to be protective against obesity-induced insulin resistance. However, the capacity of human white adipocytes to acquire a brown/beige/brite metabolism has not yet been demonstrated. We aimed at identifying the molecular and metabolic changes associated with the white-to-brown conversion of human mesenchymal adipose-derived stem (hMADS) cells following treatment by PPAR $\gamma$  (rosiglitazone, Rosi) or PPAR $\alpha$  (GW7647, GW) agonists.

**Materials and methods:** hMADS cells were differentiated into white adipocytes within 14 days. Thereafter, Rosi or GW were added for 4 additional days before molecular (microarrays, qPCR and Western blot) and metabolic measurements using radiolabelled tracers were carried out.

**Results:** Both PPAR $\gamma$  and PPAR $\alpha$  agonists promoted browning of white hMADS adipocytes, as evidenced by higher expression of UCP1 mRNA (29-fold and 18-fold respectively,  $p < 0.01$ ) and protein (18-fold and 13-fold respectively,  $p < 0.05$ ), and of other brown or beige/brite adipocyte markers (CIDEA, PGC-1 $\alpha$ , TBX1,  $p < 0.05$ ). Microarray analysis confirmed by qPCR experiments revealed that treatments stimulated both the fatty acid synthesis and oxidation pathways. Functional measurements were consistent with gene expression data, showing that Rosi and GW increased both fatty acid complete oxidation (by 70% and 66% respectively,  $p < 0.05$ ) and fatty acid incorporation into triglycerides (by 30%,  $p < 0.01$  and  $p < 0.05$  respectively). The higher fatty acid metabolism was associated with a decrease of both glucose uptake ( $p < 0.05$  and  $p < 0.01$  with Rosi and GW, respectively) and oxidation ( $p < 0.05$  with Rosi and GW). Those metabolic changes occurred without modification of triglyceride cellular content.

**Conclusion:** PPAR $\gamma$  and PPAR $\alpha$  activation in differentiated human white adipocytes promotes browning associated with a metabolic shift from glucose to fatty acid oxidation. This striking metabolic remodeling favoring fatty acid use relies on molecular mechanisms which require further investigation. *Supported by: ANR miRBAT, EU FP7 DIABAT*

## 694

### EHMT1 and the stimulation with elevated catecholamines can reinduce the perirenal brown adipocytes possessing classical features in adult humans

G. Nagano<sup>1</sup>, H. Ohno<sup>1</sup>, T. Shiwa<sup>2</sup>, K. Oki<sup>1</sup>, M. Yoneda<sup>1</sup>;  
<sup>1</sup>Department of Molecular and Internal Medicine, Hiroshima University,  
<sup>2</sup>Hiroshima City Asa Hospital, Japan.

**Background and aims:** Obesity, cause of various metabolic diseases such as type 2 diabetes, results from a chronic imbalance between energy intake and expenditure. Brown adipose tissue (BAT) generates heat against cold and obesity. According to previous reports, the adrenergic stimulation activates the thermogenic program of brown adipocytes. In addition, we previously demonstrated that EHMT1 is an essential methyltransferase in the PRDM16 complex and controls brown adipose cell fate. However, there is a current lack of studies in humans auging the perirenal BAT and EHMT1.

**Materials and methods:** We collected adipose tissues from perirenal regions in adult patients with pheochromocytoma ( $n = 11$ ) and those with non-functioning adrenal tumor ( $n = 7$ ). We performed gene expression analysis of perirenal BAT using quantitative RT-PCR and protein analysis by using western blotting for PRDM16, EHMT1 and UCP1. Morphological analyses were performed by H&E staining and immunohistochemistry.

**Results:** The expression of BAT associated markers including Ucp1 ( $p < 0.029$ ), Cidea ( $p < 0.0046$ ), Elovl3 ( $p < 0.015$ ) were significantly higher in patients with pheochromocytoma. Morphological analysis showed that brown adipocytes were more apparent in patients with pheochromocytoma. These adipose cells possessed the molecular signatures of murine classical brown adipocytes. Furthermore, the upregulation of not only PRDM16 but also EHMT1 accorded with the upregulation of BAT associated markers at both the mRNA and the protein levels.

**Conclusion:** We find that the stimulation with elevated catecholamines and both PRDM16 and EHMT1 can collaboratively reinduce the perirenal brown adipocytes in adult humans, and these cells have the molecular signatures of classical brown adipocytes.

## 695

### MSCA1 is a functional markers of human brite adipogenesis: deleterious effect of inflammation on brite adipogenesis

D. Esteve<sup>1</sup>, N. Boulet<sup>1</sup>, C. Belles<sup>1</sup>, S. Ledoux<sup>2</sup>, M. Coupaye<sup>2</sup>, B. Castel<sup>2</sup>, A. Bouloumié<sup>1</sup>, J. Galitzky<sup>1</sup>;  
<sup>1</sup>Metabolism and obesity, INSERM U1048/I2MC, Toulouse,  
<sup>2</sup>Center Support of Obesity, Hopital Louis Mourier, Colombes, France.

**Background and aims:** Obesity in humans is associated with the accumulation of immune cells in adipose tissue (AT), contributing to systemic low-grade inflammation. The promotion of brite adipogenesis has been shown to ameliorate metabolic parameters in rodents. However, their origin remains to be characterized in humans. Since native CD45-/CD34+/CD31- cells have been previously described as human adipocyte progenitors, the present study aimed to identify the brite-competent progenitor cell subset in humans and to characterize a potential relationship between brite adipogenesis and obesity-associated inflammation.

**Materials and methods:** Subcutaneous AT were collected from patient undergoing aesthetic surgery for fat removal (cohort1,  $n=55$ , BMI range 18.4 to 45 Kg/m<sup>2</sup>). Subcutaneous and matched visceral AT were collected from obese women undergoing gastric bypass (cohort 2,  $n=65$ , BMI range 33.4 to 62.8 Kg/m<sup>2</sup>). AT collection was approved by the local ethics committee and donors gave their informed consent. Using flow cytometry approaches with two additional cell surface markers, ie MSCA1, the tissue non-specific alkaline phosphatase, and CD271, a nerve growth factor receptor, we partitioned the AT CD45-/CD34+/CD31- cell population into 3 subsets. We established culture conditions to promote brite adipogenesis using short-term treatment with pharmacological inducers. We developed cell sorting approaches to selectively isolate the progenitor cell subsets. Brite adipogenic potential was assessed by lipid accumulation, gene expression analyses and protein expression of UCP1.

**Results:** We demonstrated in vitro that brite adipogenesis led to an increase of MSCA1 expression (4-fold increase,  $p < 0.05$ ) and MSCA1 alkaline phosphatase activity (4-fold increase,  $p < 0.05$ ) in human cells. Furthermore, MSCA1 alkaline phosphatase activity was closely associated to the expression of UCP1 and the inhibition of MSCA1 using pharmacological or gene silencing approaches reduced brite differentiation. We showed that human native

immunoselected MSCA1+ cells exhibited brite precursor characteristics: high mitochondrial content (2-fold more compared to other progenitor subsets,  $p < 0.01$ ), highest expression of the brite-related precursor genes TMEM26, CD137, CIDEA (2-fold, 3.5-fold and 4.5 fold more respectively compared to other progenitor subsets,  $p < 0.05$ ) and they were located predominantly in subcutaneous compared to matched visceral AT. Moreover human MSCA1+ cell subsets exhibited brite adipogenic potential in vitro. Finally, using human cohorts, we provided evidences that MSCA1+ progenitor cells accumulated with obesity and insulin resistance in subcutaneous AT. Using in vitro approaches we demonstrated that immune cells in part through inflammatory cytokines impaired brite adipogenesis by modulating MSCA1 activity.

**Conclusion:** We demonstrated the existence of brite competent progenitor cells positive for MSCA1 in human subcutaneous AT. However, we highlighted an increase of the proportion of MSCA1+ brite precursor cells in the context of obesity and insulin resistance suggesting a blockade of the terminal differentiation. Such a mechanism could be triggered by immune cells accumulation occurring with obesity.

## 696

### BMP7 is produced by a specific human adipose tissue progenitor cell subset and promotes human progenitor cell brite adipogenesis

N. Boulet<sup>1,2</sup>, D. Esteve<sup>1,2</sup>, A. Bouloumié<sup>1,2</sup>, J. Galitzky<sup>1,2</sup>;

<sup>1</sup>INSERM U1048/I2MC, <sup>2</sup>Paul Sabatier University, Toulouse, France.

**Background and aims:** Brite adipocytes share some common features with white and brown adipocytes. Adipogenesis leads to the formation of new adipocytes from the differentiation of progenitor cells. Human adipose tissue (AT) progenitor cells, characterized as CD45-/CD34+/CD31-, are a heterogeneous population composed of three distinct progenitor cell subsets. CD45-/CD34+/CD31- progenitor cells have white and brown-like adipogenic potential under pharmacological PPAR $\gamma$  agonist treatment. However in humans, endogenous signals promoting brite adipogenesis are not clearly known. In mice, bone morphogenetic protein 7 (BMP7) induces brown adipogenesis. The present study was undertaken to characterize BMP7 relevance in human AT and its effects on brite adipogenesis of human native AT progenitor cells. **Materials and methods:** Human abdominal subcutaneous AT were obtained from healthy women undergoing aesthetic surgery (body mass index (BMI) 18.4 to 39 kg/m<sup>2</sup>). AT collection was approved by the local ethics committee and donors gave their informed consent. AT cell populations (adipocytes, endothelial cells, immune cells and progenitor cells) and the three progenitor cell subsets were isolated by immunoselection/depletion approaches. BMP7 gene expression was determined by RT-qPCR analyses in the different AT cell populations and BMP7 protein was studied by western blot. BMP receptor gene expressions were performed by RT-qPCR on isolated AT progenitor cells. BMP7 signaling pathway was studied by western blot. AT progenitor cells were treated (or not, control (ctl)) for 48 hours by BMP7 (50ng/ml) then cultured in basal adipogenic media (without PPAR $\gamma$  agonist) for 9 days. At day 9, adipogenesis was evaluated by lipid accumulation quantification, brite adipocyte-related gene expressions were performed by RT-qPCR and UCP1 protein was detected by immunohistochemistry and western blotting.

**Results:** BMP7 gene expression was specifically found in a progenitor cell subset compared to adipocytes, endothelial cells and immune cells ( $n = 6-10$ ,  $p < 0.001$ ). BMP7 gene expression was positively correlated with BMI ( $n = 24$ ,  $r = 0.59$ ,  $p < 0.01$ ) as well as BMP7 pro-peptide ( $n = 7$ ). Human AT progenitor cells expressed BMP receptors ALK2, ALK3, BMPR2 and ACVR2, but not ALK6 ( $n = 12$ ). BMP7 stimulation induced phosphorylation of SMAD1/5/8 complex and P38MAPK. Early BMP7 treatment on human AT progenitor cells increased lipid accumulation (2 fold increase vs ctl,  $n = 7$ ,  $p < 0.01$ ), induced the expression of brite adipocyte-related genes ( $n = 6$ ,  $p < 0.05$ ) as well as UCP1 protein after 9 days (2 fold increase vs ctl,  $p < 0.05$ ).

**Conclusion:** Our study shows that human AT progenitor cells express BMP receptors and are responsive for BMP7 stimulation. Early BMP7 treatment induces brite adipogenesis on human AT progenitor cells. BMP7 is locally produced by a progenitor cell subset and its expression increases with obesity. These results show that human progenitor cells have a brite adipogenic potential and that BMP7 could be an endogenous brite adipogenic inducer. As brite promotion in rodent has been shown to ameliorate metabolic disorders associated with obesity, local BMP7 might be useful to fight against obesity-associated pathologies in human.

## 697

### Brown adipose tissue activity and sirtuin1 expressions in human white adipose tissue during weight loss

E. Rappou<sup>1</sup>, S.J.S. Jukarainen<sup>1</sup>, M. Tummers<sup>1</sup>, S. Kaye<sup>1</sup>, K.A. Virtanen<sup>2</sup>,

J. Kaprio<sup>3</sup>, A. Rissanen<sup>1</sup>, K.H. Pietiläinen<sup>1</sup>;

<sup>1</sup>Obesity Research Unit, University of Helsinki, <sup>2</sup>Turku University Central Hospital, Turku PET Center, Turku University Central Hospital,

<sup>3</sup>Finnish Twin Cohort Study, Hjelt Institute, Helsinki, Finland.

**Background and aims:** Caloric restriction has been suggested to delay aging-associated disease and extend lifespan through sirtuin proteins. Sirtuins are highly enriched in brown adipose tissue (BAT), but little is known about sirtuins in white adipose tissue (WAT), especially during weight loss. We aimed to study the expression levels of sirtuin1 (SIRT1) in WAT in obese adults during a 12-month weight loss intervention and to correlate these changes with changes in BAT activity.

**Materials and methods:** 19 obese volunteers (7 males, 12 females) with BMI ranges 29.1-39.0, aged 20-48 years participated in a 12-month weight loss program. 19 healthy lean subjects (7 males, 12 females) with BMI ranges 20.9-24.2, aged 23.7-36.2 years were examined as controls for the obese subjects. The control group was examined similarly as the obese group, however without PET scanning and the weight loss intervention. Total RNA was extracted from subcutaneous WAT biopsies, taken at 0, 5 and 12 months. The whole genome-scale expression profiles were analysed using Affymetrix U133 Plus 2.0 chips. Glucose uptake in BAT was measured in obese patients before and after 5 months, using positron emission tomography (PET).

**Results:** SIRT1 expression levels were significantly higher ( $p < 0.001$ ) in the control group than in obese subjects at the baseline. All obese subjects lost weight between baseline and 5 months (mean  $11.6 \pm SE 1.3$  kg). After this, 1/3 of the patients continued to lose weight (weight loss at 12 months  $17.5 \pm 2.6$  kg), while 2/3 of them maintained or slightly regained the weight (mean weight loss at 12 months  $5.0 \pm 1.2$  kg). The expression levels of SIRT1 in WAT followed inversely the BMI trend. Between 0 and 5 months, SIRT1 increased 15% ( $p = 0.0022$ ). In those with continuous weight loss, SIRT1 continued to increase at 12 months 6% ( $p = 0.049$ ), while among those with weight regain, SIRT1 reverted back to baseline levels. Also, in partial correlation analysis adjusted for sex and age, SIRT1 expression levels correlated negatively with body weight, BMI and liver fat ( $r = -0.68-0.60$ , all  $p < 0.001$ ), and positively with BAT mass ( $r = 0.53$ ,  $p = 0.04$ ) and BAT glucose uptake ( $r = 0.38$ ,  $p = 0.13$ ) and whole body insulin sensitivity ( $r = 0.66$ ,  $p < 0.0001$ ) at the baseline of the study. After weight loss, increase in SIRT1 correlated significantly with an increase in BAT glucose uptake ( $r = 0.68$ ,  $p = 0.004$ ).

**Conclusion:** Downregulation of SIRT1 expression in WAT in obesity correlates with higher liver fat and poorer whole body insulin sensitivity. SIRT1 levels in WAT increase during weight loss, together with an activation of BAT glucose uptake. This suggests that activation of SIRT1 expression in human WAT is of therapeutic potential, possibly through induction of BAT-like features in human WAT.

**Dopaminergic effects on brown adipose tissue**

F. Holleman, L. Bähler, M.R. Soeters, J.B.L. Hoekstra, H.J. Verberne;  
Academic Medical Center, Amsterdam, Netherlands.

**Background and aims:** Bromocriptine is a centrally acting dopamine receptor agonist that improves insulin sensitivity in obese subjects. Yet, no explanation has been found for this effect of bromocriptine. Brown adipose tissue (BAT), a tissue that converts calories into heat, might be involved in this process. Since the central sympathetic nervous system is the primary activator of BAT, we hypothesized that dopamine plays a role in the activation of BAT. Therefore, the aim of this study was to investigate the influence of bromocriptine on BAT activity in lean, healthy males.

**Materials and methods:** We included 8 lean (BMI 23[21-25] kg/m<sup>2</sup>), healthy Caucasian males (20.9[19-23] years). All subjects were studied before and after using bromocriptine (1st week 1,25mg/day, 2nd week 2,5mg/day in the evening) in a climate room at 21°C after an overnight fast. On these 2 study visits we measured metabolic BAT activity, defined as maximal standardized uptake value (SUVmax), using 18F-Fluorodeoxyglucose Positron Emission Tomography CT scans. Furthermore we investigated glucose metabolism with a 7 point oral glucose tolerance test, energy expenditure (EE) using indirect calorimetry, weight and body temperature. Subjects recorded their eating behavior in the 4 days before the study visits.

**Results:** The use of bromocriptine did not significantly alter metabolic BAT activity (SUVmax before 11.97[4.3-15.8]; after 10.3[2.7-18.2]), EE (before 2103 Kcal/day [1340-2486]; after 1915 [1784-2437]), body temperature (before 36.0 °C [35.6-36.4]; after 36.2 [36.0-36.7]) or weight (80 kg[72.1-82.2]; after 80 [72.1-81.8]). Unexpectedly, subjects became significantly less insulin sensitive after bromocriptine use. The area under the curve for glucose increased (before 652 [539-752]; after 857 [772-992] (p=0.02)). But the area under the curve for insulin also increased (before 27x103 [26x103-37x103]; after 44x103 [41x103-65x103] (p=0.03)). There were no changes in diet between the 2 measurements that could explain the change in insulin sensitivity.

**Conclusion:** We conclude that bromocriptine does not activate BAT and does not increase EE in lean, healthy males.

## PS 049 Animal models of obesity and type 2 diabetes

## 699

**Taurine treatment prevents obesity and diabetes through normalisation in circadian rhythms**

A.L. Castillo Figueroa<sup>1</sup>, H.A. Figueiredo<sup>1,2</sup>, S. Rebuffat<sup>1,2</sup>, R. Gomis<sup>1,2</sup>, E. Vieira<sup>1,2</sup>;

<sup>1</sup>Diabetes and Obesity Laboratory, IDIBAPS,

<sup>2</sup>CIBERDEM, Barcelona, Spain.

**Background and aims:** Obesity and type 2 diabetes are associated with disruption of circadian rhythms. It has been suggested that several nutrients are potential candidates to correct alterations in circadian rhythms and prevent these diseases. More over the aminoacid taurine has positive effects on metabolic dysfunction in obesity and diabetes in animal models of high fat diet. However, there is no study whether taurine can regulate circadian rhythms in mice. Therefore, we aim to study whether long term taurine treatment can ameliorate disturbances in circadian rhythms caused by high fat diet feeding

**Materials and methods:** Male C57BL/6 mice were divided in 4 groups. Control (C): mice fed with chow and Control+ taurine (C+T): mice fed with chow and 2.0% (w:v) of taurine in the drinking water. Obesity and diabetes were induced by HFD 45% of fat, and HFD + taurine group (HFD+T) treated with 2.0% (w:v) taurine in the drinking water. Glucose tolerance test and insulin tolerant test were performed in the last week of intervention. After 10 weeks of taurine treatment mice were sacrificed at different times of the day (6:00, 12:00, 18:00, 24:00). Plasma insulin levels were measured by ELISA. The expressions of clock genes in isolated pancreatic islets were measured by RT-PCR.

**Results:** Mice treated with HFD increased food intake (p<0.001) and insulin levels (p<0.05) during the day and night time compared to chow fed mice. HFD group increased body weight (p<0.01) and visceral fat (p<0.05). HFD group disrupted the circadian pattern of insulin and exhibited higher insulin levels throughout the 24h. HFD+T treatment prevented the increase in food intake and plasma insulin during the day and night. HFD+T group had a decrease in body weight (p<0.02) and visceral fat (p<0.05). Taurine prevents the impairment in glucose tolerance and prevents insulin resistance, decreased plasma insulin levels and restored the oscillatory pattern of insulin in mice treated with HFD. Expression of clock genes in isolated pancreatic islets was measured. Rev-erb alpha, Bmal1 and Per1 were downregulated by HFD and taurine prevents this effect normalizing the expression of Per 1 at 18h (p<0.01).

**Conclusion:** Taurine can prevent disturbances of circadian rhythm in food intake and insulin that was disrupted by HFD, and improves glucose metabolism in HFD treated mice. These results suggest that these beneficial effects of taurine could be a potential candidate to prevent obesity and diabetes.

**Effects of resveratrol in experimentally induced endotoxaemia in mice**

M.K. Nøhr<sup>1,2</sup>, A. Dudele<sup>3</sup>, S. Lund<sup>1,2</sup>, S.B. Pedersen<sup>1,2</sup>;

<sup>1</sup>Department of Clinical Medicine, <sup>2</sup>Department of Endocrinology and Metabolism C, <sup>3</sup>Department of Bioscience, Aarhus University, Denmark.

**Background and aims:** Obesity is rapidly increasing in prevalence worldwide followed by a number of comorbidities such as cardiovascular diseases and type 2 diabetes. Obesity is often characterized by a chronic low-grade inflammation, which is believed to induce insulin resistance and ultimately diabetes. The triggering factor of this inflammatory state is unknown but lipopolysaccharide (LPS) originating from the gut microbiota has been suggested as a possible explanation hereof. Resveratrol is a naturally occurring polyphenol found in especially red wine, which has potential anti-inflammatory and anti-diabetic effects. RSV activates the intracellular deacetylase sirtuin-1 (SIRT1) and inhibits nuclear factor κB (NF-κB) mediated inflammation. SIRT1 activation has been shown to mimic many of the positive effects seen of calorie restriction on metabolism.

**Materials and methods:** C57BL/6 mice were surgically implanted with miniosmotic pumps subcutaneously infusing LPS (600µg/kg/day) or saline. The mice had free access to water and normal diet (CT) or a RSV-modified diet (4g/kg) for the duration of 30 days. Body weight and food consumption were measured weekly. Glucose metabolism was evaluated by oral and intraperito-

neal glucose tolerance tests (OGTT/IPGTT). Also, tissue and blood samples were collected for biochemical analyses and gene expression data.

**Results:** LPS-infused mice had an increased daily food intake compared to controls ( $185.1 \pm 3.0$  vs.  $170.5 \pm 2.9$  g/kg,  $P < 0.01$ ), which was reversed by RSV ( $175.2 \pm 2.2$  g/kg,  $P < 0.05$ ). Despite this, there were no differences in average body weight gain after 28 days of treatment between the groups. Fasting glucose was reduced by RSV after 28 days of treatment ( $7.7 \pm 0.2$  vs.  $8.9 \pm 0.4$  mM,  $P < 0.01$ ). During an OGTT, LPS-treated mice had a reduced hyperglycemia 15 min after glucose administration compared to control animals ( $14.9 \pm 0.6$  vs.  $17.5 \pm 0.8$  mM,  $P < 0.05$ ). RSV had no effect on the glucose metabolism during OGTT. Neither RSV nor LPS had any significant effect on transcriptional expression of glucagon-like peptide-1 (GLP-1), peptide YY (PYY), glucose-dependent insulinotropic peptide (GIP), neurotensin, TNF- $\alpha$ , prohormone convertase 1/3 (PC1/3) or dipeptidyl peptidase-4 (DPP4) in the ileum of the small intestine.

**Conclusion:** LPS-infusion for 28 days induced hyperphagia without affecting the body weight. RSV reversed this LPS-induced hyperphagia. To our surprise, LPS-treated mice did not show a worsening in glucose clearance as has earlier been suggested. Actually, LPS-treated mice had a small reduction in hyperglycemia 15 min following oral glucose challenge.

### T-bet regulation of the gut microbiota impacts insulin sensitivity

E. Stolarczyk<sup>1</sup>, C. Bailey<sup>1</sup>, A.W. Walker<sup>2</sup>, N. Garrido-Mesa<sup>3</sup>, E. Marks<sup>3</sup>, J. Willis<sup>3</sup>, I. Jackson<sup>3</sup>, N. Powell<sup>3</sup>, J.B. Canavan<sup>3</sup>, G.M. Lord<sup>3</sup>, J.K. Howard<sup>1</sup>; <sup>1</sup>Division of Diabetes and Nutritional Sciences, King's College London, <sup>2</sup>University of Aberdeen, <sup>3</sup>Division of Transplantation Immunology and Mucosal Biology, King's College London, UK.

**Background and aims:** The gut microbiota plays a role in energy harvest, storage, and expenditure. Its composition differs in lean and obese humans and animals and transfer of microbiota from conventionally-raised to germ-free mice increases body fat content and insulin resistance. The immune system has co-evolved with the gut microbiota. We have recently highlighted the role of the immune cell transcription factor T-bet as a metabolic regulator uncoupling adiposity from insulin resistance. We hypothesised that the enhanced insulin sensitivity of T-bet (Tbx21) deficient mice was associated with an altered gut microbiota composition.

**Materials and methods:** Microbiota composition of T-bet deficient and control wild-type (WT) mice was analysed by 16S-pyrosequencing. Subsequent analyses of colonic metabolites (short chain fatty acids, SCFA) were assessed by gas chromatography-mass spectrometry. The impact of genotype on adiposity and glucose homeostasis was determined by glucose and insulin tolerance testing following microbiota transfer to antibiotic-treated mice.

**Results:** T-bet deficient mice showed a decrease in the Firmicutes and Deferribacteres phyla and a significant increase in the Bacteroidetes and TM7 phyla compared to wild-type mice. Furthermore, they exhibited an increase in the proportion of Clostridium species together with an increase in butyrate production ( $217.6 \pm 30.6$  vs  $336.6 \pm 32.9$   $\mu$ g/g feces, WT vs T-bet<sup>-/-</sup>,  $p=0.02$ ).

Transfer of T-bet deficient microbiota to microbiota-depleted WT hosts improved insulin sensitivity ( $256.6 \pm 7.2$  vs  $221.0 \pm 8.8$ , WT vs T-bet<sup>-/-</sup> area under the curve insulin tolerance test,  $p=0.02$ ). This was accompanied by an increase in SCFA production, especially butyrate ( $216.3 \pm 76.0$  vs  $1581.1 \pm 636.8$   $\mu$ g/g feces, WT vs T-bet<sup>-/-</sup> microbiota,  $p=0.02$ ).

**Conclusion:** Our results suggest that deficiency of the immune cell transcription factor, T-bet is associated with an altered gut microbiota composition that can enhance systemic insulin sensitivity.

### TIP27 increases insulin sensitivity through PI3-kinase/Akt pathway and regulates glucose homeostasis in mice

L. Yuan<sup>1,2</sup>, L. Li<sup>1,2</sup>, G. Yang<sup>3</sup>;

<sup>1</sup>College of Laboratory Medicine, <sup>2</sup>The Key Laboratory of Laboratory Medical Diagnostics in Ministry of Education,

<sup>3</sup>Department of Endocrinology, The Second Affiliated Hospital, Chongqing Medical University, China.

**Background and aims:** TIP27 (Juxtaposed with another zinc finger protein1) is a 27kDa transcription factor containing three putative zinc finger motifs and its expression is associated with diabetes mellitus and prostate cancer. However, little is known about its role in regulation of metabolism. In this study, we investigated the effects of TIP27 overexpression on glucose homeostasis and insulin signaling pathway in high fat diet (HFD)-fed TIP27 transgenic (Tg) mice and diabetic db/db mice.

**Materials and methods:** Mainly, we use TIP27-Tg mice as research object. Also, we established a gain-of-function model of TIP27 in db/db mice using an adenovirus-mediated cDNA. Using these models, we assessed the effects of TIP27 overexpression in both TIP27-Tg mice and db/db mice on glucose metabolism and changes in insulin sensitivity during glucose tolerance tests (GTT) and insulin tolerance tests (ITT). Hyperinsulinemic-euglycemic clamp experiments were performed in Tip27-Tg mice. Glucose rates of appearance (GRa) were determined with 3-[3H] glucose. Whole body GRa and glucose uptake (GRd) were calculated using the non-steady-state equation. mRNA and protein expressions were measured by qRT-PCR and Western blot, respectively.

**Results:** We showed that TIP27 overexpression in both TIP27-Tg mice and db/db mice led to reduced total cholesterol, fasting plasma insulin levels, enhanced glucose tolerance and insulin sensitivity. Hyperinsulinemic-euglycemic clamp experiments also demonstrated that TIP27 overexpression in TIP27-Tg mice enhanced insulin sensitivity. In addition, the expression levels of PEPCK and Glucose-6-phosphatase (G-6-Pase) mRNA as well as proteins were significantly decreased in TIP27-Tg mice, whereas the phosphorylations of insulin-receptor (IR), IRS-1, Adenosine Monophosphate Activated Protein Kinase (AMPK) and Akt were significantly increased in the insulin target tissues. Finally, inhibition of phosphatidylinositol 3-kinase (PI3-kinase)/Akt signaling by LY294002, a PI3-Kinase inhibitor, abolished the suppressive effect of TIP27 overexpression on PEPCK and G-6-Pase expression.

**Conclusion:** TIP27 plays an important role in glucose homeostasis by the regulation of hepatic glucose metabolism and insulin sensitivity and this regulation requires activation of the PI3-kinase/Akt pathway.

## 703

### LEOPARD syndrome-associated SHP2 mutation confers leanness and protection from diet-induced obesity

M. Tajan<sup>1,2</sup>, T. Cadoual<sup>1,2</sup>, A. Batut<sup>2,1</sup>, S. Deleruyelle<sup>1,2</sup>, S. Le Gonidec<sup>1,2</sup>, C. Saint-Laurent<sup>1,2</sup>, M. Vomscheid<sup>1,2</sup>, K. Treguer<sup>1,2</sup>, A. Nédélec<sup>1,2</sup>, M.-A. Marques<sup>1,2</sup>, P. Raynal<sup>2</sup>, H. Cavé<sup>3</sup>, T. Edouard<sup>4</sup>, P. Valet<sup>1,2</sup>, A. Yart<sup>1,2</sup>; <sup>1</sup>Institute of Cardiovascular and Metabolic Diseases, U1048, <sup>2</sup>Paul Sabatier University, Toulouse, <sup>3</sup>Robert Debré Hospital, Paris, <sup>4</sup>University Hospital Center, Toulouse, France.

**Background and aims:** LEOPARD syndrome (LS) is a rare autosomal dominant disorder associating various developmental defects notably cardiopathies, dysmorphism and short stature. It is mainly caused by mutations of the PTPN11 gene that catalytically inactivate the ubiquitous tyrosine phosphatase SHP2. SHP2 plays essential roles in transducing canonical signaling pathways (PI3K, MAPK) in response to a wide range of growth factors

and hormones. Recent studies using targeted invalidation of SHP2 in various tissues and organs pinpointed key roles for SHP2 in regulating energy metabolism. However, the metabolic outcomes of LS mutations have never been examined. Therefore, we aimed to evaluate the metabolic status associated with LS using an original LS mouse model expressing one of the most common LS-associated SHP2 mutations. Beyond LS pathophysiology, since this mutation results in systemic partial inhibition of SHP2, this study also allowed assessing its role in the regulation of whole body metabolism.

**Materials and methods:** We performed a comprehensive analysis of the metabolic impact of LS-associated SHP2 mutations, by combining an extensive metabolic exploration of LS mice and of their WT littermates (body composition, glucose/insulin tolerance, energy expenditure, ...) with functional analysis in cellulose. Animals were handled in accordance with the principles and guidelines established by the local Ethics Committee.

**Results:** Our results reveal that LS mice gain less weight than their WT littermates ( $p < 0.01$ ), which correlates with a strong reduction of adiposity (2/3 less at 28 weeks of age,  $p < 0.001$ ) despite similar food intake between genotypes. We provide evidences that LS mutant expression impairs adipogenesis and triggers energy expenditure ( $p < 0.001$ ), two features that can contribute to the reduced adiposity of LS mice. This lean phenotype is associated with improved glucose and insulin tolerances ( $p < 0.05$ ). Consistently, we show that expression of LS mutants in a cell line induces a hyperphosphorylation of both Akt and Erk1/2 upon insulin stimulation ( $p < 0.05$ ), suggesting enhanced insulin sensitivity. Interestingly, chronic treatment of LS mice with low doses of MEK inhibitor results in weight and adiposity gains ( $p < 0.05$ ). Moreover, LS mice appear to be resistant to high fat diet-induced obesity and protected from associated disorders as insulin resistance (HOMA-IR WT  $10.31 \pm 2.60$  vs LS:  $1.25 \pm 0.35$ ,  $p < 0.05$ ) or ectopic triglycerides deposits in the liver (WT:  $140 \pm 15$  vs LS:  $73 \pm 18$  mg/g liver,  $p < 0.05$ ) or the muscle (WT:  $0.22 \pm 0.02$  vs LS:  $0.15 \pm 0.03$  g/g prot,  $p < 0.05$ ). Importantly, preliminary data in a French cohort of LS patients show that most of them have lower-than-average body mass index, which is associated, for tested patients, with reduced adiposity.

**Conclusion:** Altogether, our study demonstrates, for the first time, that LS status is associated with a metabolic benefit in vivo. In a more general context, our findings also highlight a key role for SHP2 in the regulation of whole body energy homeostasis and suggest that partial SHP2 inactivation could be protective towards the development of obesity and associated disorders.

## 704

### Transient reduction of hyperinsulinaemia in growing female *Ins1<sup>-/-</sup>:Ins2<sup>+/-</sup>* mice protects against diet-induced obesity throughout adulthood

N.M. Templeman, X. Hu, S.M. Clee, J.D. Johnson;  
Cellular and Physiological Sciences, University of British Columbia,  
Vancouver, Canada.

**Background and aims:** There is clinical and experimental evidence that hyperinsulinemia can precede and perhaps cause diet-induced obesity. We have reported that preventing lifelong hyperinsulinemia by reducing the dosage of *Insulin 1* in *Insulin 2* null male mice (*Ins1<sup>+/-</sup>:Ins2<sup>-/-</sup>*) blocks diet-induced obesity. However, this model did not address effects of the ancestral *Ins2* gene (analogous to human *INSULIN*), nor whether protection against obesity would persist without sustained repression of hyperinsulinemia. In the present study, we examined effects of reducing the ancestral *Ins2* gene, in the absence of rodent-specific *Ins1*. Temporary repression of hyperinsulinemia in high fat-fed *Ins1<sup>-/-</sup>:Ins2<sup>+/-</sup>* females allowed us to test the hypothesis that a transient reduction of insulin secretion in young mice can provide long-term protection against obesity.

**Materials and methods:** Female *Ins1<sup>-/-</sup>:Ins2<sup>+/-</sup>* mice and *Ins1<sup>-/-</sup>:Ins2<sup>+/+</sup>* littermate controls were put on a high fat diet (HFD) or chow diet at weaning ( $n = 31$ -34). Insulin secretion, body mass, and body composition (DEXA) were tracked for at least 1 year, in addition to parameters of metabolic health including blood glucose response to glucose or insulin injections and levels of several hormones.

**Results:** Female *Ins1<sup>-/-</sup>:Ins2<sup>+/-</sup>* mice had lower circulating insulin as early as eight weeks of age, compared to *Ins1<sup>-/-</sup>:Ins2<sup>+/+</sup>* littermates ( $p < 0.05$ ). At 27 weeks, all HFD-fed females had elevated basal insulin levels, but this was reduced by nearly 50% in *Ins1<sup>-/-</sup>:Ins2<sup>+/-</sup>* females (*Ins1<sup>-/-</sup>:Ins2<sup>+/+</sup>*  $1.17 \pm 0.23$  ng/mL; *Ins1<sup>-/-</sup>:Ins2<sup>+/-</sup>*  $0.62 \pm 0.14$  ng/mL;  $p < 0.05$ ). Of note, reduced circulating insulin in *Ins1<sup>-/-</sup>:Ins2<sup>+/-</sup>* mice did not elevate blood glucose. Attenuated hyperinsulinemia in HFD-fed *Ins1<sup>-/-</sup>:Ins2<sup>+/-</sup>* females corresponded with reduced weight gain and fat mass expansion, although this divergence could not be explained by differences in energy expenditure or food intake in 17 week-

old mice. Interestingly, while *Ins1<sup>-/-</sup>:Ins2<sup>+/-</sup>* females on a HFD reached an equivalent degree of hyperinsulinemia as HFD-fed *Ins1<sup>-/-</sup>:Ins2<sup>+/+</sup>* littermates by one year (*Ins1<sup>-/-</sup>:Ins2<sup>+/+</sup>*  $1.24 \pm 0.13$  ng/mL; *Ins1<sup>-/-</sup>:Ins2<sup>+/-</sup>*  $1.21 \pm 0.23$  ng/mL;  $p = 0.8$ ), their body mass never matched the more obese *Ins1<sup>-/-</sup>:Ins2<sup>+/+</sup>* mice (*Ins1<sup>-/-</sup>:Ins2<sup>+/+</sup>*  $36.4 \pm 1.2$  g; *Ins1<sup>-/-</sup>:Ins2<sup>+/-</sup>*  $30.9 \pm 0.9$  ng/mL;  $p < 0.5$ ). Unlike control *Ins1<sup>-/-</sup>:Ins2<sup>+/+</sup>* females, 40 week-old HFD-fed *Ins1<sup>-/-</sup>:Ins2<sup>+/-</sup>* females did not have high leptin levels (*Ins1<sup>-/-</sup>:Ins2<sup>+/+</sup>*  $6.3 \pm 2.2$  ng/mL; *Ins1<sup>-/-</sup>:Ins2<sup>+/-</sup>*  $1.1 \pm 0.4$  ng/mL;  $p < 0.5$ ); other hormones such as gastric inhibitory polypeptide were similarly elevated in all HFD-fed mice. Reduced insulin sensitivity and a decline in glucose tolerance were evident in all HFD-fed mice by 52 weeks, despite decreased weight gain in *Ins1<sup>-/-</sup>:Ins2<sup>+/-</sup>* mice.

**Conclusion:** Our results demonstrate that elevated insulin levels in growing female mice are associated with increased body mass and fat mass, and the maintenance of obesity throughout life. Attenuation of hyperinsulinemia during the first six months of murine life provides a long-lasting protection from obesity. Importantly, this protection persists despite a late-onset emergence of pronounced hyperinsulinemia in high fat-fed *Ins1<sup>-/-</sup>:Ins2<sup>+/-</sup>* female mice. These findings suggest that suppressing elevated insulin levels during the growth period of adolescence and young adulthood can have far-reaching consequences on the obese phenotype of fully grown adults.

### Partial pancreatic *Ins2* gene deletion reverses diet-induced obesity in adult male mice

M.M. Page<sup>1</sup>, M. Szabat<sup>1</sup>, Y. Fan<sup>2</sup>, M. Trucco<sup>2</sup>, J.D. Johnson<sup>1</sup>;  
<sup>1</sup>Department of Cellular and Physiological Sciences, University of British Columbia, Vancouver, Canada, <sup>2</sup>Department of Pediatrics, University of Pittsburgh School of Medicine, USA.

**Background and aims:** Obesity is an epidemic affecting more than 500 million people worldwide. Furthermore, it is an important risk factor to several diseases, including heart disease, diabetes, stroke and cancer. Obesity is commonly associated with basal hyperinsulinemia and insulin resistance, but the cause and effect relationship between obesity, hyperinsulinemia, insulin resistance and type 2 diabetes remains to be fully elucidated. Some evidence suggests a causal role for hyperinsulinemia in obesity, independently of insulin resistance. Drugs that block hyperinsulinemia have been reported to cause weight loss in humans, but this has remained controversial and it has been suggested that such drugs work independently of insulin. We have recently reported that life-long suppression of basal hyperinsulinemia in male *Ins1<sup>+/-</sup>:Ins2<sup>-/-</sup>* mice resulted in protection from diet-induced obesity via mechanisms that included the reprogramming of white adipose tissue to express Ucp1. While these results provided the first evidence hyperinsulinemia can play a causal role in mammalian obesity, they were unable to distinguish between acute and chronic effects of insulin and therefore could not answer whether insulin reduction in adult, obese mice would result in weight loss. To address this critical therapeutic question, we developed a mouse model with acute 50% deletion of the insulin 2 gene.

**Materials and methods:** We generated an inducible, 50% beta-cell specific insulin gene knockout mouse model (*Pdx1CreER:Ins1<sup>-/-</sup>:Ins2f/+*) to test the hypothesis that diet-induced obesity can be lowered by simply reducing pancreatic insulin production, which would indicate that long-term developmental reprogramming of the insulin system is not required to protect mammals from obesity. Control chow (25% fat) and high fat (58% fat) diets were initiated in both female and male mice at 6 weeks of age. Following 12 weeks on the respective diets, test and littermate control mice were injected with tamoxifen (or vehicle) resulting in the inducible loss of one *Ins2* allele in test mice.

**Results:** High fat diet-induced obesity was observed by 12 weeks of diet when compared to littermate control mice fed a control chow diet, and was especially pronounced in males. Remarkably, inducible reduction of pancreatic insulin 2 gene dosage in tamoxifen-injected *Pdx1CreER:Ins1<sup>-/-</sup>:Ins2f/+* male mice resulted in a 5% rapid weight loss to the levels seen in mice on control diets within 3 weeks. This effect was also only seen in mice fed a high fat diet as body mass did not differ between mice fed a chow diet following tamoxifen injection. The weight loss observed in the HFD male mice, which was due to reduced fat mass, was not a result of hyperglycaemia, as fasted blood glucose did not differ from control male mice on the HFD (control,  $8.4 \pm 0.2$ ; test,  $8.4 \pm 1.3$ ,  $p = 0.99$ ). Gene expression patterns were assessed in multiple tissues to provide molecular clues to the rapid mechanisms of weight loss subsequent to the abrogation of diet-induced hyperinsulinemia. Energy expenditure and related parameters were assessed using metabolic cages.

**Conclusion:** Together, these data provide the first evidence in any organism that obesity can be reversed by acutely reducing the production and circulation of insulin. Our results have profound implications for nutritional guidelines and therapeutic efforts to combat obesity.

### BACE2 suppression ameliorates beta cell dysfunction induced by human islet amyloid polypeptide (IAPP) overexpression

G. Alcarraz-Vizán<sup>1,2</sup>, C. Castaño<sup>1,2</sup>, L. Cadavez<sup>1,2</sup>, M. Visa<sup>1,2</sup>, J. Montane<sup>1,2</sup>, J.M. Servitja<sup>1,2</sup>, A. Novials<sup>1,2</sup>;

<sup>1</sup>Diabetes & Obesity Laboratory, IDIBAPS, <sup>2</sup>CIBERDEM, Barcelona, Spain.

**Background and aims:** BACE2 ( $\beta$ -site APP-cleaving enzyme 2) is a  $\beta$ -protease that has been found in the brain, where it is thought to play a role in the development of Alzheimer's disease (AD). It has also been localized in the pancreas, where it seems to play a physiological role since BACE2-deficient mice elicit better glucose tolerance than control littermates. Amyloidogenic diseases, including AD and type 2 diabetes (T2D), have been reported to share the accumulation of abnormally folded and insoluble proteins that interfere with cell function. In the case of T2D, amylin (IAPP) deposits have been shown to be a key feature of the disease. The aim of the present study was to investigate the effect of BACE2 modulation on  $\beta$ -cell alterations induced by IAPP overexpression.

**Materials and methods:** Heterozygous-hIAPP mice, BACE2-KO mice and their respective controls were used to analyze their phenotype after 16 weeks with high-fat diet (HFD) feeding. Afterward, these two models were crossed in order to analyze the impact of BACE2 suppression on  $\beta$ -cell alterations observed in Tg-hIAPP mice. Insulin tolerance test (ITT) and glucose tolerance test (GTT) were performed to evaluate the metabolic phenotype, and the area under the curve (AUC) of the GTT was calculated as a measure of glucose homeostasis. The ability to secrete insulin in response to glucose (GSIS) was quantified with an ELISA kit. Proliferation was analyzed by Ki67 immunostaining and  $\beta$ -cell mass by insulin immunostaining.

**Results:** The GTT of Tg-hIAPP mice after 16 weeks of regular chow diet revealed glucose intolerance with respect to the wild type animals. These animals showed a 1.3-fold increase ( $p<0.05$ ) in  $\beta$ -cell mass, however, the secretory response of insulin was reduced after the glucose challenge (25% decrease  $p<0.05$ , vs. control littermates). 16 weeks of HFD feeding induced insulin resistance and glucose intolerance, both in Tg-hIAPP and wild type animals. On the other hand, BACE2-KO mice showed better glucose homeostasis than their wild type counterparts, which correlates with a 50% enhancement of insulin secretory response to glucose injection ( $p<0.05$ ) and an increase in  $\beta$ -cell mass and  $\beta$ -cell proliferation. Moreover, BACE2-KO mice fed with a HFD showed an 18% reduction in body weight ( $p<0.05$ ) and better glucose homeostasis than wild type animals (28% decrease in AUC of GTT), indicating that deletion of BACE2 protects against HFD. The crossed animals (Tg-hIAPPxBACE2-KO) presented a significant improvement in glucose tolerance as compared to Tg-hIAPP mice (18% decrease in AUC). This improvement was due to an enhanced insulin secretory response to glucose load (15% increase vs. Tg-hIAPP mice,  $p<0.05$ ), indicating a potential effect of BACE2 deletion on  $\beta$ -cell function.

**Conclusion:** The inhibition of BACE2 compensates glucose tolerance defects induced by hIAPP overexpression in the  $\beta$ -cell. Thus, targeting BACE2 may represent a good therapeutic strategy to improve  $\beta$ -cell function in T2D.

### Altered energy metabolism in vivo and in vitro with amyloid beta42 administration

J.K. Czeczor, T. Connor, A.J. Genders, K. Walder, S.L. McGee; School of Medicine, Metabolic Research Unit, Waurin Ponds, Australia.

**Background and aims:** Amyloid  $\beta_{42}$  ( $A\beta_{42}$ ) is a peptide associated with the onset of Alzheimer's Disease (AD) and impairment of neuronal metabolism.  $A\beta_{42}$  is also peripherally secreted and increased levels of circulating  $A\beta_{42}$  are found in obese and diabetic patients. It is unknown whether circulating  $A\beta_{42}$  contributes to altered glucose metabolism or insulin action in Type 2 diabetes (T2D). The aim of our study was to determine whether administration of  $A\beta_{42}$  alters glucose metabolism of insulin sensitive cells *in vitro*, and whole body metabolism *in vivo*.

**Materials and methods:** Basal and insulin stimulated glucose uptake and glucose production was measured in 3T3-L1 adipocytes and FAO hepatocytes respectively after treatment with either monomeric (m) $A\beta_{42}$  or aggregated (a) $A\beta_{42}$  at various concentrations (0, 100, 200, 300nM) for 48h; scrambled (scr) $A\beta_{42}$  was used as control. For *in vivo* studies, 6 week old, male C57Bl/6J mice (n=10 per group) were injected i.p. with recombinant m $A\beta_{42}$  or control scr $A\beta_{42}$  for five weeks (1 $\mu$ g/day). Bodyweight and composition, indirect calorimetry and glucose and insulin tolerance were measured before and after treatment to determine the effect of m $A\beta_{42}$  administration on these measures. The clearance rate of m $A\beta_{42}$  from plasma was determined from mice that had been treated for two weeks, with plasma samples collected at various time points before (0) and post i.p. injection (1, 15, 30, 60min, 2, 4, 8, 24h) of m $A\beta_{42}$  and scr $A\beta_{42}$ .

**Results:** Monomeric  $A\beta_{42}$  increased both basal ( $p<0.001$ ) and insulin ( $p<0.01$ ) suppressed glucose production at higher doses (200; 300nM) in FAO hepatocytes compared with respective controls, while a $A\beta_{42}$  had no effect. In 3T3-L1 adipocytes, m $A\beta_{42}$  as well as a $A\beta_{42}$  impaired basal ( $p<0.001$ ) and insulin stimulated ( $p<0.01$ ) glucose uptake at higher doses (200; 300nM) compared with respective controls. *In vivo* administration of m $A\beta_{42}$  increased basal circulating levels of m $A\beta_{42}$  compared with scr $A\beta_{42}$  treated mice (3.4ng/ $\mu$ l vs 0.8ng/ $\mu$ l;  $p<0.05$ ) and also total m $A\beta_{42}$  exposure over 24 hours in m $A\beta_{42}$  treated mice ( $p<0.05$ ). Administration of m $A\beta_{42}$  had no effect on bodyweight, body composition or food intake compared with control mice and did not induce glucose or insulin intolerance. However, m $A\beta_{42}$  treated mice displayed increased fasting glucose compared with control mice. There was no change in oxygen consumption between the two treatments, but administration of m $A\beta_{42}$  resulted in a decrease in RER compared with control mice.

**Conclusion:** Our *in vitro* data suggest that primarily m $A\beta_{42}$  impairs insulin dependent and independent glucose metabolism in multiple cell types. In contrast to recently published studies, our *in vivo* data show that treatment with physiological levels of m $A\beta_{42}$  had no impact on glucose or insulin tolerance, despite elevated fasting glucose levels and a substrate shift towards lipid oxidation compared with control animals. These data suggest that not only is  $A\beta_{42}$  involved in the pathology of AD, but that  $A\beta_{42}$  could also be involved in the dysregulation of metabolism in obesity and T2D via insulin dependent and/or independent mechanisms.

### Transgenerational phenotypic changes in selectively bred mice for different susceptibilities to diet-induced glucose intolerance

M. Nagao, A. Asai, H. Sugihara, S. Oikawa; Department of Endocrinology, Diabetes and Metabolism, Graduate School of Medicine, Nippon Medical School, Tokyo, Japan.

**Background and aims:** Gene-environment interactions (GEI) play a crucial role in the development of type 2 diabetes. To establish novel rodent models that can mimic the GEI, we have performed a selective breeding of mice. In brief, using 3 inbred strains (C57BL/6, C3H, and AKR) as background, mice exhibiting superior and inferior glucose tolerance after high fat diet (HFD) feeding have been bred repetitively over 20 generations to establish 2 distinct mouse lines with different susceptibilities (resistant and prone) to HFD-induced glucose intolerance, and designated SDG-R and SDG-P, respectively. Here, we analyzed transgenerational changes of metabolic phenotypes in the selective breeding of SDG-R and SDG-P to explore the hereditary predisposition to diet-induced glucose intolerance.

**Materials and methods:** All mice were fed with HFD (32% energy from fat) for 5 weeks (5–10 weeks of age) for the selective breeding of SDG-R and SDG-P. During the 5–20th generations, HFD intake was monitored every week, body weight was measured at the end of HFD feeding, and OGTT (2 g glucose/kg body weight) was performed within 1 week after the end of the HFD feeding period. In the OGTT, mice of both sexes showing lower and higher blood glucose levels at 120 min ( $BG_{120\text{ min}}$ ) were selected to breed the next generations of SDG-R and SDG-P, respectively.

**Results:** The selection index  $BG_{120\text{ min}}$  was markedly increased as the generations proceeded in SDG-P mice of both sexes (male,  $p<0.0001$ ; female,  $p<0.0001$ : Jonckheere-Terpstra trend test). Although  $BG_{120\text{ min}}$  was also elevated slightly in SDG-R mice (m,  $p=0.0016$ ; f,  $p=0.0091$ ), distinct differences were seen in  $BG_{120\text{ min}}$  between the 2 lines at the 20th generation [SDG-R vs. SDG-P (mean $\pm$ SEM mmol/l, *t*-test): m, 5.60 $\pm$ 0.23 vs. 19.9 $\pm$ 1.13 ( $p<0.0001$ ); f, 4.34 $\pm$ 0.17 vs. 9.60 $\pm$ 0.62 ( $p<0.0001$ )]. In addition, fasting blood glucose levels (FBG) were increased in SDG-P mice of both sexes (m,  $p<0.0001$ ; f,  $p<0.0001$ ), whereas it was not altered in male ( $p=0.553$ ) and gradually de-

creased in female ( $p<0.0001$ ) SDG-R mice. Post-HFD body weight was increased in SDG-P mice of both sexes (m,  $p<0.0001$ ; f,  $p<0.0001$ ) as the generations proceeded, whereas it was not altered in male ( $p=0.709$ ) and decreased slightly in female ( $p=0.0006$ ) SDG-R mice. Despite the increasing trend of body weight in SDG-P mice, HFD intake was not altered in male ( $p=0.084$ ) and even decreased in female ( $p=0.0002$ ) SDG-P mice. In SDG-R mice, HFD intake was significantly decreased in both sexes (m,  $p<0.0001$ ; f,  $p<0.0001$ ). Linear regression analysis revealed that differences in the average values of BG120 min, FBG, post-HFD body weight, and HFD intake between the 2 lines became more evident as the generations proceeded.

**Conclusion:** Even though BG<sub>120 min</sub> was the sole criterion for the selective breeding, SDG-P mice became more susceptible to HFD-induced obesity as well as glucose intolerance. In SDG-P mice, despite the increasing trend in body weight, HFD intake was not increased as generations proceeded, suggesting that SDG-P mice had acquired a “thrifty metabolism” through the selective breeding. On the other hand, SDG-R mice had reduced HFD intake as the generations proceeded, suggesting that SDG-R mice had adapted feeding regulation to maintain glucose tolerance under HFD. These differences may determine the distinct susceptibilities to diet-induced metabolic impairments in the 2 lines of mice.

## PS 050 Adipose tissue function: animal models

### 709

#### Adipose tissue mRNA expression of WHR-associated genes exhibit inter-depot variability and correlates with fat distribution

J. Krüger<sup>1</sup>, M. Prellberg<sup>1</sup>, B. Gutschmann<sup>1</sup>, D. Schleinitz<sup>1</sup>, J. Breitfeld<sup>1</sup>, M. Kern<sup>2</sup>, N. Klötting<sup>1</sup>, M. Blüher<sup>1,2</sup>, M. Stumvoll<sup>1,2</sup>, P. Kovacs<sup>1</sup>;

<sup>1</sup>IFB Adiposity Diseases,

<sup>2</sup>Department of Medicine, University of Leipzig, Germany.

**Background and aims:** Body fat distribution (FD) is one of the main predictors of obesity associated complications. There is good evidence that fat distribution is controlled by genetic factors. Genome-wide association studies revealed novel loci associated with waist to hip ratio (WHR). Here, we hypothesized that genes within these loci exhibit fat depot-specific mRNA expression, which correlates with obesity-related traits. Furthermore, we conducted expression quantitative trait loci (eQTL) analyses to test whether WHR-associated variants may affect the mRNA expression of the corresponding genes in adipose tissue (AT).

**Materials and methods:** By using qRT-PCR, we measured mRNA levels of *LYPLAL1*, *ADAMTS9*, *VEGFA*, *CPEB4*, *RSPO3*, *ITPR2*, *SSPN*, *LY86* in paired human samples of visceral and subcutaneous AT from 570 individuals with detailed metabolic testing. Previously reported single nucleotide polymorphisms (SNPs) associated with WHR were genotyped in all subjects for subsequent eQTL analyses. Since one of the SNPs (rs6795735) maps within the *ADAMTS9-Antisense RNA 2 (ADAMTS9-AS2)*, we measured also the mRNA expression of *ADAMTS9-AS2*.

**Results:** All tested genes exhibited significantly higher mRNA levels in visceral relative to subcutaneous AT. In addition, the mRNA levels correlated with WHR (*ADAMTS9*, *VEGFA*, *SSPN*, *LY86*), % body fat (*ADAMTS9*, *VEGFA*, *CPEB4*, *LYPLAL1*) and BMI (*ADAMTS9*, *CPEB4*). None of the SNPs was significantly associated with the mRNA levels or metabolic traits including WHR or BMI, which is likely to be attributed to the small sample size, and so lack of statistical power. However noteworthy, we observed a strong correlation between the mRNA expression of *ADAMTS9-AS2* and *ADAMTS9*, suggesting that the previously reported association of the WHR-associated SNP rs6795735 might be mediated by its effects on *ADAMTS9-AS2*.

**Conclusion:** Our data including the inter-depot variability of mRNA expression and its strong correlation with metabolic traits suggest a role of genes within the WHR-associated loci in the regulation of fat distribution. In particular *ADAMTS9*, *VEGFA* and *CPEB4* are promising candidates for functional analysis of their role in adipocyte biology. This work is currently going on.

### 710

#### GLP-1 receptor agonist-induced lipolysis in adipocyte is mediated by SIRT1

F. Xu, B. Lin, Z. Chen, Z. Li, H. Ai, H. Liang, H. Xu, J. Weng;

Endocrinology, The Third Affiliated Hospital of Sun Yat-Sen University;

Guangdong Provincial Key Laboratory of Diabetology, Guangzhou, China.

**Background and aims:** Accumulated evidence suggests GLP-1 and its mimetics exert their beneficial effects in extra-pancreatic organs. Here, we found that GLP-1 receptor agonist exenatide might reduce visceral fat by increasing lipolysis in adipocytes, and we also explored the potential role of SIRT1 in this effect both in vivo and in vitro.

**Materials and methods:** In this study, 8 weeks male SIRT1 heterozygous knockout mice (SIRT1<sup>+/-</sup>) in C57BL/6J gene background and their wild type littermates (WT) were used. After 12 weeks chow diet feeding or high-fat diet (HFD) challenge, animals were randomly divided into the following 5 groups: WT+chow diet, WT+HFD+saline, WT+HFD+exenatide, SIRT1<sup>+/-</sup>+HFD+saline and SIRT1<sup>+/-</sup>+HFD+exenatide. Mice were treated with intraperitoneal injection of exenatide (24 nmol/kg) or normal saline control daily for another 8 weeks. Systemic evaluations were carried out including body weight, FBG, ip GTT, ip ITT, blood lipids profile, and weight of epididymal fat. Quantitative RT-PCR and western blot were used to detect mRNA and protein expression in epididymal fat, respectively. In differentiated 3T3-L1 adipocytes, lentivirus vector expressing SIRT1 RNAi sequence was transfected

to knock down SIRT1, and transfected cells were then treated with exendin-4 for 24 h.

**Results:** The animal study showed that both body weight and epididymal fat weight were sharply decreased after exenatide treatment compared with saline control in WT+HFD group. However, the decrease in SIRT1<sup>+/+</sup>+HFD group after exenatide treatment was much milder. While lipids profile showed the same change. Both RT-PCR and western blot results indicated that the expression of SIRT1 was up-regulated in WT+HFD group with exenatide treatment as compared with saline control; however, no significant difference was observed in SIRT1<sup>+/+</sup>+HFD mice after exenatide treatment. In differentiated 3T3-L1 adipocytes, exendin-4 up regulated SIRT1 and p-AMPK expression in a dose-dependent way. Lipolytic related factors including p-ACC, ACC and ATGL were all induced by exendin-4. After knocking down SIRT1 with SIRT1 RNAi, these factors were down regulated dramatically even with exendin-4 treatment.

**Conclusion:** Our data demonstrated that GLP-1 receptor agonist exenatide could reduce visceral fat by inducing lipolysis in adipocytes, and this effect is mediated by SIRT1 both *in vivo* and *in vitro*. It might be a new mechanism for GLP-1 and its mimetics in the role of losing weight.

### Activation of adipose tissue cannabinoid receptors 1 (CB1R) alters antilipolytic action of insulin and increases lipolysis in mice

P. Degrace, T. Muller, S. Troy-Fioramonti, L. Demizieux, J. Gresti, M. Bouam, B. Vergès;

Equipe Physiopathologie des Dyslipidémies, UMR866 INSERM-Université de Bourgogne, Dijon, France.

**Background and aims:** Recent data indicate that activation of peripheral endocannabinoid system (ECS) in tissues such as liver, muscle or adipose tissue may directly influence carbohydrate and lipid metabolism. The existence of cannabinoid receptors 1 (CB1R) and ECS enzymatic machinery has been demonstrated in mature adipocytes, nevertheless studies regarding their role in lipogenesis and lipolysis control are often conflicting. This study was designed to examine the consequence of ECS activation by anandamide on lipolysis activity and related regulation pathways.

**Materials and methods:** Lipolysis activity was estimated measuring for 45 min plasma glycerol release in response to  $\beta$ 3-adrenergic receptor agonist (BRL37344) in wild type, DIO or CB1R<sup>-/-</sup> mice after acute peripheral anandamide injection compared with vehicle. Additional *in vitro* experiments were conducted to test direct effects of anandamide on glycerol release and signaling pathways on adipose tissue explants exposed to various concentrations of insulin and norepinephrine.

**Results:** While anandamide alone had no remarkable effects on basal lipolysis, ECS activation potentiated the effect of BRL37344 on glycerol release in wild type mice. The effect of anandamide on stimulated lipolysis was strongly reduced in CB1R<sup>-/-</sup> while it was amplified in obese animals whose adipose tissue CB1R mRNA expression was much higher than in lean mice. In control mice, the stimulatory effect of BRL37344 on glycerol release was totally counteracted by insulin injection (0,025UI/kg) while it was partially maintained in the presence of anandamide suggesting that ECS activation may be associated with an alteration of the inhibitory action of insulin on lipolysis. These findings were also observed in cultured explants exposed to anandamide in which inhibition of glycerol release by insulin was abrogated. Further, anandamide treatment increased protein levels of the active form of hormone-sensitive lipase and reduced level of Akt and Pi3K phosphorylation compared to control in accordance with a decrease in the activity of insulin-dependent signaling cascade.

**Conclusion:** All together, these data showed that activation of ECS in adipose tissue increases lipolysis by altering the antilipolytic action of insulin. This suggests that antagonism of CB1R may constitute a new strategy to limit ectopic fat deposition associated with obesity.

### Increased BMP4 improves insulin sensitivity and increases beige/brown adipogenesis in adult mice

J.M. Hoffmann<sup>1</sup>, J.R. Grünberg<sup>1</sup>, I. Elias<sup>2</sup>, F. Bosch<sup>2</sup>, A. Hammarstedt<sup>1</sup>, S. Hedjazifar<sup>1</sup>, U. Smith<sup>1</sup>;

<sup>1</sup>Department of Molecular and Clinical Medicine/Diabetes, The Lundberg Laboratory for Diabetes Research, Gothenburg, Sweden,

<sup>2</sup>Department of Biochemistry and Molecular Biology, CBATEG (Center of Animal Biotechnology and Gene Therapy), Barcelona, Spain.

**Background and aims:** Bone Morphogenic Proteins (BMPs) belong to the transforming growth factor beta superfamily and regulate a wide range of developmental and cellular processes. BMP4 has been shown to be critical for adipose precursor cell commitment and differentiation to the white adipose lineage. However, recent data also suggest a role of BMP4 in beige/brown adipose cell differentiation. A previous study has examined the developmental effect of BMP4 in mice genetically engineered to overexpress BMP4 in the adipose tissue. However, to be a potential therapeutic target it is important to examine if BMP4 also is able to increase beige/brown adipogenesis in adult animals. This is further underscored by our recent findings that adipose precursor cells in obesity exhibit a resistance to the effects of BMP4. To examine the effect of BMP4, we injected adult mice with AAV8-BMP4 or AAV8-null virus vectors targeting the liver and, thus, increasing circulating BMP4 levels. **Materials and methods:** Six weeks old male C57BL6/N mice received a retro-orbital injection of AAV8 expressing BMP4 or control (null) virus. The mice were fed a high fat diet (HFD) for 16 weeks and they underwent ip GTT, ip ITT and DEXA. Adipose tissue and muscle were taken for gene and protein analyses and immunohistochemistry was performed on paraffin-embedded, formalin fixed tissue samples. All reported results are statistically significant. Statistical analyses were performed using Students t-test or Mann-Whitney non-parametric U-test.

**Results:** HFD-BMP4 mice gained less weight than the HFD-null mice in spite of having the same food intake. They also had reduced total adipose tissue mass and smaller adipose cells. Furthermore, they had an improved glucose tolerance and were more insulin-sensitive than the HFD-null mice. In addition to the reduced fat mass they also had increased lean body mass. Both gene and protein expression of beige/brown adipose markers (TMEM26, CD137 and UCP1) were increased in the subcutaneous adipose tissue. Markers of mitochondrial biogenesis, like PGC1 $\alpha$ , were significantly increased in both skeletal muscles and the adipose tissue. Since obesity also has been shown to lead to increased adipose tissue fibrosis and BMP4 may exert an anti-fibrotic effect, we examined markers of this process. Interestingly, both  $\alpha$ -SMA and CTGF mRNA levels were significantly reduced in the obese BMP4 mice.

**Conclusion:** We here demonstrate that increased circulating levels of BMP4 in obese and adult mice lead to clear positive phenotypic changes with reduced body fat, increased lean body mass together with increased insulin sensitivity and improved glucose tolerance. These effects are probably due to the marked induction of beige/brown adipose cells in the subcutaneous adipose tissue as well as increased mitochondrial biogenesis also seen in the skeletal muscles. BMP4 also reduced markers of adipose tissue fibrosis known to be increased in obesity.

## 713

### Glyoxalase-1 overexpression reduces body weight and adipokine expression, and improves insulin sensitivity in high-fat diet-induced obese mice

D. Maessen<sup>1</sup>, O. Brouwers<sup>1</sup>, T. Miyata<sup>2</sup>, C. Stehouwer<sup>1</sup>, C. Schalkwijk<sup>1</sup>;

<sup>1</sup>Internal Medicine, Maastricht University Medical Centre, Netherlands,

<sup>2</sup>Centre of Translational and Advanced Research, Tohoku University, Sendai, Japan.

**Background and aims:** The development of obesity, and especially the expansion of visceral adipose tissue (VAT), is associated with the development of inflammation and insulin resistance. We previously demonstrated an accumulation of advanced glycation endproducts (AGEs) in obese VAT, leading to dysregulated expression of adipokines. In addition, the increased AGE levels were associated with the development of insulin resistance. Based on previous work, we hypothesized that inhibition of the major AGE precursor methylglyoxal (MGO) attenuates the impaired adipokine profile and improves insulin sensitivity in obesity. Because MGO can be detoxified by the

glyoxalase-1 (GLO-1) enzyme, we used a GLO-1 overexpressing transgenic mouse model which was fed with a high-fat diet (HFD).

**Materials and methods:** After a run-in period of 4 weeks, both wild-type (WT) mice and GLO-1 transgenic mice (10 weeks old) were either fed with a low-fat diet (LFD, 10% kcal% fat) or a HFD (45% kcal% fat) for 15 weeks. In the last two weeks of the study we performed an intraperitoneal glucose tolerance test (ipGTT) and insulin tolerance test (ipITT). All mice were euthanized after 15 weeks of LFD or HFD and multiple organs were collected for *ex vivo* examination.

**Results:** Endogenous GLO-1 mRNA levels of the VAT were significantly lower in WT mice of the HFD group compared to the WT mice of the LFD group ( $p < 0.01$ ). Activity of the GLO-1 enzyme was also reduced in the VAT of the HFD group ( $p < 0.05$ ). Bodyweight gain was significantly increased after 15 weeks of HFD feeding compared to the LFD group ( $15.2 \pm 4.7$  vs  $6.5 \pm 2.2$  gram, respectively;  $p < 0.001$ ). Overexpression of GLO-1 in mice fed with the HFD inhibited the bodyweight gain significantly compared to the WT mice ( $10.5 \pm 4.5$  vs  $15.2 \pm 4.7$  gram, respectively;  $p < 0.05$ ), despite equal calorie intake ( $13.1 \pm 2.0$  vs  $12.3 \pm 1.6$  kcal/day, respectively;  $p = 0.30$ ). Furthermore, the VAT of the HFD group was characterized by a pro-inflammatory profile, as indicated by an upregulated mRNA expression of MCP-1, F4/80, MHC-II, CD11c and TNF $\alpha$  (all  $p < 0.05$ ). Overexpression of GLO-1 in the HFD mice attenuated these increases in mRNA levels. Finally, HFD-induced insulin resistance was attenuated by GLO-1 overexpression, as assessed by the ipGTT ( $p_{\text{trend}} < 0.001$ ) and the ipITT ( $p_{\text{trend}} = 0.08$ ).

**Conclusion:** Our data demonstrate that overexpression of the GLO-1 enzyme is a potential mechanism to reduce body weight gain, carbonyl stress, adipose tissue inflammation and insulin resistance in HFD-associated obesity. Modulating the GLO-1 pathway may be a novel approach to prevent obesity-associated complications.

## 714

### Deletion of inhibitory G proteins protects from obesity

V. Leiss<sup>1</sup>, A. Novakovic<sup>1</sup>, T. Sartorius<sup>2</sup>, J. Machann<sup>3</sup>, H.-U. Häring<sup>2</sup>, B. Nürnberg<sup>1</sup>;

<sup>1</sup>Pharmacology and Toxicology, <sup>2</sup>Internal Medicine IV,

<sup>3</sup>Experimental Radiology, University Hospital Tübingen, Germany.

**Background and aims:** Many hormones and other substances involved in the breakdown or storage of fatty acids signal via G protein coupled receptors (GPCRs). Upon binding of such ligands to the respective GPCRs the associated heterotrimeric G proteins are activated causing a dissociation of G $\alpha$  subunits from G $\beta\gamma$  dimers. The G $\alpha$  subfamily of inhibitory G proteins (G $\alpha_i$ ) shows a sequence identity of up to 95% among the three isoforms G $\alpha_{i1}$ , G $\alpha_{i2}$ , and G $\alpha_{i3}$ . Due to this high homology it has been suggested that G $\alpha_i$  proteins serve the same functions, i.e. they are activated by a similar set of GPCRs and signal to an overlapping set of effectors. Interestingly, recent publications describe more and more individual tissue- and cell-specific functions for the different isoforms. In this study we aim to clarify the specific roles of G $\alpha_{i2}$  and G $\alpha_{i3}$  proteins for body weight gain in mouse models on normal (ND) and high-fat diet (HFD) conditions.

**Materials and methods:** In G $\alpha_{i2}$ - and G $\alpha_{i3}$ -deficient mice we analysed *in vitro* differentiation of adipocytes isolated from 4-6-week-old mice and *in vivo* body composition of mice fed a ND or HFD for 14 weeks by magnetic resonance imaging (MRI).

**Results:** G $\alpha_{i2}$  and G $\alpha_{i3}$  are both expressed in white adipose tissue. Interestingly, both G $\alpha_{i2}$ - and G $\alpha_{i3}$ -deficient mice show a lean phenotype on ND compared to their respective littermates. However, time occurrence of the weight differences is detectable in a genotype-dependent manner. G $\alpha_{i2}$ -deficient mice weigh less already at weaning, whereas G $\alpha_{i3}$ -deficient mice showed initially no differences. Magnetic resonance imaging revealed that 18-week-old G $\alpha_{i2}$ -deficient mice had significantly lower amounts of subcutaneous and visceral adipose tissue mass. In contrast, in G $\alpha_{i3}$ -deficient mice a reduced fat mass determined by MRI was first observed in 36-week old mice, which gained statistical significance at 56-weeks of age. In addition, G $\alpha_{i2}$ - and G $\alpha_{i3}$ -targeted mice were protected from remarkably weight gain on HFD. Since G $\alpha_{i2}$ -deficient mice have pronounced weight differences starting at an early stage, we analysed differentiation of white adipocytes *in vitro*. Significantly less Oil-red-O-positive G $\alpha_{i2}$ -deficient adipocytes were detectable, whereas G $\alpha_{i3}$ -deficient *in vitro* adipocyte differentiation was similar to wild-type cells.

**Conclusion:** We conclude that deletion of G $\alpha_{i2}$  and G $\alpha_{i3}$  protects from weight gain in an age-dependent manner and results in a leaner phenotype. Our data

suggest specific and independent roles of both isoforms in the differentiation of white adipocytes as well as in the regulation of adipose tissue mass.

## 715

### 14-3-3 $\zeta$ controls mitotic clonal expansion and adipocyte differentiation via p27Kip1

G.E. Lim<sup>1</sup>, T. Albrecht<sup>1</sup>, J. Lee<sup>1</sup>, C. Nislow<sup>2</sup>, J.D. Johnson<sup>1</sup>;  
<sup>1</sup>Cellular and Physiological Sciences, <sup>2</sup>Pharmaceutical Sciences,  
University of British Columbia, Vancouver, Canada.

**Background and aims:** Obesity is a major risk factor for type 2 diabetes, but the molecular mechanisms underlying adipogenesis are not fully known. While undergoing mitotic clonal expansion, adipocytes acquire specific transcriptional networks to drive differentiation. Proper localization of transcriptional regulators depends on molecular adaptor proteins, such as those of the 14-3-3 protein family. Previously, we identified essential roles of 14-3-3 $\zeta$  in the regulation of adipogenesis *in vitro* and *in vivo*. Given its ability to regulate many transcription factors, we sought to examine the effects of 14-3-3 $\zeta$  knockdown on the adipogenic transcriptome.

**Materials and methods:** 3T3-L1 cells were treated with insulin, IBMX, and dexamethasone for 0, 24, or 48 hours to induce differentiation. Cells were transfected with siRNA targeting 14-3-3 $\zeta$  or a scrambled control (siCon). Libraries for RNA-Seq were analyzed with an Illumina Hi-Seq 2500 (20 million paired-end reads per sample). Differentially expressed genes ( $p < 0.001$  cut-off) were subjected to Gene-set enrichment analysis (GSEA; FDR < 25%) to determine biological processes affected by differentiation or si14-3-3 $\zeta$ . Flow-cytometry was used to quantify the proportion of cells at stages of the cell cycle. Adipocyte differentiation was assessed by Oil Red-O staining and immunoblotting for Ppar $\gamma$ .

**Results:** RNA sequencing revealed that >5000 genes were significantly altered ( $p < 0.001$ ) during the first 48 hr of differentiation. Categorization of differentially expressed genes by GSEA showed negatively enriched gene sets ( $p < 0.0001$ ) that were related to the cell cycle, fat cell differentiation, and regulation of transcription in 14-3-3 $\zeta$ -depleted cells. Induction of numerous genes associated with the cell cycle (GO:000749) and mitotic cell cycle phase transition (GO:0044772), such as Cdc25a, Cdk6, and Cdkn1b, were significantly impaired following 14-3-3 $\zeta$  knockdown. To further explore the effect of 14-3-3 $\zeta$  on the cell cycle, si14-3-3 $\zeta$ -transfected 3T3-L1 cells were induced to differentiate and subjected to flow cytometry at 0, 24, and 48 hours. Knockdown of 14-3-3 $\zeta$  prevented cells from entering S-phase (25% vs 8%,  $p < 0.01$ ). P27Kip1 (encoded by Cdkn1b) regulates G1-S transition, and depletion of 14-3-3 $\zeta$  promoted a 4-fold increase ( $p < 0.05$ ) in p27Kip1 in undifferentiated cells. Differentiation caused a gradual decrease in p27Kip1 levels, but its expression remained elevated in si14-3-3 $\zeta$ -transfected cells. To test if elevated p27Kip1 contributes to the defects in si14-3-3 $\zeta$ -mediated cell cycle progression and differentiation, 3T3-L1 cells were co-transfected with siRNA against 14-3-3 $\zeta$  and p27Kip1. No effects on adipogenesis were observed in siCon- or sip27Kip1-transfected cells; however, co-transfection of sip27Kip1 into 14-3-3 $\zeta$ -deficient cells restored adipogenesis.

**Conclusion:** Our results demonstrate a novel role for 14-3-3 $\zeta$  in the cell cycle, as 14-3-3 $\zeta$  negatively regulates p27Kip1 expression. Loss of 14-3-3 $\zeta$  induces premature cell cycle arrest and ultimately blocks adipogenesis. Despite broad changes in global gene expression of pre-adipocytes, reductions in p27Kip1 alone are sufficient to rescue the defect in differentiation in 14-3-3 $\zeta$  deficient cells. These findings suggest that modulating 14-3-3 $\zeta$  or p27Kip1 expression could represent novel therapeutic approaches for the treatment of obesity.

### Deleted in breast cancer 1 (DBC1) plays a bifunctional role in adipocyte differentiation and inflammation

J. Moreno-Navarrete, M. Moreno, M. Vidal, F. Ortega, M. Serrano, G. Xifra, W. Ricart, J.M. Fernandez-Real;  
Hospital of Girona, Spain.

**Background and aims:** Deleted in breast cancer 1 (DBC1) is a pleiotropic nuclear protein that interacts and modulates the activity of several molecules, including Sirt1, NF- $\kappa$ B and Rev-erba, which exert important roles in adipocyte differentiation. Here, we aimed to investigate the possible role of DBC1 in adipose tissue physiology and in adipocyte differentiation.

**Materials and methods:** In two independent cohorts [cohort 1, participants with different degree of obesity (n= 105) and cohort 2, morbidly obese participants (n=47)], DBC1 gene expression was investigated in adipose tissue according to obesity and insulin resistance. DBC1 mRNA and protein levels during adipocyte differentiation and the effects of DBC1 knockdown (using Dbc1-targeted and control shRNA lentiviral particles) in the early stage of this process were also evaluated.

**Results:** DBC1 mRNA was detected at substantial levels in both visceral (VAT) and subcutaneous (SAT) adipose tissue (mainly in the adipocyte fraction), decreased in obese subjects, and directly associated with the expression of lipogenic and lipolytic genes in two both independent cohorts. Strikingly, DBC1 was linked to TNF mRNA levels in obese and morbidly obese participants and the administration of macrophage conditioned medium resulted in increased DBC1 gene expression in adipocytes. In line with these findings, in the early stages of adipocyte differentiation, Dbc1 knockdown led to decreased lipid accumulation and adipogenic gene expression in parallel to the increase of Sirt1 and AMPK activity. On the other hand, Dbc1 gene knockdown also led to a significant reduction in the expression of inflammatory genes (Tnf, Il6, Stamp2, Lbp and Mcp1) at the end of adipocyte differentiation.

**Conclusion:** Altogether these findings suggest that DBC1 exerts a bifunctional role in adipocyte physiology, being essential for adipocyte development, but also involved in adipocyte inflammation in the late stage of adipocyte differentiation.

### Antenatal antipsychotic exposure induces multigenerational and sex-specific programming of body weight and diabetes susceptibility in adult mouse offspring

E. Courty<sup>1</sup>, P. Gobalakichenane<sup>1,2</sup>, M. Garcia<sup>1</sup>, T. Ledent<sup>1</sup>, D. Mitanchez<sup>2</sup>, M. Buyse<sup>1,2</sup>, B. Fève<sup>1,2</sup>;

<sup>1</sup>INSERM U938, <sup>2</sup>APHP, Paris, France.

**Background and aims:** Atypical antipsychotic medications have revolutionized the treatment of severe mental diseases, but their metabolic side effects have been pointed, including obesity and diabetes. Among them, Olanzapine use has been reported during pregnancy and breastfeeding, but so far no clinical trials assessed the safety of in utero olanzapine exposure to fetuses and infants, or long term health outcome. In this study we analysed the transgenerational impact on metabolic homeostasis of mouse fetal antipsychotic exposure throughout gestational period.

**Materials and methods:** At 7d gestation, pregnant F0 CD1 mice received olanzapine (olz4 or olz8: 4 or 8 mg/kg/d) or haloperidol (hld: 2 mg/kg/day) or vehicle (control) through mini-osmotic pump until they gave birth naturally. F1 female offspring exposed in utero to olz (mat-olz) and hld (mat-hld) were bred to produce F2 offspring. Offsprings were weight every 3 days until the age of 3 weeks then weekly until 3 months of age. Glucose metabolism was investigated by insulin tolerance test (ITT), oral glucose tolerance test (OGTT) and plasma insulin measurement at the age of 3 months and 1 year for F1 offsprings, and at the age of 3 months for F2. Part of the F1 offspring cohort was sacrificed at 3 months and 1 year to analyse body and tissue composition and measure biochemical and hormonal parameters.

**Results:** The litter size of F1 mice was not influenced by the maternal treatment. However birth weight of mat-antipsychotic offspring groups of both sexes was significantly decreased compared to mat-control (p<0.01), suggesting an antipsychotic-induced intrauterine growth retardation. Only few weeks after birth, the initial difference in weight between mat-hld, female mat-olz and control disappeared. However, decreased weight of male mat-olz persisted throughout life (p<0.05). The results of OGTT and insulin measurement performed at the age of 3 months on F1 offspring were not different between mat-olz, mat-hld and control both in males and females. However mat-olz offspring developed a significant insulinoreisistance compared to mat-ctrl. At the age of 1 year, a sexual dimorphism was observed. Concerning F1 male mat-olz, no modification in glucose metabolism (OGTT, ITT) or in hormonal parameters (insulin, leptin, adiponectin) or body mass composition was observed despite persistent lower weight compared to control (p< 0.05). However at the same time, mat-olz female developed impaired glucose tolerance (olz 4 and olz 8 vs ctrl p<0.05), hyperinsulinemia (olz 8 vs ctrl p<0.05) associated with insulinoreisistance (olz 4vs ctrl p<0.05). Besides, increased leptin and adiponectin plasma level associated with expanded subcutaneous adipose depot and higher body weight were found in olz female offspring. Strikingly, for F2 olz-offspring, both male and female mice devel-

oped a marked glucose intolerance, hyperinsulinemia and insulinoreisistance compared to F2 controls, with a female-specific increase body weight (olz 4 vs ctrl p<0.05, olz 8 vs ctrl p<0.01).

**Conclusion:** These data suggest that in utero antipsychotic exposure is sufficient to provoke sharp health outcomes in sex-specific manner, indicating varying developmental vulnerabilites between sexes towards metabolic diseases. They also evidence the transgenerational programming of diabetes susceptibility in response to maternal antipsychotic treatment.

**Fat accumulates preferentially in the right liver lobe in non-diabetic subjects: implications for the diagnosis of NAFLD**

H. Bian<sup>1,2</sup>, A. Hakkarainen<sup>3</sup>, Y. Zhou<sup>2</sup>, N. Lundbom<sup>3</sup>, X. Gao<sup>1</sup>, H. Yki-Järvinen<sup>2</sup>;

<sup>1</sup>Department of Endocrinology and Metabolism, Zhong Shan Hospital, Fudan University, Shanghai, China, <sup>2</sup>Minerva Foundation Institute for Medical Research, Helsinki, <sup>3</sup>Department of Radiology, Helsinki Medical Imaging Center, Helsinki University Central Hospital, Finland.

**Background and aims:** The right lobe of the liver preferentially receives blood flow from superior mesenteric vein, while the left lobe mainly drains the spleen. In obese subjects, the rate of visceral lipolysis is increased compared to non-obese subjects and can account for up to 50% of free fatty acids (FFA) delivery to the liver. Many obese subjects accumulate fat in the liver due to non-alcoholic causes (NAFLD) and therefore possibly an increased flux of FFA from visceral fat to the superior mesenteric vein. Studies using Doppler ultrasonography in healthy volunteers have shown that in response to a meal, intrahepatic portal vein blood flow increases more in the right than the left lobe. FFA delivery from both the meal and from visceral lipolysis might preferentially increase liver fat content more in the right than the left lobe. Metabolic consequences of hepatic insulin resistance in NAFLD such as hyperinsulinemia and hypertriglyceridemia could therefore also be better correlated with fat in the right than the left lobe. We aim to examine the distribution of liver fat (LFAT) in non-diabetic subjects and to test whether the fat in the right as compared to the left lobe correlate better with components of the metabolic syndrome or not.

**Materials and methods:** We determined LFAT by <sup>1</sup>H-MRS in the right lobe (LFAT%MRS), and by MRI (LFAT%MRI) in four regions of interest (ROIs 1-4, ROI1-2 in the left and ROI 3-4 in the right lobe) in 97 carefully phenotyped non-diabetic subjects (age range 22-74 yrs, BMI 18-41 kg/m<sup>2</sup>) and compared the accuracy of LFATMRI in the different ROIs in diagnosing non-alcoholic fatty liver disease (NAFLD) using areas under the receiver operator characteristic (AUROC) curves.

**Results:** 38% of the subjects had NAFLD (LFAT%MRS). LFAT%MRI in ROIs 1, 2, 3 and 4 averaged: 4.8±0.5%, 5.5±0.5%, 5.8±0.5% and 5.7±0.5%. The LFAT%MRI was significantly lower in ROI 1 than in ROI 2, ROI 3 and ROI 4. LFAT%MRI was significantly higher in the right (5.7±0.5%) than the left (5.1±0.4%) lobe (p<0.02). LFAT%MRI in ROI 3 showed excellent accuracy in diagnosing NAFLD (AUROC = 0.936±0.023, p< 0.001, sensitivity 94.6%, specificity 83.3%). The AUROC for ROI 1 was good (AUROC = 0.879±0.034, p< 0.001, sensitivity 70.3%, specificity 90.0%) but significantly lower than that of AUROC for ROI 3 (p<0.02). Likewise, the AUROC was significantly higher using LFAT%MRI in the right (AUROC = 0.934±0.025, p< 0.001, sensitivity 86.5%, specificity 90.0%) than in the left lobe (AUROC = 0.894±0.032, p< 0.001, sensitivity 73.0%, specificity 91.7%) lobe (p<0.05). The correlation coefficients between BMI, waist and hip circumference, body fat, intra-abdominal and subcutaneous fat, S-AST, S-ALT and LFAT%MRS were significantly higher than those between these metabolic features and LFAT%MRI in ROI 1. The correlation coefficient between HOMA-IR, S-AST, S-ALT and LFAT% MRI in ROI 2 was significantly lower than those between LFAT%MRS and these metabolic features. The correlation coefficients between the metabolic parameters and LFAT%MRI in ROIs 3 and 4 did not differ from those relating the respective parameters and LFAT%MRS.

**Conclusion:** Measurement of fat in the right lobe provides a more accurate diagnosis of NAFLD than fat in the left lobe.

719

**Pivotal role of TNF-alpha in the development and progression of non-alcoholic fatty liver disease in a murine model**

S. Kakino, T. Ohki, H. Nakayama, X. Yuan, S. Otobe, T. Hashinaga, N. Wada, Y. Kurita, K. Tanaka, K. Hara, E. Soejima, Y. Tajiri, K. Yamada; Endocrinology and Metabolism, Kurume University, Japan.

**Background and aims:** Non-alcoholic fatty liver disease (NAFLD) represents the hepatic component of the metabolic syndrome, incorporating a wide spectrum of liver disease from simple steatosis to non-alcoholic stea-

tohepatitis (NASH) leading to cirrhosis and ultimately hepatocellular carcinoma. However, mediators of this progression are incompletely understood. Previously we have reported that adipocyte-specific nSREBP-1c transgenic (Tg) mice spontaneously developed hepatic lesions similar to those of human NASH. nSREBP-1c Tg mice are insulin resistant and their circulating levels of TNF-alpha are significantly higher than wild-type mice. In this study we assessed the role of TNF-alpha in the progression of NAFLD.

**Materials and methods:** We established a Tnf(-/-) nSREBP-1c Tg mouse line on C57B/6 background. Liver sections were stained with hematoxylin and eosin or azocarmine and aniline blue (Azan). mRNA levels of acetyl-CoA carboxylase (Acc1), stearyl-CoA desaturase-1 (Scd1), monocyte chemoattractant protein-1 (Mcp1), transforming growth factor-beta (Tgfb1), collagen type I alpha 1 (Col1a1), and tissue inhibitor of metalloproteinase 1 (Timp1) were determined by quantitative reverse transcription PCR. TIMP1 protein levels were assessed by Western blotting and immunohistochemical staining. Primary hepatocytes isolated from Tnf(-/-) C57BL/6 mice were cultured in Williams' medium E.

**Results:** All of 17 nSREBP-1c Tg mice had fatty liver at the age of 20 weeks. However, significant fat deposits were observed only in 5 of 20 age-matched Tnf(-/-) nSREBP-1c Tg mice (p<0.0001). When compared with nSREBP-1c Tg mice, the prevalence of liver fibrosis was low in Tnf(-/-) nSREBP-1c Tg mice (11/17 vs. 3/20, p=0.006). nSREBP-1c Tg mice showed higher expression of Acc1, Scd1, Mcp1, Tgfb1, Col1a1, and Timp1 in the liver than wild-type C57BL/6 mice. The protein levels of Timp1 were also increased in the liver from nSREBP-1c Tg mice. The expression levels of the genes and the Timp1 protein levels were reduced in Tnf(-/-) nSREBP-1c Tg mice. Incubation with 10 ng/ml TNF-alpha up-regulated the Timp1 expression in primary cultured hepatocytes from Tnf(-/-) C57BL/6 mice.

**Conclusion:** These observations indicate that TNF-alpha is involved in the development of NAFLD through the induction of key enzymes of lipid metabolism, ACC1 and SCD1. TNF-alpha was also associated with the increase of inflammatory cytokines, MCP1 and TGF-beta. Several studies have shown that TIMP1 is increased in liver fibrosis both in murine models and human samples, and promotes liver fibrosis development. Here we showed that Timp1 mRNA was decreased in the liver from Tnf(-/-) mice, and the supplementation of TNF-alpha increased the expression of Timp1 in primary cultured Tnf(-/-) hepatocytes. Thus TNF-alpha may play a pivotal role in both the development of NAFLD and progression to NASH in insulin resistant state.

720

**Proteomic analysis of livers from fat-fed mice deficient in either PKCδ or PKCε**

B.M. Liao<sup>1</sup>, K. Raddatz<sup>2</sup>, C. Schmitz-Peiffer<sup>1</sup>;

<sup>1</sup>Diabetes and Obesity Research Program, Garvan Institute of Medical Research, Sydney, Australia, <sup>2</sup>Competence Centre Functional Genomics – Pathoproteomics, University of Greifswald, Germany.

**Background and aims:** The two isoforms of protein kinase C (PKC), PKCδ and PKCε, have been associated with insulin resistance in the liver, which is a characteristic of Type 2 diabetes. Our previous comparison between PKCδ knockout (KO) mice and PKCε KO mice revealed roles for both of the kinases in the generation of insulin resistance, yet opposing roles in hepatic triglyceride accumulation. Therefore we aim to gain mechanistic insights into the roles of PKCs in the modulation of insulin action and lipid metabolism using a proteomics approach.

**Materials and methods:** We conducted an unbiased *in vivo* spike-in SILAC proteomic profiling of livers from one week high fat diet-fed PKC KO mice and their wild-type counterparts.

**Results:** A total of 3359 proteins and 3488 proteins were identified from the PKCδ KO and PKCε KO study groups respectively, and we showed that several enzymes of lipid metabolism were affected by the fat diet. In fat-fed mice, 23 proteins showed significant changes upon PKCδ deletion while 19 proteins were affected by PKCε deletion. Notably, retinol pathway was significantly upregulated in fat-fed mice with either deletion. The majority of the proteins affected in this pathway belonged to the Cyp450 family which is involved in the metabolism of all-trans retinoic acid (atRA). Thus it is possible that alterations in atRA or its derivatives protect PKC KO mice from fat diet-induced insulin resistance. Furthermore, gene ontology (GO) analysis showed proteins involved in biological processes such as lipid biosynthesis and oxidation-reduction were enriched in the absence of either PKC isoform. However certain GO terms such as monosaccharide metabolism were enriched solely in PKCδ KO and

isoprenoid biosynthesis only in PKC $\epsilon$  KO. Taken together, these further suggest that PKC $\delta$  and PKC $\epsilon$  exert partly overlapping and differential effects on liver metabolism in response to fat oversupply.

**Conclusion:** These studies therefore provide a detailed comparison of the effects of fat feeding and deletion of PKC isoforms at the protein level, which will aid further understanding of the function of these PKCs, given their association with defective glucose homeostasis.

## 721

### The hepatokine betatrophin is increased in nonalcoholic fatty liver disease and may affect insulin secretion in prediabetes

A. Peter<sup>1</sup>, K. Kantartzis<sup>1</sup>, A. Königsrainer<sup>2</sup>, I. Königsrainer<sup>2</sup>, H. Staiger<sup>1</sup>, F. Machicao<sup>1</sup>, H.-U. Häring<sup>1</sup>, A. Fritsche<sup>1</sup>, N. Stefan<sup>1</sup>;

<sup>1</sup>Department of Internal Medicine IV, Institute of Diabetes Research and Metabolic Diseases of the Helmholtz Center Munich at the University of Tübingen and German Center for Diabetes Research, University of Tübingen,

<sup>2</sup>Department of General, Visceral and Transplant Surgery, Germany.

**Background and aims:** Animal data suggest that the liver-secreted protein betatrophin is elevated in insulin resistant states and improves glucose tolerance by expanding beta cell mass. We now investigated whether betatrophin is a hepatokine that may be increasingly produced in nonalcoholic fatty liver disease (NAFLD) and may affect insulin secretion in humans.

**Materials and methods:** In liver tissue samples from 92 donors the relationship of hepatic betatrophin mRNA expression with liver triglyceride (TG) content, and in a subgroup of 29 donors the relationship of betatrophin mRNA expression with circulating betatrophin was studied. The associations of the cholesterol-regulating single nucleotide polymorphism (SNP) rs2278426 in the betatrophin-encoding gene DOCK6, with insulin secretion was studied in a cross-sectional study (N=2136) and during 9 month of a lifestyle intervention (N=344).

**Results:** Betatrophin mRNA expression correlated positively with liver TG content ( $r=0.31$ ,  $p=0.0025$ ). In addition, a positive relationship was found between betatrophin mRNA expression and betatrophin plasma levels ( $r=0.41$ ,  $p=0.03$ ). The minor T allele of the SNP rs2278426, that also associated with lower plasma cholesterol levels in the present study ( $p=0.002$ ), associated with higher insulin secretion, adjusted for sex, age and insulin sensitivity, in subjects with prediabetes (N=701,  $p=0.044$ ), but not in subjects with normal glucose regulation (N=1435,  $p=0.78$ ). The minor T allele of the SNP rs2278426 also predicted a larger increase in adjusted insulin secretion during the lifestyle intervention in subjects with prediabetes ( $p=0.01$ ) and associated with higher arginine-stimulated insulin secretion ( $p=0.04$ ) in 97 subjects during a hyperglycaemic clamp.

**Conclusion:** We provide novel information that the liver-secreted protein betatrophin is increasingly expressed in NAFLD and that it may not only be involved in cholesterol metabolism, but also in glucose metabolism in subjects who are at increased risk for type 2 diabetes.

## 722

### Acute elevation of triglycerides and free fatty acids does not modulate plasma betatrophin levels in healthy individuals

D. Tripathy<sup>1,2</sup>, T. Arakawa<sup>1</sup>, A. Chavez-Velazquez<sup>1</sup>, Z. Perez-Cadena<sup>1</sup>, R. DeFronzo<sup>1</sup>;

<sup>1</sup>Diabetes, Medicine, University of Texas Health Science Center,

<sup>2</sup>Audie L Murphy Veterans Affairs Hospital, San Antonio, USA.

**Background and aims:** Betatrophin (ANGPTL8) is a liver-derived protein, and its overexpression in liver has been shown to cause beta cell proliferation, increased insulin secretion and hypertriglyceridemia in mice. ANGPTL8 knockout leads to marked reduction in postprandial triglyceride levels in mice. However, the relationships between plasma triglycerides, free fatty acids (FFA), and betatrophin have not been studied in humans.

**Materials and methods:** We examined the effect of acute elevation of plasma triglycerides and FFA on plasma betatrophin levels in 9 healthy NGT subjects (7 male/2 female, age =  $42 \pm 4$  yrs, BMI =  $26.3 \pm 1.0$  kg/m<sup>2</sup>, FPG =  $90 \pm 3$  mg/dl, 2h PG =  $135 \pm 11$  mg/dl), without family history of T2DM. Subjects received on two different occasions either a lipid (intralipid 60 ml/h) or saline

(0.9% NaCl 60 ml/h) infusion for 6 hours followed by euglycemic insulin clamp (80 mU/m<sup>2</sup>.min) for 2 hours. Plasma triglyceride, FFA, and betatrophin levels were measured at baseline, 6 hours, and 8 hours.

**Results:** Plasma triglyceride levels during the lipid infusion increased from  $187 \pm 39$  mg/dl at baseline to  $455 \pm 59$  mg/dl at 6 hours and declined to  $398 \pm 62$  mg/dl at 8 hours, and during the saline infusion decreased from  $183 \pm 60$  mg/dl to  $129 \pm 28$  mg/dl at 6 hours and  $106 \pm 25$  mg/dl at 8 hours. Plasma FFA levels during the lipid infusion increased from  $370 \pm 39$   $\mu$ M to  $846 \pm 68$   $\mu$ M at 6 hours and declined to  $496 \pm 66$   $\mu$ M at 8 hours. Plasma FFA concentrations did not change during the saline infusion. Insulin-mediated glucose disposal (Rd) was reduced during the lipid versus saline infusion ( $9.08 \pm 1.5$  vs  $11.3 \pm 1.4$  mg/kgFFM.min,  $p = 0.02$ ). Plasma betatrophin concentrations during the lipid infusion were  $22 \pm 15$ ,  $27 \pm 16$ , and  $27 \pm 17$  ng/ml at 0, 6, and 8 hours, respectively ( $p=ns$ ). The corresponding values of betatrophin during the saline infusion were  $21 \pm 6$ ,  $18 \pm 6$ , and  $24 \pm 5$  ng/ml, respectively. There was no relationship between plasma triglyceride, FFA, betatrophin concentrations, or insulin mediated whole body glucose disposal.

**Conclusion:** Short-term physiologic increase in plasma FFA, and triglycerides induce insulin resistance in skeletal muscle, but does not affect plasma betatrophin levels in healthy subjects. The association between betatrophin and lipids reported in animals is not observed in humans.

## 723

### ZBTB20 regulates lipid metabolism

W. Zhang<sup>1</sup>, L. Zhou<sup>1</sup>, L. Li<sup>1</sup>, Y. Zhang<sup>1</sup>, X. Jiang<sup>1</sup>, R. Chen<sup>1</sup>, D. Zou<sup>2</sup>;

<sup>1</sup>Department of Pathophysiology, Second Military Medical University,

<sup>2</sup>Department of Endocrinology, Shanghai Hospital, Shanghai, China.

**Background and aims:** We aims to investigate the potential role of novel zinc finger protein ZBTB20.

**Materials and methods:** We established liver-specific Zbtb20 knockout mice (LZB20KO) by Cre/LoxP, analyzed phenotypes, determined gene expression by RT-PCR and Western blot, and examined protein/DNA interaction by ChIP and reporter assay.

**Results:** Specific deletion of ZBTB20 in the liver resulted in a marked reduction in plasma lipid levels and hepatic triglyceride contents, and a significant improvement of high carbohydrate diet-induced hepatic steatosis and insulin resistance. Hepatic lipogenesis was substantially impaired in the absence of ZBTB20, which was associated with decreased expression of ChREBP- $\alpha$  and its target genes critical for glycolysis and lipogenesis, and could in part be restored by overexpression of ChREBP- $\alpha$ . Furthermore, liver ZBTB20 expression was significantly increased in ob/ob mice. Strikingly, liver-specific deletion of ZBTB20 in ob/ob mice could dramatically suppress hepatic lipogenesis, and improve obesity-induced hyperglycemia, dyslipidemia, hepatic steatosis, and insulin resistance.

**Conclusion:** Together, these data indicate that liver ZBTB20 is essential for lipid metabolism and may serve as a therapeutic target for metabolic syndrome.

### The role of starvation-induced autophagy in gluconeogenesis and ketogenesis

M. Kondo, A. Takagi, S. Kume, S. Ugi, T. Uzu, H. Maegawa;

Department of Medicine, Shiga University of Medical Science, Japan.

**Background and aims:** During starvation, fatty acids released from adipose tissue are mainly used for hepatic gluconeogenesis and ketogenesis to maintain systemic energy homeostasis in animals. Autophagy, a major intracellular degradation system, is induced by starvation. Systemic autophagy-deficient mice die in neonatal starvation period, suggesting that autophagy is a critical survival response against starvation. However, the exact role of starvation-induced autophagy in systemic energy homeostasis remains unclear.

**Materials and methods:** To determine the importance of autophagy in each organ, we examined starvation-induced gluconeogenesis and ketogenesis in liver specific Atg5 knockout mice (L-Atg5<sup>-/-</sup>), kidney proximal tubular epithelial cells specific Atg5 knockout mice (K-Atg5<sup>-/-</sup>), and their control mice (Atg5lox/lox).

**Results:** Under ad-libitum feeding condition, there were no significant differences in plasma ketone levels. But under 36-h fasting condition, increase in plasma ketone levels was impaired in L-Atg5<sup>-/-</sup> mice but not in K-Atg5<sup>-/-</sup> mice. The impairment of ketogenesis in L-Atg5<sup>-/-</sup> mice was incomplete. In

addition, the oil-red-O-stained lipid accumulation as a main source of ketogenesis and elevation of expression of HMG-CoA synthase, a rate-limiting enzyme of ketogenesis were observed in the kidney likely in the liver. We then hypothesized that the kidney compensated for the absence of ketone in L-Atg5<sup>-/-</sup> mice. To examine this hypothesis, we generated the mice lacking Atg5 in both the liver and kidney. These mice showed further decline in plasma ketone concentrations compared to L-Atg5<sup>-/-</sup> mice during a 36-h fast. Starvation-induced lipid droplets formation was impaired in Atg5-deficient organs. No significant differences in blood glucose levels and the expression of some enzymes for gluconeogenesis were observed among each type of mice, even with starvation.

**Conclusion:** These results suggest that starvation-induced autophagy is essential for ketogenesis relating with lipid accumulation from free fatty acid, and that the kidney potentially has a function to generate ketone bodies.

### 725

**The Cohen diabetic rat: a matter of mitochondrial disorder?**

A. Kogot-Levin<sup>1</sup>, C. Mantzur<sup>1</sup>, A. Saada<sup>2</sup>, I. Raz<sup>1</sup>, S. Weksler-Zangen<sup>1</sup>;

<sup>1</sup>Department of Internal Medicine, Diabetes Unit,

<sup>2</sup>Department of Human Genetics and Metabolic Diseases, Hadassah University Hospital, Jerusalem, Israel.

**Background and aims:** The Cohen diabetic rat model consists of two strains: the Cohen diabetic sensitive rat (CDs) developing hyperglycemia and decreased glucose stimulated insulin secretion (GSIS) on the diabetogenic-high-sucrose diet (HSD) and the Cohen diabetic resistant rat (CDr) which remains normoglycemic on HSD. Although underlying mechanisms causing inhibited GSIS in CDs remains yet elusive, we recently showed reduced activity of the mitochondrial respiratory-chain enzyme, cytochrome *c* oxidase (COX) and ATP content in islets of hyperglycemic-CDs, tightly linking inhibited GSIS to COX deficiency. We examined whether CDs has a ubiquitous COX deficiency, thus suggesting a model of mitochondrial disorder related diabetes.

**Materials and methods:** CDs and CDr males, eight weeks old were fed a regular-diet (RD) or a diabetogenic-diet containing 72% sucrose for 30 days. Activity of COX normalized to citrate-synthase (CS) was determined in pancreatic-islets, lymphocytes, pancreas, heart and liver homogenates spectrophotometrically. Expression levels of COX subunits 1 & 2 (COX1 & COX2) and their chaperons Sco1, COX11 and COX17 were examined in RNA extracted from islets by qRT-PCR and expressed as a fold-change of the expression in CDr fed RD. Mitochondrial DNA (mtDNA) content was analyzed in DNA from islets by qRT-PCR. COX1 protein levels were determined in islets by Western-blot analysis.

**Results:** An initial significant decrease in COX activity was observed in islets, lymphocytes, pancreas, heart and liver of normoglycemic-CDs demonstrating 85, 40, 30, 40 and 30% respective reduction ( $p < 0.01$ ) compared to CDr fed RD. On the diabetogenic-HSD, COX activity was significantly ( $p < 0.01$ ) reduced in hyperglycemic-CDs and normoglycemic-CDr but the decrease in hyperglycemic-CDs was more evident. Activity of the ubiquitous mitochondrial matrix enzyme CS used as an estimation of mitochondrial content was not different between groups. Islets COX1 and COX2 expression levels were 0.3-fold reduced in CDs fed RD, ( $p < 0.01$ ) and Sco1, COX11 and COX17, COX assembly proteins, were 0.5, 0.3 and 0.2 fold reduced respectively ( $p < 0.01$ ), compared to CDr. COX1 protein levels were also reduced in islets of CDs fed RD. mtDNA content was 0.5-fold decreased ( $p < 0.01$ ) in islets of CDs fed RD, compared to CDr.

**Conclusion:** We demonstrate a widespread impairment of COX activity in islets, lymphocytes, pancreas, heart and liver of the normoglycemic-CDs deteriorating furthermore on diabetogenic diet. The more prominent COX deficiency observed in islets presumably explains why the clinical outcome in CDs is mainly manifested as diabetes, while the phenotype is milder in the other tissues. Moreover, alterations in mitochondrial function are likely to have deleterious effects in cells that have a high energy requirement, such as the  $\beta$ -cell. These finding links COX deficiency and  $\beta$ -cell dysfunction and positions the Cohen diabetic rat as a good model to study mitochondrial disease-related diabetes.

### 726

**Weight loss in obese ob/ob mice improves mitochondrial dynamics in liver, muscle and adipose tissue**

J. Schultz, S. Baltrusch;

Institut of Medical Biochemistry and Molecular Biology, Rostock, Germany.

**Background and aims:** Mitochondrial dysfunction has been proposed to play an important role in the development of type 2 diabetes. Six proteins are currently known in mammals regulating the mitochondrial live cycle. The Mitofusin 1 and 2 (Mfn1/2) and the optic atrophy protein 1 (Opa1) are essential for mitochondrial fusion, whereas the fission protein 1 (Fis1), the

mitochondrial fission factor (Mff) and the dynamin related protein 1 (Drp1) control fission. Recent studies indicate that obesity deteriorates mitochondrial dynamics, and thus, mitochondrial function. In this study we investigated regulation of mitochondrial dynamics in liver, muscle and adipose tissue of ob/ob mice after calorie-restricted feeding compared to ad-libitum feeding.

**Materials and methods:** Three month old male obese ob/ob (B6.V-lebob/ob) mice were fed for twelve weeks with a calorie-restricted diet, whereas the control group had unrestricted access to feed. Age matched ob/+ (B6.V-lebob/+) mice served as lean controls. Finally mice were killed and tissues were analyzed for Mfn1/2, Opa1, Fis1, Mff and Drp1 expression by quantitative PCR analyses. Fis1 protein expression was investigated using western blot and immunofluorescence analyses. The mitochondrial network was visualized by Mito Tracker DeepRed staining and fat accumulation by Red Oil staining.

**Results:** At the age of three month ob/ob mice showed a significantly higher body weight than ob/+ mice ( $46 \pm 2$  vs.  $31 \pm 1$  g). After twelve weeks of calorie-restricted diet obese ob/ob mice showed a significantly lower body weight compared to ad-libitum feed mice ( $39 \pm 2$  vs.  $62 \pm 2$  g). In addition a lower level of fat accumulation in liver and muscle was observed in ob/ob mice after calorie-restricted diet. Gene expression of all fusion and fission proteins was lower in liver, muscle and adipose tissue of ob/ob mice compared to lean control mice, indicating reduction of mitochondrial dynamics. Calorie-restricted diet resulted in ob/ob mice in a significantly higher expression of all genes involved in mitochondrial fission and fusion compared to ad-libitum feeding. The strong increase of Fis1 expression in calorie-restricted feed ob/ob mice could be confirmed in liver, muscle and adipose tissue on the protein level. Obese ob/ob mice showed formation of mitochondrial cluster in liver and fatty tissue whereas a more homogenous network of mitochondria was observed in diet feed ob/ob mice.

**Conclusion:** We observed a correlation between reduced body weight and lower fat accumulation and improved mitochondrial dynamics in liver, muscle and adipose tissue of ob/ob mice. Thus, a calorie-restricted diet has a beneficial effect on mitochondrial morphology in obese subjects. Mitochondrial function in liver, muscle and adipose tissue is significant to maintain insulin sensitivity and glucose tolerance. Our study provides further evidence that obesity induced mitochondrial dysfunction contributes to the development of type 2 diabetes.

## 727

### An mtDNA mutation in the cytochrome c oxidase changes mitochondrial dynamics and favours development of type 2 diabetes mellitus

J. Niemann, C. John, J. Schultz, M. Tiedge, S. Baltrusch;  
Institute of Medical Biochemistry and Molecular Biology, University  
Rostock, Germany.

**Background and aims:** Mutations in the mitochondrial genome (mtDNA) affect subunits of respiratory chain complexes and can impair their function. It has been postulated that mtDNA mutations which accumulate with age contribute to the pathogenesis of type 2 diabetes mellitus (T2DM). We have shown that the conplastic mouse strain C57BL/6NTac-mtNOD/AtJ (mtNOD) with a mtDNA point mutation in the subunit 3 of cytochrome c oxidase (OXPHOS complex IV) has a higher ROS production with age compared to controls. In this study we investigated mitochondrial morphology and mitochondrial fission-fusion processes in hepatocytes of this conplastic mouse strain.

**Materials and methods:** Primary hepatocytes were isolated from 3, 6, 9 and 12 month old mtNOD and C57BL/6NTac (control) mice. Hepatocytes were stained with MitoTrackerGreen. Thereafter mitochondrial morphology was investigated by fluorescence microscopy and the median mitochondrial elongation level was calculated using AutoQuant software. Gene expression of the mitochondrial fusion proteins OPA1, MFN1 and MFN2 and of the fission proteins FIS1 and DNMI1 was determined by quantitative PCR analyses.

**Results:** The median mitochondrial elongation level in 3 month old hepatocytes of mtNOD mice was significantly lower compared to control mice. The median mitochondrial elongation level decreased with age in hepatocytes of control mice. In contrast, an increase of the median mitochondrial elongation level was observed in hepatocytes of mtNOD mice. Gene expression of the mitofusin MFN1 and MFN2 declined during ageing in control mice, whereas the expression of both genes increased in mtNOD mice. At the age of 12 month the expression was in mtNOD mice twice as high as in control mice. In addition, the expression of the fission protein DNMI1 was significantly lower in 12 months old mtNOD compared to control mice.

**Conclusion:** The observed mitochondrial phenotype correlated with the gene expression profile of mitochondrial fission and fusion genes at the

investigated points of age. Our results indicate that a mtDNA mutation in the cytochrome c oxidase triggers a higher mitochondrial elongation level of hepatocytes with age. This process could be mediated by an interaction between the higher ROS production and the up-regulation of MFN1 and MFN2 in aged mtNOD mice. Thus, the C57BL/6NTac-mtNOD/AtJ mouse strain represents an interesting model to study trigger effects of age dependent mitochondrial phenotypes in the pathogenesis of T2DM.

## 728

### Dual effect of Nd2 gene mutation in complex I of the respiratory chain: ROS generation and induction of mitoprotective effects in the course of ageing

M. Wietzke, E. Meyer, F. Koch, J. Niemann, H. Weiss, S. Baltrusch,  
M. Tiedge;  
Institute of Medical Biochemistry and Molecular Biology, Rostock,  
Germany.

**Background and aims:** The mitochondrial genome of the diabetes-resistant B6-mtALR mouse strain is characterized by a mt-DNA encoded Nd2 polymorphism in complex I of the respiratory chain. In metabolically active organs such as the liver disorders of the mitochondrial electron transfer with increased ROS generation are linked to accelerated aging. It was the aim of the study to investigate the production of reactive oxygen species (ROS), the expression of antioxidant enzymes and the expression of the aging marker p53 in liver tissue of conplastic B6-mtALR mice compared to B6-mtAKR control strain.

**Materials and methods:** Conplastic B6-mtAKR (AKR) and B6-mtALR (ALR) mice were examined over a period of 2 years. AKR and ALR animals were killed and liver tissue was collected at the age of 3, 6, 9, 12, 18 and 24 months. The gene expression of Nd2, Sod1, Sod2, catalase, UCP2, TFAM and mTOR was quantified by real-time RT-PCR and the p53 protein expression was quantified by Western blot analyses. The measurement of mitochondrial ROS production in the liver was performed by fluorescence microscopy after injection of the ROS sensor Mitosox.

**Results:** The gene expression of mt-Nd2 in the ALR strain showed no differences compared to the control strain AKR. The ROS production in the liver at the ages of 6 and 12 months was significantly increased in AKR mice (2-18-fold,  $p < 0.05$ ). Only at the age of 18 months ROS production in the liver of ALR animals was significantly increased by 100% ( $p < 0.05$ ). Furthermore, the AKR strain showed higher expression of cytoprotective genes SOD2, SOD1 and catalase with advanced aging whereas for the ALR strain only at the time of impaired ROS generation an increased expression of UCP2 (3x,  $p < 0.05$ ) and catalase (2.7x,  $p < 0.05$ ) was detectable. The aging markers p53 showed a higher expression in the liver of AKR mice compared to the ALR strain with the mt-ND2 mutation (x3.5,  $P < 0.01$ ).

**Conclusion:** The mt-ND2 mutation in complex I of the respiratory chain favors the formation of reactive oxygen species in the liver. The potential of increased ROS generation does not accelerate the aging process if antioxidant and mitoprotective genes provide sufficient protection as a process of mitohormesis. Only at advanced age the decreased expression of mitochondrial protective structures cannot counteract negative ROS effects on organ function and aging.

## 729

### The role of p66Shc in the development of obesity and metabolic disorders: a translational study

S. Cicilioti<sup>1,2</sup>, M. Albiero<sup>2</sup>, N. Poncina<sup>1,2</sup>, L. Menegazzo<sup>1,2</sup>, M. Foletto<sup>3</sup>,  
D. Nitti<sup>3</sup>, M. Giorgio<sup>4</sup>, A. Avogaro<sup>1,2</sup>, G. Fadini<sup>1,2</sup>;

<sup>1</sup>Department of Medicine, University of Padova, <sup>2</sup>Venetian Institute of  
Molecular Medicine, Padova, <sup>3</sup>Clinica Chirurgica I, University of Padova,

<sup>4</sup>Department of Experimental Oncology, European Institute of Oncology,  
Milan, Italy.

**Background and aims:** p66Shc is a redox enzyme and adaptor protein, potentially associated with lifespan determination. Multiple evidences indicate that p66shc plays a role in the cellular response triggered by oxidative stress and the development of chronic diabetic complications. There are preliminary and contradictory data on the role of p66Shc in the development of obesity and type 2 diabetes. In this translational study, the role of p66Shc was evaluated in obesity and metabolic syndrome, studying the expression

of p66Shc in human adipose tissue and the characteristics of visceral adipose (VAT) and subcutaneous adipose tissue (SAT) in p66Shc<sup>-/-</sup>Ob/Ob mice at 18 and 30 weeks of age.

**Materials and methods:** 4 different mouse models were used: C57/BL6 wt mice, Ob/Ob mice, p66<sup>-/-</sup> mice, p66<sup>-/-</sup> Ob/Ob mice. 2 time points: 18 and 30 weeks of age. Both visceral (VAT) and sub-cutaneous (SAT) white adipose tissue samples were analysed.

**Results:** p66Shc<sup>-/-</sup>Ob/Ob mice develop obesity, but at 30 weeks, their body weight was significantly lower than in Ob/Ob controls. The size of visceral adipocytes was reduced in p66Shc<sup>-/-</sup> mice at 18 weeks, but not significantly different compared to control Ob/Ob mice at 30 weeks. The number of apoptotic cells in VAT was increased in Ob/Ob mice compared to wt, but significantly reduced by p66Shc deletion. The number of macrophages in VAT was also reduced in p66Shc<sup>-/-</sup>Ob/Ob compared to Ob/Ob mice. Based on ITT and GTT, p66Shc<sup>-/-</sup>Ob/Ob mice at 18 weeks are less glucose intolerant and insulin resistant compared to Ob/Ob mice, but become insulin resistant at 30 weeks of age. In a sample of 46 individuals undergoing bariatric surgery, the expression of p66Shc linearly correlates with BMI in VAT, but inversely correlates in SAT, only in young subjects.

**Conclusion:** These data support the hypothesis that p66Shc modulates the processes occurring during the development of obesity and metabolic disorders, affecting adipogenesis and inflammation of visceral adipose tissue. The role of p66Shc appears to be influenced by age, most likely in relation to the role of this protein during aging.

## 730

### Regulation of skeletal muscle lipolysis and oxidative metabolism by G0/G1 switch gene 2

C. Laurens, P.-M. Badin, K. Louche, D. Langin, V. Bourlier, C. Moro; Institute of Metabolic and Cardiovascular Diseases, Inserm UMR1048, Toulouse, France.

**Background and aims:** Intramyocellular triacylglycerol (IMTG) pool is an important energy source in skeletal muscle, especially during exercise. Recent data suggest that the *adipose triglyceride lipase* (ATGL) plays a key role in providing energy substrate from IMTG and perturbations of its expression/activity are linked to altered energy metabolism in skeletal muscle. However, little is known about its regulation. The aim of this study was to investigate the role of the protein *G0/G1 Switch Gene 2* (G0S2), recently described as an inhibitor of ATGL in white adipose tissue, in the regulation of lipolysis and oxidative metabolism in skeletal muscle.

**Materials and methods:** G0S2 was overexpressed and knocked down in human primary myotubes obtained from *rectus abdominis* biopsies in healthy volunteers and transduced with adenoviruses and lentiviruses, respectively. ATGL activity, IMTG content, fatty acid mobilization and oxidation, glucose oxidation and glycogen synthesis were assessed by using radiolabeled substrates. Metabolic studies were supplemented with the investigation of mitochondrial phenotype using fluorescent probes and RT-qPCR (for the analysis of key gene expression).

**Results:** Our results show that G0S2 is expressed in human myotubes and inhibits ATGL activity (-47% ; P<0.05). G0S2 downregulation induces a decrease in IMTG pool (-70% ; P<0.001) and an increase in fatty acid mobilization (+500% ; P<0.001) and oxidation (+300% ; P<0.001). Glucose oxidation and glycogen synthesis are decreased (-35% and -63% respectively ; P<0.01). The increase of fatty acid flux goes along with an increase in mitochondrial mass (+67% ; P<0.001) and membrane potential (+108% ; P<0.01). These effects may be mediated by the activation of *Peroxisome Proliferator Activated Receptor δ* (PPARδ) target genes *Perilipin 2*, *PPAR Gamma Coactivator 1α* and *Pyruvate Dehydrogenase Kinase 4* (+89%, +93%, and +295%, respectively ; P<0.01). Opposite effects are observed when G0S2 is overexpressed.

**Conclusion:** Collectively, the data indicate that G0S2 plays an important role in the regulation of human skeletal muscle lipolysis and oxidative metabolism, by modulating fatty acid flux and expression of PPARδ target genes.

## 731

### Role of L-Carnitine on skeletal muscle hypertrophy and mitochondrial function

L. Luzi<sup>1,2</sup>, A. Montesano<sup>1</sup>, P. Senesi<sup>1,2</sup>, I. Terruzzi<sup>3</sup>;

<sup>1</sup>University of Milan, <sup>2</sup>Metabolism Research Centre and Department of Endocrinology and Metabolic Diseases, San Donato Hospital and Scientific Institute, <sup>3</sup>Div. Metabolic and Cardiovascular Sciences. Metabolism, Nutrigenomics and Cellular Differentiation, San Raffaele Scientific Institute, Milan, Italy.

**Background and aims:** Type 2 diabetes mellitus (T2DM) is a metabolic disease associated with hyperglycaemic condition due to impairments in insulin release and/or function. Insulin Resistance (IR) is defined as a reduced response to insulin biological effects in target tissues, like skeletal muscle. There is evidence that mitochondrial dysfunction is associated with IR and T2DM. In particular, oxidative stress has an important role in the inhibition of muscle metabolism: the progressive reduction in the number and efficiency of mitochondria has been proposed as a mechanism able to induce muscle atrophy in T2DM. L-Carnitine (CARN) is an essential nutrient and plays an important role in mitochondrial β-oxidation and in the ubiquitin-proteasome system regulation. Muscle cells are unable to synthesize CARN. As a dietary supplement to ameliorate pathological condition characterized by myofibrils degeneration or improve athletic performance, CARN has been studied for its potential to enhance β-oxidation. However, CARN effects on myogenesis, mitochondrial capacity and atrophy process are not completely elucidated. This study aims to investigate CARN action on skeletal muscle remodeling, in particular in differentiation and atrophy processes, in normal and insulin resistance conditions.

**Materials and methods:** We analyzed muscle cell differentiation and morphological features in C2C12 myoblasts exposed to 5 mM CARN. To study the RAN dose-response relationship we treated neo myotubes with 1, 5 and 25 mM CARN for 24 hours (h). 5 mM CARN turned out to be the dose able to stimulate morphological changes and hypertrophic process in neoformed myotubes. 5 mM CARN was added to C2C12 during skeletal muscle proliferation, differentiation and on neo formed myotubes assessing cellular insulin response, mitochondrial function, oxidative stress pathways and atrophy genesis.

**Results:** Our data showed that CARN positively regulate the kinetics of C2C12 cell growth curve, accelerate myotubes formation and induce morphological changes indicating the start of hypertrophy process. In addition, CARN improved AKT phosphorylation and downstream cellular synthetic pathways. CARN positively regulated mitochondrial biogenesis whilst negatively modulated the pathways related to oxidative stress/ROS productions (SOD modulation).

**Conclusion:** We provide an interesting novel mechanism of the potential therapeutic use of CARN to treat insulin resistance condition characterized by skeletal muscle morphological and functional impairment, mitochondrial dysfunction and oxidative stress production in atrophy process.

## PS 053 Metabolic effects of dietary composition, caloric restriction and bariatric surgery

732

**Associations of dietary fibre intake and risk factors of the metabolic syndrome. The lipid and glucose under prospective surveillance (LUPS) study**

J. Haas<sup>1</sup>, H. Pinnschmidt<sup>2</sup>, M. Toeller<sup>1</sup>, A. Partenheimer<sup>1</sup>, K. Wegscheider<sup>2</sup>, D. Mueller-Wieland<sup>1</sup>;

<sup>1</sup>Department of General Internal Medicine and Institute for Diabetes Research, Asklepios Clinic St. Georg, Asklepios Medical School, Faculty of Medicine of Semmelweis Medical University,

<sup>2</sup>Department of Medical Biometry and Epidemiology, University Medical Center, Hamburg, Germany.

**Background and aims:** The metabolic syndrome is classified by a clustering of metabolic and cardiovascular risk factors, in particular, elevated waist circumference, serum triglycerides, blood pressure, fasting glucose and reduced HDL-cholesterol. The exact etiology remains unclear, but it is known to be a complex interaction between genetic, metabolic, and environmental factors. Amongst exogenous factors nutrition has a central role in the development of the metabolic syndrome, and dietary fibre intake is supposed to be an important factor in this respect. Therefore we aimed to evaluate associations of dietary fibre intake and the prevalence of risk factors of the metabolic syndrome in the LUPS cohort.

**Materials and methods:** Baseline data from the prospective LUPS cohort (1887 healthy workers, 1274 men and 613 women, aged 25–60 years) were investigated for associations between dietary fibre intake and risk factors of the metabolic syndrome (classification criteria) using logistic regression and Jonckheere-Terpstra test. Fibre intake was assessed by a standardized semi-quantitative food frequency questionnaire with 85 items covering typical food choices and portion sizes in Germany.

**Results:** Mean dietary fibre intake (g/1000 Kcal/day) was 11.9 (95% CI: 11.6; 12.3) in women and 9.9 (95% CI: 9.7; 10.1) men. The highest prevalence of risk factors for the metabolic syndrome was seen for increased blood pressure in 70% of men and 40% of women. The prevalence of the other risk factors of the metabolic syndrome in the cohort decreased from elevated waist circumference (28%), high triglycerides (20%), reduced HDL-cholesterol (19%) to increased fasting blood glucose (10%). Only elevated waist circumference showed a higher prevalence in women (37%) than in men (25%). Significant negative associations were found between fibre intake and waist circumference (-6.36 standardized JT-statistics with continuous variable, odds ratio 0.952 for grouped variable; waist circumference for men  $\geq 102$  cm and  $\geq 88$  cm for women) as well as for fibre intake and fasting triglyceride levels (-5.57 standardized JT-statistics, odds ratio 0.927; triglycerides  $\geq 150$  mg/dl), while positive associations were seen between fibre intake and HDL-cholesterol (8.66 standardized JT-statistics, odds ratio 0.948; HDL-cholesterol  $< 40$  mg/dl for men and  $< 50$  mg/dl for women) (all  $p < 0.05$ ), however no associations were observed between fibre intake, and elevated blood pressure ( $\geq 130/85$  mmHg) as well as fibre intake and increased fasting glucose ( $\geq 100$  mg/dl) in the baseline investigation of the LUPS cohort.

**Conclusion:** Dietary fibre intake, in the range commonly consumed by healthy workers, was significantly related to important risk factors of the metabolic syndrome in the LUPS study. Higher fibre intake was associated with smaller waist, lower triglycerides and higher HDL-cholesterol.

733

**Dairy lipids, proteins, and abdominal obesity (DairyHealth): a 12-week, randomised, parallel-controlled, human intervention study**

K. Hermansen, M. Bohl, S. Gregersen;

Dept of Endocrinology and Metabolism, Aarhus University Hospital, Denmark.

**Background and aims:** Abdominal obesity is associated with increased risk of cardiovascular disease (CVD), type 2 diabetes, and overall mortality. Obesity leads to exaggerated postprandial lipaemia (PPL), an independent risk factor for CVD. Food quality has been found to affect PPL. Milk protein, especially whey and milk fat naturally enriched with short- and medium-

chain saturated fatty acids (SMC-SFA) seem to possess health beneficial effects. However, long-term human intervention studies are lacking. The aim was to test if whey protein and milk fat enriched in SMC-SFA has beneficial and synergistic effects on the postprandial lipid responses.

**Materials and methods:** 12-week, randomized, double-blinded, human intervention study. 63 subjects were randomized to one of four diets in a 2x2 Latin square design. Participants consumed daily 60g milk protein (whey or casein) and 63g milk fat (two different SMC-SFA compositions) daily. Before and after the 12-week intervention a high-fat meal test (65 E% fat, 19 E% carbohydrates, and 16 E% protein; 4,500 kJ) was performed and changes from baseline in postprandial triglyceride, ApoB-48 (reflecting chylomicrons of intestinal origin), free fatty acids (FFA), insulin, glucose and glucagon were measured. Two-way ANOVA analysis was used. Power calculation showed that we needed 13 in each group to detect a difference of 20% in triglyceride response ( $\alpha = 0.05$ ,  $\beta = 0.80$ ).

**Results:** 52 subjects completed the study. Baseline characteristics were similar between the four groups. We found that the ApoB-48 response decreased significantly after whey compared to casein ( $P=0.025$ ). We found no significant differences in postprandial triglyceride, FFA, insulin, glucose or glucagon responses to whey versus casein or to the two different SMC-SFA compositions. No interaction between protein and fat was observed.

**Conclusion:** 12-week intervention with whey supplementation resulted in a decreased postprandial chylomicron response in subjects with abdominal obesity. This opens for the development of whey enriched dairy products that may possess beneficial effects on the risk of CVD.

**Lysophospholipids in human blood and their interaction with white adipose tissue under an isocaloric high-fat diet in the NUGAT-study**

T. Frahnow<sup>1</sup>, M.A. Osterhoff<sup>1,2</sup>, A.C. Seltmann<sup>1</sup>, S. Hornemann<sup>1</sup>, M. Kruse<sup>1</sup>, S. Sales<sup>3</sup>, J.L. Sampaio<sup>3</sup>, A.F.H. Pfeiffer<sup>1,2</sup>;

<sup>1</sup>Clinical Nutrition, German Institute for Human Nutrition Potsdam-Rehbrücke, Nuthetal, <sup>2</sup>Charité – University of Medicine Berlin, <sup>3</sup>Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany.

**Background and aims:** Diets high in saturated fats increase diabetes risk and fatty liver. Apart from the cholesterol metabolism their detailed effects on the lipids are not well established which we therefore studied using cutting edge technology.

**Materials and methods:** In the NUGAT study (NUtriGenomic Analysis in Twins) we used a twin-design with 92 healthy participants and two isocaloric nutritional interventions to investigate the impact of a six-week carbohydrate rich, low fat followed by a six-week high fat low carbohydrate diet. Extensive characterization of the metabolic responses was performed after the low fat (LF) and after 1 (HF1) or 6 (HF6) weeks of high fat diet to evaluate rapid and long-term effects. Apart from other 145 lipids, 20 lysophospholipids were analyzed within and in connection with measured biomarkers of blood and white adipose tissue. The fold changes (FC) between two clinical investigation days were calculated and the Benjamini-Hochberg method (BH) was used to adjust the global significance level for multiple testing.

**Results:** Lysophosphatidylcholines (LPC) and -ethanolamines (LPE) showed an almost continuous decrease during the six weeks on high-fat diet (LPC:  $FC_{LF, HF6} \approx 0.55$ ; LPE:  $FC_{LF, HF6} \approx 0.73$ ), whereas other measured lipid classes reacted biphasically and more adaptively. Members of LPC as well as LPE were also highly connected within and between these two lipid classes, partly reflecting their known biosynthesis. The lysophospholipids were associated with biomarkers of signal transduction, apoptosis (i.e. SQSTM1/p62:  $\tau \approx 0.36$ ,  $p_{BH} < 0.05$ ) as well as members of inflammatory pathways and the immune system (i.e. TBX21:  $\tau \approx -0.41$ ,  $p_{BH} < 0.05$ ). These associations were not only given for basal values but also for differences between the clinical investigation days. The gene expression of NFKBIA/IkBa, which decreased significantly during the study ( $FC_{LF, HF6} \approx 0.80$ ), also showed high associations with the LPEs and LPCs (i.e.:  $\tau \approx 0.40$ ,  $p_{BH} < 0.001$ ). However, TLR2 and TLR4 were independent of the lysophospholipids (TLR2:  $p_{BH} > 0.41$ ; TLR4:  $p_{BH} > 0.31$ ).

**Conclusion:** Although extensive adaptation occurs in our healthy participants after 6 weeks on a high-fat diet, parts of the metabolism remain disturbed. The decreasing lysophospholipids seem to accompany the activation of the immune system as well as higher inflammatory processes. Our analysis

shows novel pathways by which saturated fats increase inflammation independent of the known TLR4-related mechanisms of inflammation.

### The effect of meal frequency on fatty acid composition in serum phospholipids in patients with type 2 diabetes

H. Kahleova<sup>1</sup>, H. Malinska<sup>1</sup>, L. Kazdova<sup>1</sup>, L. Belinova<sup>1</sup>, M. Hill<sup>2</sup>, T. Pelikanova<sup>1</sup>;

<sup>1</sup>Diabetes Centre, Institute for Clinical and Experimental Medicine,

<sup>2</sup>Institute of Endocrinology, Prague, Czech Republic.

**Background and aims:** Fatty acids are important cellular constituents that may affect many metabolic processes relevant for the development of diabetes and its complications. We demonstrated previously the superior effect of two meals a day, breakfast and lunch (B2) on body weight, hepatic fat content and insulin sensitivity compared to the same diet divided into six smaller meals a day (A6). The aim of this secondary analysis was to explore the effect of frequency of meals on the fatty acid composition of serum phospholipids in subjects with type 2 diabetes (T2D).

**Materials and methods:** In a randomised, crossover study, we assigned 54 patients with T2D to follow two regimens of a hypocaloric diet (-500 kcal/day), each for 12 weeks: six meals (A6), and two meals a day, breakfast and lunch (B2). The diet in both regimens had the same macronutrient and energy content. The procedures were performed at weeks 0, 12 and 24. The fatty acid composition of serum phospholipids was measured by gas liquid chromatography. Insulin sensitivity was derived as an oral glucose insulin sensitivity (OGIS) index.

**Results:** Saturated fatty acids (mainly the myristic and palmitic acids) decreased ( $p < 0.001$ ) and n6 polyunsaturated fatty acids increased ( $p < 0.001$ ) in response to both regimens, more with B2 ( $p < 0.001$  for both). Monounsaturated fatty acids decreased ( $p < 0.05$ ) and n3 polyunsaturated fatty acids increased ( $p < 0.001$ ) in response to both regimens with no difference between the treatments. The increase in OGIS correlated positively with changes in proportion of linoleic acid in B2. This correlation remained significant even after adjustment for changes in BMI ( $r = +0.38$ ;  $p = 0.012$ ).

**Conclusion:** We demonstrated that meal frequency affects fatty acid composition of serum phospholipids. We observed more marked positive effects of B2. The increase in linoleic acid could partly explain the insulin-sensitising effect of B2 in T2D.

### Early undernutrition worsens the metabolic effects of high-lipid diets

E. Lizárraga-Mollinedo<sup>1,2</sup>, J. de Toro-Martín<sup>1</sup>, E. Fernández-Millán<sup>2</sup>, M. García-San Frutos<sup>3</sup>, T. Fernández-Agulló<sup>3</sup>, M. Ros<sup>3</sup>, C. Álvarez<sup>1,2</sup>, F. Escrivá<sup>1,2</sup>;

<sup>1</sup>Bioquímica y Biología Molecular II, Facultad de Farmacia, UCM,

<sup>2</sup>Ciberdem, ISCIII, <sup>3</sup>Ciencias de la Salud, Universidad Rey Juan Carlos, Madrid, Spain.

**Background and aims:** Early undernutrition is associated with increased risk of diseases in adulthood. Interventions on nutrition of mothers and children have short-term benefits on health but growth-retarded offspring overfed undergoes a rapid catch-up growth and become long-term heavier than normal. Paradoxically, the West's obesity epidemic is spreading into developing countries in conjunction with a high prevalence of malnutrition. This raises the question whether previous undernutrition exacerbates the metabolic alterations associated with calorie-dense foods. Published results are contradictory about. The aim of present study is: A) to investigate the impact of undernutrition in hypothalamus; B) to explain how this condition worsens some alterations associated with subsequent high-fat diets.

**Materials and methods:** Wistar rats were subjected to undernutrition from 14th d of foetal life until 70 d (U). Control (C) animals were fed a standard chow ad libitum (3% fat). From 70 days (C70d, U70d) until 9 m, several groups were established: C70 was segregated into two groups, given the commercial chow (C9m) or a cafeteria diet (C9mCaf) of high lipid concentration, but lower than used in most similar studies (13% fat). A group of undernour-

ished rats was kept under restriction (U9m), other was transferred to cafeteria diet (U9mCaf) and other was transferred to commercial chow (U9mC). Adiposity was calculated by RMI. Hypothalamic POMC and NPY mRNA, as well as hepatic MCP-1 mRNA, were quantified. Insulin sensitivity was assessed by euglycemic clamp.

**Results:** Calorie intake of restricted rats under the high-fat diet exceeded that of controls, which was consistent with a reduced POMC protein and increased NPY expression. These alterations could derive from an impaired neonatal "leptin surge". All rats feeding cafeteria diet weighed more than their matched standard chow animals. In controls, this implied a mild obesity, not found in the pre-restricted. The relative increase in visceral fat over previous content was higher in U9mCaf than in C9mCaf rats: 6-fold vs. 2-fold, respectively. Insulin-resistance was established in both groups. Hyperlipidemia and triglyceride deposits were increased only in liver and muscle of U9mCaf rats, in which a marked increase of hepatic MCP-1 mRNA was also found.

**Conclusion:** Metabolic effects of a cafeteria diet are worsened by previous undernutrition, specifically: ectopic lipid storage and dislipemia. Also, increased MCP-1 in liver suggests accumulation of inflammatory macrophages, as hepatic injury in chronic liver diseases. These results indicate that previous food restriction increases vulnerability to the harmful effects of fatty diets.

### Severe food restriction induces stress and adipose tissue inflammation, contributing to the promotion of insulin resistance

Y.-S. Lee, C. Lee, H.-S. Jun;

Lee Gil Ya Cancer and Diabetes Institute, Gachon University, Incheon, Republic of Korea.

**Background and aims:** Accumulation of proinflammatory immune cells in adipose tissue contributes to the development of obesity-associated disorders. To reduce of obesity, food restriction has been recommended as an effective therapeutic strategy for weight loss. Many studies have shown that food-intake schedule can alter biological rhythms. Here, we studied whether food restriction program induces stress and cause immune cells infiltration in adipose tissue, contributing to the insulin resistance.

**Materials and methods:** C57BL/6 mice were fed 60% high fat diet for 8 weeks and randomly divided into three groups: the control group was continuously fed 60% high fat diet (100%); the 50% food restriction groups were fed 50% of the mean amount of food consumed by the control mice, fed 50% once a day (FR1; 50%-1, 9:00 AM) or fed 25% twice a day (FR2; 25%-2, 9:00 AM, 9:00 PM) for 3 days. Body weight was monitored and immune cell infiltration of epididymal adipose tissue was examined by hematoxylin and eosin staining. In addition, the expression of lipolysis or inflammatory related genes in adipose tissue was analyzed by qRT-PCR and the serum corticosterone levels were measured by ELISA. To investigate the association between stress hormone and adipose tissue inflammation, high fat diet induced obese mice were treated with vehicle or corticosterone (15 ug/h via an osmotic minipump, subcutaneously) for 3 days, and the expression of lipolysis and inflammatory related genes was analyzed by qRT-PCR, blood glucose levels were measured, and insulin tolerance tests were performed.

**Results:** Body weight loss was induced in food restricted groups (FR1 and FR2 group) compared to control group, with further body weight loss in FR1 group than FR2 group ( $P < 0.05$ ). The infiltrated adipose tissue immune cell population was increased in FR1 group but not in FR2 group compared with control group ( $P < 0.05$ ). The expression of MCP-1 and TLR-4 mRNA expression was increased in FR1 group but not in FR2 group compared with control mice ( $P < 0.05$ ). The expression of lipolysis related genes, adipose triglyceride lipase (ATGL), hormone sensitive lipase (HSL), and lipoprotein lipase (LPL) mRNA was increased in FR1 group compared with FR2 group ( $P < 0.05$ ). The serum corticosterone levels were significantly increased in both FR1 and FR2 compared with control group ( $P < 0.05$ ), with much higher in FR1 group than FR2 group ( $P < 0.05$ ). After corticosterone infusion for 3 days, the expression of ATGL mRNA was increased in adipose tissue ( $P < 0.01$ ) and blood glucose levels was increased ( $P < 0.01$ ) and impaired insulin tolerance ( $P < 0.001$ ).

**Conclusion:** These results indicate that severe food restriction could induce stress, lipolysis, adipose tissue immune cell infiltration and inflammation, which in turn may influence insulin resistance.

**The effects of bariatric surgery on pancreatic lipid metabolism in morbidly obese subjects**

H. Honka<sup>1</sup>, J. Koffert<sup>1</sup>, J.C. Hannukainen<sup>1</sup>, J.J. Tuulari<sup>1</sup>, H.K. Karlsson<sup>1</sup>, V. Oikonen<sup>1</sup>, P. Salminen<sup>2</sup>, M. Soinio<sup>3</sup>, A. Mari<sup>4</sup>, P. Iozzo<sup>5</sup>, P. Nuutila<sup>1,3</sup>; <sup>1</sup>Turku PET Centre, University of Turku, <sup>2</sup>Division of Digestive Surgery and Urology, Turku University Hospital, <sup>3</sup>Department of Endocrinology, Turku University Hospital, Finland, <sup>4</sup>Institute of Biomedical Engineering, National Research Council, Padua, <sup>5</sup>Institute of Clinical Physiology, National Research Council, Pisa, Italy.

**Background and aims:** As a treatment modality for morbid obesity, bariatric surgery leads to a sustained weight loss and a high remission rate of type 2 diabetes. However, the exact mechanisms behind the improved glucose tolerance are not fully elucidated. In the present study we investigated whether bariatric surgery is able to improve pancreatic lipid metabolism in obese subjects.

**Materials and methods:** Totally, 24 morbidly obese subjects (BMI 41±4.0 kg/m<sup>2</sup>, age 42±9.5 years) eligible for bariatric surgery, of which ten had type 2 diabetes, and 15 healthy age-matched subjects were recruited in the study. Pancreatic fatty acid (FA) uptake was measured at fasting state using PET/CT and a palmitate analogue [<sup>18</sup>F]FTHA. Pancreatic total volume, and fat and parenchymal volumes were measured using a CT based approach as recently described. Oral glucose tolerance test (OGTT) was performed to quantitate glucose tolerance and empirical/model-derived β-cell function parameters. Obese subjects were studied preoperatively and six months after bariatric surgery procedure (either Roux-en-Y gastric bypass or sleeve gastrectomy).

**Results:** Before surgery, obese subjects had higher rate of pancreatic FA uptake (1.4±0.6 versus 0.7±0.3 μmol/min, P < 0.001) and fat percent (19±22 versus 4.0±4.0 %, P < 0.01), and had greater amount of ectopic fat (17±21 versus 3.0±3.1 ml, P < 0.01) than healthy controls. After bariatric surgery, obese subjects lost 24% of their weight (P < 0.0001), but were still obese (BMI 32±4.2 kg/m<sup>2</sup>). Fasting plasma glucose and HbA1c were lower (both by 12%, P < 0.0001), whereas no difference was found in plasma FFA levels (0.82±0.22 versus 0.76±0.18 mmol/l, NS). In subjects with type 2 diabetes preoperatively, parameters of β-cell function (insulinogenic index, glucose sensitivity, rate sensitivity) were improved (all P < 0.02), and in eight out of ten diabetes was in remission. In the obese group, pancreatic FA uptake (1.4±0.6 versus 1.0±0.4 μmol/min, P < 0.01), fat percent (19±22 versus 14±13 %, P < 0.01), and ectopic fat volume (17±21 versus 11±12 ml, P < 0.01) were decreased, whereas parenchymal volume was unchanged (79±29 versus 72±22 ml, NS) after operation. Diminishment of ectopic fat was independent of weight loss and FA uptake (NS). Decrease in total pancreatic volume was associated with improved glucose tolerance, as measured with mean glucose during OGTT (r = 0.59, P < 0.005), and insulinogenic index (r = -0.45, P = 0.04).

**Conclusion:** The present study shows that, pancreatic lipid accumulation in obesity is reversible and modified by bariatric surgery. The results of the study imply that decreased pancreatic FA metabolism and loss of ectopic fat play a role in the improved glucose tolerance seen after bariatric surgery.

**The metabolic signature of RYGB is similar to that of equivalent caloric restriction**

I. Lingvay<sup>1</sup>, L. Golici<sup>1</sup>, M. Poduri<sup>1</sup>, L.K. Mitchell<sup>1</sup>, A. Coster<sup>2</sup>, T. Zhao<sup>3</sup>; <sup>1</sup>Endocrinology, <sup>2</sup>Pharmacology, <sup>3</sup>Molecular Genetics, University of Texas Southwestern Medical Center, Dallas, USA.

**Background and aims:** Diabetes improves or remits within days following gastric by-pass surgery. It is debated whether this dramatic effect is due to the strict caloric restrictions imposed in the peri-operative period or due to surgery-specific changes in metabolism.

**Materials and methods:** Ten patients with type 2 diabetes underwent a strictly-observed 9-day inpatient caloric restriction intervention. Following re-equilibration to baseline characteristics (average 3.3 months), they were readmitted for a second identical intervention (identical daily oral intake) during which they also underwent gastric bypass. All measurements (6-hrs Mixed Meal Challenge Test) were performed before and after each study period (total of four measurements/patient). This precise study design allowed us to separate the effects of diet (first period) from the effects of surgery (second

period-first period) on the hormonal changes observed after surgery. Paired t-test was used to compare changes observed during each period.

**Results:** Patients were 54.1±/-8.7 years old, 3 males, 70% minorities, BMI 50.8±/-9 kg/m<sup>2</sup>, with advanced diabetes (9.2±/-8 years duration, treated with 1.5 oral agents, additionally 7 were also treated with insulin, median dose 0.8 u/kg). There was comparable and significant improvement in glycaemia, insulin sensitivity and beta-cell function. The diet only period fared better in regards to changes in ghrelin, GIP, and hepatic glucose output. Surgery induced large increases in GLP-1 and PYY (figure).

**Conclusion:** The severe caloric restriction employed immediately post gastric bypass surgery is primarily responsible for the rapid improvement in glycaemia. The increase in incretin hormones is specific to surgery, but does not seem to have a direct effect on glycaemia, insulin resistance, nor beta-cell function. Their effect, if any, is likely mediated through central mechanisms which control appetite and promote the long term adherence to such restricted caloric intake.

**Immediate post-operative effects after a mixed-meal test and long-term effects on hormone expression in the alimentary limb in gastric-bypassed patients**

A. Lindqvist<sup>1</sup>, J. Berggren<sup>2</sup>, B. Nergård<sup>3</sup>, L. Groop<sup>1</sup>, J. Hedenbro<sup>4</sup>, N. Wierup<sup>1</sup>;

<sup>1</sup>Clinical Sciences, Malmö, <sup>2</sup>Department of Surgery, Kalmar, <sup>3</sup>Aleris Obesity, Lund, <sup>4</sup>Department of Surgery, Lund, Sweden.

**Background and aims:** Gastric bypass surgery (GBP) is the most effective treatment for morbid obesity. Also, GBP results in rapid improvement in glycaemia long before significant weight loss. In the present study we aimed to 1) investigate the influence of pre-surgery caloric restriction with that of the immediate effect of GBP on glycemia and 2) assess long-term effects of GBP on gut hormone expression in the alimentary limb.

**Materials and methods:** Obese women (47±1 years) were subjected to a mixed meal test (MMT) four weeks before (MMT-4w), 4h before (MMT-4h) and one day after (MMT+1d) Roux-en-Y gastric bypass surgery. MMT-4w was performed before initiation of the low-calorie diet regimen and MMT+1d constituted the first meal the patients received after surgery. Blood was collected at -10, -5, 0, 5, 10, 15, 30, 60 and 90 minutes upon initiation of MMT-ingestion. Glucose, insulin, glucose-dependent insulinotropic peptide (GIP) and active glucagon-like peptide 1 (GLP-1) were analyzed for the MMTs. In another study, female patients were recruited and biopsies from the alimentary limb were obtained during surgery and via gastroscopy 12 months after GBP. Samples were analyzed for all major enteroendocrine cell populations using immunocytochemistry and morphometry.

**Results:** While there was difference in glucose levels between the various MMTs, the insulin response was markedly increased immediately at MMT+1d, compared to both the MMT-4w and MMT-4h (2.4-fold and 2.8-fold, respectively). Active GLP-1 levels were similar in all MMTs, whereas the GIP-response was higher at the MMT+1d, compared to MMT-4w and MMT-4h (1.6-fold and 1.4-fold, respectively). The elevation in insulin and GIP resulted in increased insulin AUC-to-GIP AUC-ratio (p<0.01). Also, an immediate post-operative effect was observed on insulin AUC-to-glucose AUC ratio (p<0.05). No differences were observed for any of the parameters analyzed when comparing MMT-4w and MMT-4h. One year after GBP, the alimentary limb of the patients displayed increased density of serotonin-immunoreactive (IR) cells (2.1-fold; p<0.05) and GLP-1-IR cells (3.6-fold; p<0.01), while there was no difference in villi length, density of ghrelin-IR cells, cholecystokinin-IR cells, secretin-IR cells, neurotensin-IR cells or GIP-IR cells.

**Conclusion:** Our data suggest that pre-surgery caloric restriction has no effect on the parameters analyzed; rather the re-arrangement of the gastrointestinal tract elicits an immediate stimulatory effect on insulin and GIP levels in response to a meal test. Our data also suggest that with this experimental

design, GIP is a strong contributor to the enhanced insulin secretion. Furthermore, we report for the first time the effects of GBP on expression of gut hormones in the alimentary limb one year after GBP. Our data showing that GLP-1 and serotonin immunoreactive cells are markedly increased in the alimentary limb 12 months after GBP provide anatomical prerequisites for sustained hormonal changes after GBP.

### Searching for biomarkers determining the early efficacy of bariatric surgery in the treatment of type 2 diabetes mellitus

M. Ciborowski<sup>1</sup>, P. Samczuk<sup>1</sup>, M. Luba<sup>2</sup>, A. Citko<sup>1</sup>, J. Godzien<sup>3</sup>, H. Razak Hady<sup>2</sup>, J. Dadan<sup>2</sup>, C. Barbas<sup>3</sup>, M. Gorska<sup>4</sup>, A. Kretowski<sup>4,1</sup>; <sup>1</sup>Clinical Research Centre, Medical University of Bialystok, <sup>2</sup>1st Clinical Department of General and Endocrine Surgery, Medical University of Bialystok, Poland, <sup>3</sup>Center for Metabolomics and Bioanalysis (CEMBIO), Universidad CEU San Pablo, Madrid, Spain, <sup>4</sup>Department of Endocrinology, Diabetology and Internal Medicine, Medical University of Bialystok, Poland.

**Background and aims:** Bariatric surgery is an effective treatment for obesity and in 80–90% of subjects with type 2 diabetes improves significantly glycaemic control, independently of weight loss. Recent studies suggest different mechanisms that affects metabolic changes after surgery: incl. alterations in gut hormones secretion (ex. GLP-1), neurohumoral pathways modulation, changes in bile acid concentrations in the blood and/or altered intestinal microbiota. The recovery rate of the T2DM is also related to the method of bariatric surgery with the higher T2DM remission rate observed for a Roux-en-Y gastric bypass (RYBG) in comparison to a laparoscopic adjustable gastric banding (LAGB). The aim of this study was to search for the preoperative and postoperative metabolic biomarkers, which could determine the efficacy of the bariatric surgery and predict an early remission failure in the treatment of T2DM.

**Materials and methods:** The study was performed in the group of 49 obese patients with T2DM, who underwent bariatric procedures (laparoscopic sleeve gastrectomy - LSG or Roux-Y gastric bypass - RYGB) and were evaluated for an early remission failure (1 month after the surgery) of T2DM. The fasting serum samples were fingerprinted by LC-QTOF-MS and data were collected in ESI (+) mode (50–1,000 m/z). Chromatograms were aligned and quality assurance of obtained data was performed. Statistical analysis was conducted to compare patients before and one month after the surgery (paired t-test), and to compare (before the surgery) patients who recovered from T2DM in one month post-surgery with those who did not. Patients before the surgery were compared by use of t-test or Mann-Whitney test depending on the normality of variables distribution. Identification of significant features was performed based on custom library with accurate mass and retention time of more than 100 metabolites.

**Results:** We found that before bariatric surgery lower serum levels of lipid compounds (incl. lysophosphatidylcholines, phosphatidylethanolamines, sphingomyelins, ceramides) and lower vitamin D3 metabolites concentrations significantly predicted an early T2DM remission failure ( $p < 0.01$  for all). One month after bariatric surgery, in all subjects with T2DM remission, the decrease in level of free lipids ( $p$  value  $< 0.05$ – $0.01$ ), acylcarnitines ( $p$  value  $< 0.04$ – $0.008$ ) and choline ( $p = 0.0006$ ) was observed. On the other hand, in subjects without early T2DM recovery, no significant changes in acylcarnitines level were found.

**Conclusion:** Current results indicate, that changes in lipid metabolites contribute to the improvement of glycaemia and remission of the T2DM after bariatric surgery. The rate of regulation of fatty acid oxidation and mitochondrial function pathways may contribute to the time of the T2DM remission.

## PS 054 Inflammation and beta cell in type 2 diabetes

### 742

#### IA-2(256-760), the only marker of islet autoimmunity that increases by increasing the degree of obesity in type 2 diabetes patients

C. Tiberti, M. Spoletini, G. Campagna, S. Zampetti, L. Marandola, R. Buzzetti, NIRAD Study Group; Sapienza University, Rome, Italy.

**Background and aims:** Approximately 5–6% of type 2 diabetes patients (T2DM), in Italian population, are positive for antibodies specific to type 1 diabetes (T1DM), although the same antibodies present significant quantitative difference compared to T1DM. Glutamic acid decarboxylase (GADs) is the marker with the highest prevalence, however also protein tyrosine phosphatase (IA-2IC) antibodies were shown to be an important autoimmunity marker frequently found in these patients. We have previously demonstrated an extreme heterogeneity of T2DM positive patients in terms of phenotype, specifically the BMI varies widely. In the light of these findings we aim to evaluate whether the type and frequency of beta-cell specific antibodies vary according to different degrees of BMI in T2DM positive patients.

**Materials and methods:** In  $n = 1850$  T2DM subjects recruited in central Italy from the Non Insulin Requiring Autoimmune Diabetes (NIRAD) study cohort of 5330, clinical and biochemical characteristics as well as the following antibodies were evaluated at recruitment: GADA, IA-2IC and IA-256-760. All patients were subdivided into three groups according to BMI:  $BMI \leq 25$ ,  $25 < BMI < 30$ ,  $BMI \geq 30$ . The differences of mean values of GADA, IA-256-760 and IA-2IC between groups were evaluated through the Anova and Benjamini-Hochberg test. A  $p$  value  $< 0.05$  was considered statistically significant.

**Results:** Out of  $n = 1850$  type 2 diabetes patients  $n = 120$  (6.5%) were positive for at least one of the following antibodies: GADA (4.1%), IA-256-760 (3.3%) or IA-2IC (1.1%). As we consider the  $n = 120$  T2DM antibody positive patients, GADA and IA-2 IC showed decreasing frequencies with the increase of BMI ( $p$  for trend 30 (80% of positive patients). Analyzing GADA, IA-256-760 and IA-2IC titers in all T2DM subjects subdivided according to BMI, we observed a decreasing mean values of GADA and IA-2IC titers with the increase of BMI ( $p$  for trend  $< 0.0001$  and  $p$  for trend = 0.02, respectively). The mean values of IA-256-760 titer, instead, were similar between the three groups of BMI.

**Conclusion:** We conclude that the IA-2 (256-760) specifically identify autoimmunity in obese T2DM.

### 743

#### Human adenovirus-36 is uncommon in type 2 diabetes and is associated with increased insulin sensitivity in adults in Sweden

A. Hilding<sup>1</sup>, M. Almgren<sup>2</sup>, R.L. Atkinson<sup>3</sup>, J. He<sup>3</sup>, K. Brismar<sup>1</sup>, M. Schalling<sup>1</sup>, C.-G. Östenson<sup>1</sup>, C. Lavebratt<sup>1</sup>;

<sup>1</sup>Dept. of Molecular Medicine and Surgery, <sup>2</sup>Dept. of Clinical Neuroscience, Karolinska Institutet, Stockholm, Sweden, <sup>3</sup>Obetech Obesity Research Center, Virginia Commonwealth University, Richmond, USA.

**Background and aims:** Human adenovirus-36 (Adv36) increases adiposity, but also upregulates distal insulin signaling *in vitro* in human adipose and muscle tissue and *in vivo* in the rodent independent of adiposity. Accordingly, healthy adults and children with antibodies against Adv36 had increased insulin sensitivity and reduced hepatic lipid accumulation. We hypothesized that Adv36 infection would be less frequent in individuals with type 2 diabetes or impaired glycaemic control.

**Materials and methods:** Presence of antibodies against Adv36 was analyzed for association to type 2 diabetes or impaired glycaemic control in a longitudinal population-based sample of well-examined adults ( $n = 1734$ ). Indices of impaired glycaemic control included oral glucose tolerance, and circulating fasting levels of glucose, insulin and insulin-like growth factor binding protein-1 (IGFBP-1).

**Results:** Adv36 seropositivity was more common in those with NGT (normal glucose tolerance) than in those with diabetes (females: OR=17.2, 95% CI=4.0–74.3, males: OR=3.5, 95% CI=1.8–6.7). Also, females with NGT had higher frequency of Adv36 seropositivity than females with prediabetes (impaired glucose tolerance or impaired fasting glucose, OR=1.8, 95% CI=1.1–3.1). Within the female prediabetes group Adv36 seropositivity was

associated with higher insulin sensitivity reflected by reduced HOMA-IR and increased IGFBP-1.

**Conclusion:** Adv36 infection associated with lower occurrence of type 2 diabetes and better insulin sensitivity in adults, particularly among females.

### AKT/JNK switch induces beta cell apoptosis as part of TLR3 signalling during Coxsackievirus infection

N. Busse<sup>1</sup>, F. Paroni<sup>1</sup>, E. Domszen<sup>2</sup>, J. Kerr-Conte<sup>3</sup>, A. Dotzauer<sup>1</sup>, K. Maedler<sup>1</sup>;

<sup>1</sup>Center for Biomechanical Interactions, University of Bremen, Germany,

<sup>2</sup>Center for Infection Medicine, Karolinska Institutet, Stockholm, Sweden,

<sup>3</sup>University of Lille, France.

**Background and aims:** Type 1 diabetes results from a sophisticated interplay between genetic factors, immune system and environmental factors. Among environmental factors, viruses, mainly enteroviruses such as members of the Coxsackie B virus family, have been suspected since long time to trigger diabetes. Intra-islet viral particles have been detected in pancreata from patients with T1DM and T2DM, and known to cause  $\beta$ -cell dysfunction in vitro, suggesting that a direct infection contributes to onset of diabetes. Nonetheless the mechanisms of a correlation between virus infection and diabetes progression are poorly understood. Clarification of the viral triggered  $\beta$ -cell dysfunction and apoptosis may provide an indication to develop preventive therapies. We previously identified Toll-like receptor 3 (TLR3) and Protein kinase R (PKR) as first defensive defensive line during coxsackie virus infection. In this study we asked the question of what is the contribution of PKR and TLR3 in  $\beta$ -cell apoptosis during CVB3 infection.

**Materials and methods:** Isolated human islets and CM cell line were infected with coxsackievirus serotype B3. Replication of CVB was confirmed by immunostaining of viral protein 1 (VP1) and titration of islet lysate. shRNA and siRNA were used to silence TLR3 and PKR in both human islets and CM cells. Plasmids encoding for TLR3 and TBK1 were used for overexpression experiments. Either dominant negative expression constructs or specific inhibitors were used to study the role of JNK and AKT in human islets. Islet protein expression and phosphorylation were analyzed by western blot. Binding of CVB ssRNA and dsRNA was investigated by immunoprecipitation-RT-PCR coupled assays.

**Results:** A time course analysis of CVB3 infection for downstream signaling showed AKT activation at 1h post-infection, which lasts for several hours. AKT was down-regulated at 24h post infection, when activation of pJNK, Caspase-3 and VP1 appeared in human islets. A possible correlation between AKT activation and PKR/TLR3 signaling was investigated. Knock down of PKR resulted in increased virus infection (VP1), JNK phosphorylation and activation of caspase 3, while AKT phosphorylation was PKR-independent. Lack of TLR3 had a pro-survival effect in CVB3 infected human islets leading to a reduced reduced JNK phosphorylation, caspase activation and VP1 as well as TBK1 phosphorylation. In contrast, overexpression of TLR3 enhanced AKT activation together with VP1 induction. Overexpression of TLR3/TBK1 further enhanced phosphorylation of AKT, viral replication and caspase activation suggesting pivotal role of AKT, enhanced by TLR3. AKT inhibition reduced viral replication, activation of caspase 3 and phosphorylation of JNK. Overexpression of DN-JNK led to a decrease in apoptosis indicated by the decreased level of cleaved caspase 3 but not of VP1. Treatment of human islets with the JNK inhibitor confirmed the protective effects of JNK inhibition.

**Conclusion:** In summary, our data show that CBV infections have a direct deleterious effect on  $\beta$ -cell survival, resulting from virus-induced apoptosis, and potentiated by the AKT/TLR3 signaling pathway. With our present data we provide novel targets towards protecting the  $\beta$ -cell during virus infection.

## 745

### DPP-4 inhibitors: anti-inflammatory effects on M1 activation

E. Derlindati, V. Curella, I. Zavaroni, R.C. Bonadonna;

Clinical and Experimental Medicine, University of Parma, Italy.

**Background and aims:** Macrophages are a heterogeneous cell population which, in response to the cytokine milieu, differentiate in either classically activated macrophages (M1) or alternatively activated macrophages (M2).

This plasticity is essential to regulate inflammation, immune response and tissue remodeling and it may be a novel therapeutic target in inflammatory-based diseases such as atherosclerosis. Some recent evidence suggests that dipeptidyl peptidase 4 may play a role in in cardiovascular diseases and that its inhibition might be beneficial in curbing inflammation and atherogenesis. The aim of this study was to evaluate the anti-inflammatory effects of a DPP-4 inhibitor on classical macrophage activation.

**Materials and methods:** Monocytes were isolated from healthy donors' buffy coats. After differentiating into macrophages, cells were stimulated with IFN $\gamma$  and LPS in order to induce M1 activation, in presence or in absence of 2 $\mu$ M of DPP-4 inhibitor (KR-62436, Sigma Aldrich) for 24 hours. The working concentration of DPP-4 inhibitor was selected after dose finding experiments. Resting macrophages (RM) -no added stimuli- were used as a control. The expression of DPP-4 was evaluated in each experimental conditions, both by real time PCR and cytofluorimetric assay. Key pro-inflammatory genes and chemokines (IL6, IL8, TNF-alpha, MCP-1, COX2, SOD2, SOCS1) were evaluated by real time PCR. Protein expression of IL-6 and TNF-alpha were evaluated by ELISA. Results were obtained by means of six biological replicates. DPP-4 activity is presently being assessed.

**Results:** M1 macrophages showed a significant up-regulation of DPP-4 mRNA compared to RM (p=0.015), which was unchanged by DPP-4 inhibition. These data were confirmed by cytofluorimetric analysis. M1 significantly up-regulated also the expression of pro-inflammatory genes SOCS1, IL-6, COX2 (by one hundred-fold), IL8, TNF-alpha (by fifty-fold), and MCP1, SOD2 (by ten-fold) compared to RM (p<0.05 or less). The addition of DPP-4 inhibitor significantly reduced the mRNA expression of IL-6, TNF-alpha, MCP1 and COX2 (p<0.05), restoring the same gene expression level as RM, except for COX2 that remained significantly higher (by five-fold, p<0.05). TNF-alpha and IL6 proteins resulted significantly up regulated in M1 compared to RM (by forty five-fold and six-fold respectively, p<0.01) and decreased by DPP-4 inhibition (p <0.05) although remaining significantly higher compared to RM (by three-fold, p<0.05). DPP-4 activity is currently under investigation in order to assess its role, if any, in anti-inflammatory effects.

**Conclusion:** This study shows that DPP-4 is overexpressed in classical activated macrophages, setting the stage for an involvement of DPP-4 in inflammatory processes. DPP-4 inhibition induced a significant reduction of the principal pro-inflammatory genes and proteins, but without affecting DPP-4 expression. These data suggest an anti-inflammatory effect of DPP-4 inhibitors that might be beneficial in the treatment of inflammatory related disease.

## 746

### In the long run hyperbaric oxygen therapy attenuates pro-inflammatory processes in streptozotocin induced diabetes in rats

E.M. Horvath<sup>1</sup>, R. Benko<sup>1</sup>, V.A. Agoston<sup>2</sup>, K. Ihionvien<sup>1</sup>, M. Szabo<sup>1</sup>, N. Beres<sup>1</sup>, Z. Benko<sup>1</sup>, C. Repas<sup>1</sup>, B. Bakk-Nurdísány<sup>1</sup>, M. Szepes<sup>1</sup>, L. Kiss<sup>1</sup>, Z. Nagy<sup>2</sup>;

<sup>1</sup>Institute of Human Physiology and Clinical Experimental Research,

<sup>2</sup>Department of Cardiology, Laboratory of Cell Biology, Section of Vascular Neurology, Semmelweis University, Budapest, Hungary.

**Background and aims:** Hyperbaric oxygen therapy (HBOT) is frequently used in diabetic patients with ulcerated wounds; however its possible negative consequences raise questions. In our previous experiments we showed that weeks after HBOT cardiovascular functions of rats with streptozotocin induced diabetes were improved or unaltered. In the present study our aim was to examine the effect of HBOT on systemic oxidative-nitrative stress and cytokine production in the same setting.

**Materials and methods:** Wistar rats (15) weighing 300 g were administered with a single dose of 70 mg/kg streptozotocin to induce diabetes mellitus. 7 diabetic and 8 controls underwent one-hour long hyperbaric oxygen treatment (HBOT: 2.5 bar) 12 times (in 16 days). 6 controls and 8 diabetic rats remained untreated. Two weeks after the completion of HBOT series, heparinized blood plasma and lymphocyte samples were collected. Malonyl-dialdehyde assay (MDA) were performed on the plasma samples and nitrotyrosine immunostaining (NT) was done on lymphocyte smears. Altered cytokines were identified by Rat Cytokine Antibody Array (R&D). According to the results the following cytokines were selected for ELISA measurement: Cytokine-induced neutrophil chemoattractant 1 (CINC-1), lipopolysaccharide induced CXC chemokine (LIX/CXCL-5), tissue inhibitor of metalloproteinase 1 (TIMP-1). For data analysis Two Way ANOVA and Bonferroni's post hoc test were implemented.

**Results:** Without HBOT plasma MDA levels were significantly higher in diabetic rats compared to control animals (9.03  $\mu$ M [6.33, 12.69] vs. 21.56  $\mu$ M

[7.63, 34.18],  $p \leq 0.01$ ), however this difference was abolished after HBOT (6.24  $\mu\text{M}$  [5.08, 6.71] vs. 9.68  $\mu\text{M}$  [6.47, 19.24], NS.). Leukocyte tyrosine nitration was elevated due to diabetes with (23.78 $\pm$ 3.43% vs. 41.2 $\pm$ 3.49%,  $p \leq 0.01$ ) or without HBOT (20.44 $\pm$ 4.08% vs. 38.1 $\pm$ 4.12%,  $p \leq 0.01$ ). The plasma levels of pro-inflammatory cytokines were increased in untreated diabetes (CINC-1: 69.1 ng/L [63.85, 74.63] vs. 137.1 ng/L [66.71, 343.8],  $p \leq 0.01$ ; LIX: 282 ng/L [141.9, 382] vs. 430.8 ng/L [327, 604.4],  $p \leq 0.05$ ), however due to HBOT this difference was ceased (CINC-1: 66.96 ng/L [61.3, 83.5] vs. 96.9 ng/L [70.73, 147.5], NS.; LIX: 245.3 ng/L [172.6, 340.3] vs. 346.8 ng/L [276.9, 774.6], NS.). The anti-inflammatory factor TIMP-1 was not altered by diabetes in the lack of HBOT (24.49  $\mu\text{g/L}$  [21.48, 26.41] vs. 27.79  $\mu\text{g/L}$  [22.18, 29.73], NS.), on the other hand after HBOT the plasma level of TIMP-1 was significantly higher in diabetic animals (20.76  $\mu\text{g/L}$  [18.43, 25.62] vs. 32.31  $\mu\text{g/L}$  [21.65, 38.43],  $p \leq 0.01$ ).

**Conclusion:** According to our results two weeks after HBOT, the oxidative stress and pro-inflammatory cytokine production induced by experimental diabetes were abolished. Also the anti-inflammatory factor TIMP-1 is elevated as a response to HBOT in diabetic animals. On the other hand nitritative stress is not altered by the therapy. These findings suggest that HBOT is not just safe to use in diabetic patients, but may also have beneficial effect on their chronic subclinical inflammation.

## 747

### The anti-inflammatory protein NUPR1 (p8) generally enhances viability of pancreatic islets but does not prevent lipotoxicity

B. Mihic-Necic<sup>1</sup>, A.E. Mehana<sup>1,2</sup>, C. Liu<sup>1</sup>, L. Parsons<sup>1,3</sup>, J. Straetener<sup>1</sup>, J. Baumann<sup>1</sup>, N. Perakakis<sup>1</sup>, K. Laubner<sup>1</sup>, J. Seufert<sup>1</sup>, G. Páth<sup>1</sup>;

<sup>1</sup>Department of Internal Medicine II, Division of Endocrinology and Diabetology, University Hospital of Freiburg, <sup>2</sup>University of Freiburg, Faculty of Biology, Germany, <sup>3</sup>School of Biosciences, Cardiff University, UK.

**Background and aims:** Type 2 diabetes is closely related to obesity. According to the so-called “nutrition overflow hypothesis”, type 2 diabetes results from nutrition-induced local tissue inflammation leading to insulin resistance, insulin secretory dysfunction and finally pancreatic beta cell loss. Free fatty acids acting through toll-like receptors are key mediators of this lipotoxic inflammatory response. (1) We previously demonstrated that cocultured human bone marrow-derived mesenchymal stromal cells (hMSC-TERT) protect rat INS-1E beta cells from alloxan- and streptozotocin-induced injury. (2) We further demonstrated that mice with beta cell-specific overexpression of the intracellular protein NUPR1 maintained insulin secretion and storage during high fat diet-induced local low grade inflammation and intense inflammatory stress by insulinitis. Here, we investigated the anti-lipotoxic potential of (1) cocultured hMSC-TERT and (2) beta cell-specific *Nupr1* overexpression.

**Materials and methods:** For coculture, INS-1E were seeded in wells and hMSC-TERT were seeded in inserts with 1  $\mu\text{m}$  pores to allow soluble factors but not cells to pass the membrane. Primary mouse islets were obtained from transgenic (Tg) mice with beta cell-specific *Nupr1* overexpression under the control of the rat insulin gene 1 promoter (RIP1). Non-transgenic littermates served as WT controls. Lipotoxicity was induced by palmitate. Viability of cells and islets was measured by MTS assay.

**Results:** We first evaluated by kill curve experiments that 24 h exposure to 0.13 mM palmitate inhibits the viability of INS-1E by 50%. Experiments were performed with 0.1 mM palmitate. (1) 24 h exposure to 0.1 mM palmitate reduced viability of INS-1E by 42%. Cocultured hMSC-TERT could not prevent this loss of viability. (2) Tg islets with ectopic NUPR1 demonstrated 1.5-fold enhanced viability compared to WT controls. However, ectopic NUPR1 did not reduce lipotoxicity since 24 h exposure to 0.1 mM palmitate reduced viability by 50% in both WT and Tg islets.

**Conclusion:** Despite their protective effects in other experimental settings, cocultured hMSC-TERT and also ectopic *Nupr1* did not prevent lipotoxicity. Ectopic NUPR1 overproduction generally enhances viability of Tg islets and thereby contributes to enhanced beta cell function during inflammatory tissue stress in Tg mice compared to WT controls.

## 748

### Protection of pancreatic beta cells in vitro and in vivo by NUPR1 (p8) protein during inflammatory diabetogenic stresses

A.E. Mehana<sup>1,2</sup>, I. Pilz<sup>1</sup>, B. Dufner<sup>1</sup>, C. Jäger<sup>1</sup>, S. Sojka<sup>1</sup>, J. Baumann<sup>1</sup>, M. Alt<sup>1</sup>, C. Liu<sup>1</sup>, L. Parsons<sup>1,3</sup>, K. Laubner<sup>1</sup>, N. Perakakis<sup>1</sup>, G. Páth<sup>1</sup>, J. Seufert<sup>1</sup>;

<sup>1</sup>Division of Endocrinology and Diabetology, Department of Internal Medicine II, University Hospital of Freiburg, <sup>2</sup>University of Freiburg, Faculty of Biology, Germany, <sup>3</sup>Cardiff University, School of Biosciences, UK.

**Background and aims:** Type 2 diabetes is closely associated with obesity. Chronically enhanced circulating free fatty acids activate toll-like receptors and induce local inflammation leading to insulin resistance, insulin secretory dysfunction and finally pancreatic  $\beta$ -cell loss. However, many obese subjects do not develop diabetes. This observation suggests the existence of molecular defence systems that prevent  $\beta$ -cell degradation in non-susceptible individuals. Therefore, identification of molecular mechanisms that provide anti-inflammatory protection and control  $\beta$ -cell turnover are of key interest. The intracellular protein NUPR1 has been shown to reduce tissue damage during acute pancreatitis in *Nupr1*<sup>-/-</sup> mice. The protein is also expressed in the endocrine pancreas. To investigate its potential protective role and cellular mechanisms in the under diabetogenic stress, we generated transgenic mice with  $\beta$ -cell-specific *Nupr1* overexpression under the control of the RIP1 promoter (Tg).

**Materials and methods:** We induced low-grade inflammation by feeding mice with high fat diet (HFD) and/or insulinitis by multiple low dose STZ injections. Glucose tolerance was evaluated by measuring non-fasting random blood glucose, intraperitoneal glucose tolerance test (ipGTT), intraperitoneal insulin tolerance test (ipITT) and serum insulin levels (ELISA).  $\beta$ -cell mass was determined morphologically. Islet inflammation was quantified by numbers of infiltrating CD45+ lymphocytes and NF- $\kappa$ B activation (Western blot). Ex vivo isolated islets from untreated wild type (Wt) and Tg animals and from animals after 20 weeks of feeding with HFD were cultured for 16 days without treatment and subsequently exposed for 24hrs to 10ng/ml IL-1 $\beta$  or 0.33mM STZ were evaluated by glucose stimulated insulin secretion and content (GSIS), cleaved PARP (Asp214) for apoptosis (ELISA) and BrdU for cell proliferation.

**Results:** Immunohistochemically, we observed an islet enriched expression of NUPR1 in non-Tg mice. In vivo, Tg mice displayed improved glucose tolerance, improved insulin secretion and increased  $\beta$ -cell mass during HFD and/or insulinitis as compared to Wt controls. NUPR1-Tg islets also showed reduced lymphocyte infiltration and reduced NF- $\kappa$ B activation. Ex vivo, Tg islets displayed greatly reduced apoptosis while insulin secretion and content was significantly enhanced compared to Wt islets during 16 days of culture or in response to 24 h exposure to IL-1 $\beta$  or STZ. Further, Wt islets showed a massively reduced proliferation rate in response to diabetogenic injuries, whereas this was completely maintained in isolated NUPR1-Tg islets.

**Conclusion:** NUPR1 protein may be an important molecular mediator in the stress defence system of pancreatic  $\beta$ -cells. It exhibits potent protection of insulin biosynthesis, secretion and content during inflammatory pancreatic  $\beta$ -cell stress by reducing activation of NF- $\kappa$ B and apoptosis and enhancing proliferation capacity as a possible mechanism to compensate for the diabetogenic decrease in pancreatic  $\beta$ -cell mass.

## 749

### Siglec F knockout impairs glucose stimulated insulin secretion in isolated mouse islets

K. Stolz, G. Dharmadhikari, K. Maedler;

Centre for Biomolecular Interactions, University of Bremen, Germany.

**Background and aims:** Type 1 diabetes mellitus (T1DM) and type 2 diabetes mellitus (T2DM) result from a decline in  $\beta$ -cell function and survival partly as a consequence of islet inflammation. The inflammatory signaling and the activation of immune cells are caused by secreted stimulators or via cell-cell interactions. A group of cell surface adhesion and signaling molecules, the Siglecs (sialic acid-binding immunoglobulin (Ig)-like lectins) mediate such interactions. In humans, Siglecs are differentially expressed in  $\alpha$ - and  $\beta$ -cells and show protective effects on  $\beta$ -cell function and survival upon overexpression. In this study we investigated, if the knockout (KO) of the functionally relevant paralog Siglec F shows an effect on  $\beta$ -cell function in mice.

**Materials and methods:** To investigate the effect of the knockout isolated mouse islets were treated with diabetogenic conditions (2ng/ml IL-1 $\beta$ /1000 U/ml IFN- $\gamma$  or 22.2mM Glucose/0.5mM Palmitate) for 3 days and subjected

Glucose stimulated Insulin secretion. Expression studies were carried out by FACS analysis and quantitative RT-PCR. For depletion of infiltrated macrophages isolated mouse islets were treated with Chlodronate containing liposomes for 48 hours.

**Results:** Knockout of Siglec F shows no effect under diabetogenic treatment, but significant lower Insulin release upon Glucose stimulation under control conditions ( $p < 0.05$  versus wildtype). FACS analysis of dispersed wild type (WT) mouse islets showed Siglec F expression only in a very small cell population that did not occur in KO Islets. Quantitative RT-PCR demonstrated the low expression of mouse Siglecs in isolated Islets, which disappeared after depletion of macrophages with Chlodronate-liposomes. Chlodronate treated WT and KO islets show no difference in Glucose stimulated Insulin secretion. **Conclusion:** Siglec F knockout islets show impaired Insulin secretion due to altered interaction with infiltrating macrophages.

## 750

### The role of S100A8 and S100A9 in inflammatory interaction between pancreatic islets and macrophages

H. Inoue, J. Shirakawa, K. Orime, Y. Togashi, K. Tajima, Y. Terauchi; Yokohama City University, Japan.

**Background and aims:** The numbers of macrophages in the pancreatic islets of type 2 diabetes patients were reportedly increased. Yet, the pathophysiological significance of macrophages infiltration into islet is unclear. In this study, we focused on S100A8 and S100A9 (S100A8/A9) in islets induced by a combination of macrophage and free fatty acids. They are inflammatory proteins mainly expressed in monocyte and neutrophil. To address the mechanism of mutual interaction of islets with macrophage, we investigated the role of S100A8/A9 in this process.

**Materials and methods:** Isolated C57BL/6J mouse pancreatic islets were co-cultured with unstimulated peritoneal macrophages in the presence of lipopolysaccharide (LPS), palmitate, oleate, or adipocytes derived from epididymal fat, *in vitro*. To study the effect of S100A8/A9 on beta cell function, we examined glucose-stimulated insulin secretion in S100A8- and S100A9-adenoviral-overexpressed islets. Furthermore, we also analysed S100A8/A9 expressions in islets from obese diabetic db/db mice. To elucidate the effect of S100A8/A9 on macrophages, macrophages were stimulated with medium used for co-culturing islet and macrophages.

**Results:** In the presence of macrophages, the mRNA expressions of IL-1 $\beta$ , TNF- $\alpha$ , IL-6, CCL2, S100A8, and S100A9 in islets were increased (2.3-fold\*\*, 2.9-fold\*\*, 7.3-fold\*\*, 9.6-fold\*\*, 13.3-fold\*\* and 72.7-fold\*\*). LPS enhanced the macrophages-induced expression of TNF- $\alpha$ , IL-6 and CCL2 in islets (1.7-fold\*, 2.4-fold\*\* and 2.3-fold\*\*), whereas palmitate augmented the expression of S100A8 and S100A9 under the same conditions (4.8-fold\*\* and 3.6-fold\*\*). Oleate didn't affect those gene expression levels in islets. Neither LPS nor palmitate was sufficient to facilitate S100A8/A9 expressions in islets in the absence of macrophage. When islets were co-cultured with adipocytes, the expressions of IL-1 $\beta$ , TNF- $\alpha$ , IL-6 and CCL2, S100A8 and S100A9 in islets were tended to elevate. The induction of TNF- $\alpha$ , S100A8 and S100A9 expressions by adipocytes in islets were up-regulated by the addition of macrophages (2.4-fold\*\*, 2.3-fold\*\* and 4.8-fold\*\*). The expression levels of S100A8 and S100A9 were potentiated at high glucose concentration (22.2 mM) compared with those at low glucose concentration (5.6 mM) in the presence of palmitate (7.3-fold\*\* and 4.6-fold\*\*). Immunoblot and ELISA suggested S100A8/A9 were secreted from co-cultured islets to supernatant. Adenoviral-overexpression of S100A8/A9 in islets didn't affect insulin secretion. Immunohistochemical analysis indicated that only beta cells, but not alpha cells or acinar cells, expressed S100A8/A9 in pancreas. In islets from db/db mice, the expression of IL-1 $\beta$ , TNF- $\alpha$ , IL-6, CCL2, S100A8, and S100A9 in islets were higher than that in islets from db/+ mice (6.1-fold\*\*, 2.6-fold\*\*, 19.4-fold\*\*, 7.7-fold\*\*, 18.2-fold\* and 10.7-fold†, respectively). Culture supernatant from islet, macrophage, and palmitate up-regulated the expression level of IL-6 in unstimulated peritoneal macrophages (2.3-fold\*\*). ( $\dagger p < 0.1$ , \* $p < 0.05$ , \*\* $p < 0.01$ )

**Conclusion:** These results suggest that S100A8/A9 proteins in beta cells were enhanced by macrophages, free fatty acids and high glucose, like diabetic condition. Secreted S100A8/A9 were thought to trigger the inflammatory cytokine expression in macrophages. Taken together, S100A8/A9 may mediate the inflammatory interaction between pancreatic islets and macrophages in the progression of diabetes.

## 751

### Angiotensin II causes pancreatic islet dysfunction and inflammation independently of vasoconstriction

C. Thienel<sup>1</sup>, N.S. Sauter<sup>1</sup>, K. Kampe<sup>2</sup>, E. Dror<sup>1</sup>, S. Xu<sup>1</sup>, K. Timper<sup>1</sup>, A.W. Jehle<sup>2</sup>, M. Böni-Schnetzler<sup>1</sup>, M.Y. Donath<sup>1</sup>;

<sup>1</sup>Clinic of Endocrinology, Diabetes and Metabolism and Department of Biomedicine, University Hospital of Basel and University of Basel,

<sup>2</sup>Division of Nephrology and Transplantation Immunology, University Hospital of Basel and University of Basel, Switzerland.

**Background and aims:** Pathological activation of the renin-angiotensin system (RAS) is closely associated with the metabolic syndrome and new-onset of type 2 diabetes (T2D) can be delayed by RAS inhibition. In animal models of T2D RAS blockage enhances glycemic control and pancreatic islet function. The aim of this study was to investigate the effects of angiotensin II on islet function and underlying mechanisms, independently of its effects on blood pressure.

**Materials and methods:** For *in vitro* experiments, angiotensin II-treated human or mouse pancreatic islets and the rat beta-cell line INS-1E were used for glucose-stimulated insulin secretion assays, RNA extraction or protein measurements. *In vivo* studies were done with C57Bl/6J mice fed a high fat diet (HFD) for 12 weeks followed by implantation of angiotensin II-releasing osmotic pumps. Hydralazine was given in the drinking water to avoid vasoconstriction. After 4 weeks, at the end of the study, intraperitoneal glucose or insulin tolerance tests were performed and heart blood and organs were taken for further analysis.

**Results:** Treatment of human islets with angiotensin II significantly increased the expression of the pro-inflammatory cytokines IL-1 $\beta$ , IL-6 and the chemokine MCP-1, caused beta-cell apoptosis (increase 3.1-fold  $\pm$  1.34) and impaired glucose-stimulated insulin secretion (stimulatory index reduced by 23.7%,  $p < 0.005$ ). The angiotensin II-induced upregulation of IL-6 was inhibited by an IKK-2 inhibitor and by the IL-1Receptor antagonist IL-1Ra. Similarly angiotensin II reduced the stimulatory index of glucose-stimulated insulin secretion in mouse islets (31.9% reduction) and INS-1E cells and up-regulated IL-6 levels (1.49-fold  $\pm$  0.25). *In vivo* cotreatment with angiotensin II and hydralazine normalised the blood pressure. Glucose tolerance testing revealed impaired glucose homeostasis in angiotensin II- and hydralazine-treated HFD mice compared to saline- or hydralazine-treated HFD mice. This was associated with impaired insulin secretion whereas insulin sensitivity was unchanged. Further, animals revealed increased circulating and islet-derived IL-6 levels (2.28-fold increase vs. hydralazine group). Treatment with an anti-IL-1 $\beta$  antibody rescued the phenotype of the angiotensin II- and hydralazine-treated mice by restoring glucose-stimulated insulin secretion along with a reduction of islet-associated immune cells.

**Conclusion:** We conclude that chronic local RAS activation leads to islet dysfunction *in vitro* and *in vivo* and independently of vasoconstriction. Further, the rescue with NF $\kappa$ B inhibition and IL-1 blockage suggests that inflammation promotes angiotensin II-mediated islet dysfunction.

## PS 055 Inflammation in adipose tissue and muscle

### 752

#### Lycopene attenuates the inflammatory adipose tissue response to high fat feeding by regulating both macrophage recruitment and M1/M2 status

M. Nagashimada, Y. Ni, N. Nagata, L. Xu, F. Zhuge, S. Kaneko, T. Ota; Brain/Liver Interface Medicine Research Center, Kanazawa University, Japan.

**Background and aims:** Obesity activates the innate immune system with subsequent recruitment of immune cells such as macrophages and T cells, which contribute to the development of insulin resistance. In particular, adipose tissue macrophages (ATM) recruitment and polarization are considered pivotal in obesity-induced inflammation and insulin resistance. However, promising treatment modalities targeting ATM for insulin resistance and type 2 diabetes remain limited. Here, we show that lycopene, an antioxidant carotenoid compound, ameliorates adipose tissue inflammation and whole-body insulin resistance in high-fat diet (HFD)-induced obese (DIO) mice by regulating both macrophage recruitment and M1/M2 status.

**Materials and methods:** C57BL/6J mice were fed a HFD or a HFD containing lycopene (HFD+LY; 12 mg/kg body weight) for a total of 8 weeks. The histology of epididymal white adipose tissue (eWAT) and insulin sensitivity were examined. Next, we quantified immune cells in stromal vascular fraction of eWAT, peripheral blood, and bone marrow by fluorescence-activated cell sorter (FACS).

**Results:** After 8 weeks of feeding, lycopene improved HFD-induced glucose intolerance, and hyperinsulinemia (HFD  $4.0 \pm 0.2$  vs HFD+LY  $2.0 \pm 0.1$  ng/ml,  $p < 0.01$ ; fed state), and also enhanced insulin signaling assessed by IR $\beta$  and Akt phosphorylation in eWAT of DIO mice. HFD+LY mice had decreased macrophage infiltration and crown-like structure formation in eWAT compared with HFD mice even though weight and adiposity were similar. In addition, lycopene administration decreased expression of mRNA for MCP-1 by 50% and pro-inflammatory cytokines, such as TNF $\alpha$  and interleukin-1 $\beta$ , by 62% and 55%, respectively (all  $p < 0.01$ ) in eWAT of DIO mice. DIO mice had 2.3-fold increase in the levels of thiobarbituric acid reactive substances (TBARS) in eWAT compared to wild type (WT) mice, whereas lycopene reduced lipid peroxidation by 50% ( $p < 0.01$ ) in DIO mice. These findings were associated with reduction of ER stress (CHOP/GRP78), and attenuation of JNK/p38MAPK and NF- $\kappa$ B activation in eWAT. To further assess the impact of lycopene on adipose tissue inflammation, FACS analysis was performed on stromal vascular cells isolated from eWAT. ATMs identified as CD45<sup>+</sup>CD11b<sup>+</sup>F4/80<sup>+</sup> cells were increased in DIO mice by 11.4-fold compared with WT mice. In addition to reduction of total ATM content, HFD+LY mice had 35% fewer CD11c<sup>+</sup>CD206<sup>+</sup>(M1) ATMs whereas 60% more CD11c<sup>+</sup>CD206<sup>+</sup>(M2) ATMs than HFD mice, resulting in predominance of M2 over M1 ATM population. However, the predominance of the Ly6C<sup>+</sup> over Ly6C<sup>hi</sup> monocyte population was not observed in both peripheral blood and bone marrow of HFD+LY mice. Moreover, the numbers of either CD3<sup>+</sup>, CD4<sup>+</sup>, or CD8<sup>+</sup> T cells were decreased by 36%, 52%, or 38% respectively (all  $p < 0.05$ ) in eWAT of HFD+LY group compared with HFD mice. In parallel, lycopene (10–50 nM) suppressed LPS-induced M1 markers mRNA expression (TNF $\alpha$ , MCP-1, and RANTES) in Raw264.7 macrophage cells whereas it augmented IL-4-induced M2 markers mRNA expression (IL-10 and Arg1) in a dose-dependent manner.

**Conclusion:** Lycopene, a potent antioxidant, decreases ATM recruitment and causes a dynamic M2 dominant shift of ATM, and thereby attenuates obesity-induced inflammation and insulin resistance. Reduction of oxidative stress might be a relevant strategy to limit inflammatory adipose tissue response and subsequent development of insulin resistance.

### 753

#### CD11c<sup>+</sup> adipose tissue macrophages are bone marrow-derived proliferating cells with a mixed polarization phenotype that accumulate early in obesity

S.M.W. Wetzel<sup>1,2</sup>, E. Wijnands<sup>3,2</sup>, J.J.G. van Wegberg<sup>1,2</sup>, K.H. Gaens<sup>1,2</sup>, E.A.L. Biessen<sup>3,2</sup>, C.D.A. Stehouwer<sup>1,2</sup>, C.G. Schalkwijk<sup>1,2</sup>, K. Wouters<sup>1,2</sup>; <sup>1</sup>Department of Internal Medicine, <sup>2</sup>Carim, <sup>3</sup>Department of Pathology, Maastricht University Medical Centre, Netherlands.

**Background and aims:** Accumulation of pro-inflammatory (M1) macrophages in adipose tissue (AT) is a key event in obesity. These adipose tissue macrophages (ATMs) express CD11c (CD11c<sup>+</sup>), in contrast to resident CD11c<sup>-</sup> (M2) ATMs. ATMs have been shown to be capable of proliferating. However, the exact dynamics and relative contribution of recruitment and local proliferation is unknown. We aimed to identify the origin of CD11c<sup>+</sup> ATMs and investigate the temporal dynamics of ATM accumulation.

**Materials and methods:** We created mice expressing CD45.2 on resident immune cells and CD45.1 on bone marrow-derived immune cells by a bone marrow transplantation strategy. After 6 weeks recovery, the mice were given a control or high fat diet (HFD) for 10 days or 5 weeks. Stromal vascular fraction (SVF) of epididymal AT was analysed and sorted with flow cytometry. qPCR was performed on sorted ATMs to measure proliferation and activation markers. Data were analysed using t-tests or 1-way ANOVA.

**Results:** In lean mice, virtually all CD11c<sup>+</sup> ATMs were from donor origin, while 20% of the CD11c<sup>-</sup> ATMs remained from acceptor origin. Upon HFD, CD11c<sup>+</sup> ATMs already increased after 10 days ( $14.84 \pm 0.46$  vs  $12.22 \pm 0.95\%$  SVE,  $p < 0.05$ ) and further accumulated until 5 weeks ( $18.43 \pm 0.93$  vs  $12.22 \pm 0.95\%$  SVE,  $p < 0.001$ ). CD11c<sup>-</sup> ATMs were only increased after 5 weeks of HFD ( $26.59 \pm 0.88$  vs  $18.25 \pm 1.28\%$  SVE,  $p < 0.001$ ). In line, monocytes are also increased after 10 days of HFD ( $10.31 \pm 0.88$  vs  $6.59 \pm 0.55\%$  SVE,  $p < 0.001$ ) and levels remain constant after 5 weeks. Flow cytometry showed that only CD45.1 cells were accumulated upon HFD ( $14.40 \pm 0.44$  vs  $11.81 \pm 0.89\%$  SVE,  $p < 0.05$ ) while resident CD45.2 cells were not affected. qPCR analysis of sorted ATMs revealed that M1 CD11c<sup>+</sup> ATMs display high TNF and Arginase-1 expression while expression of Mannose Receptor and MCP1 was lower compared to the putative M2 CD11c<sup>-</sup> ATMs. Additionally, HFD only marginally affected gene expression of both M1 and M2 markers. Moreover, only CD11c<sup>+</sup> ATMs displayed an increased expression of the proliferation marker Ki67 upon HFD compared CD11c<sup>-</sup> M2 ATMs.

**Conclusion:** Our data show that monocytes numbers and CD11c<sup>+</sup> “M1” ATMs accumulate in the early phases of obesity suggesting that recruiting monocyte precursors of CD11c<sup>+</sup> M1 ATMs from bone marrow is an early event in obesity. Moreover, these ATMs have increased Ki67 expression suggesting that local proliferation of recruited cells contributes to accumulation in obese AT. Interestingly, ATM-subtypes have mixed M1/M2 profiles and obesity affects cell numbers rather than inflammatory phenotype.

#### Adipocyte hypertrophy, inflammation and fibrosis: early changes in subcutaneous adipose tissue in healthy, non-obese subjects predisposed to type 2 diabetes

A.M.J. Henninger, B. Eliasson, L.E. Jenndahl, A. Hammarstedt; Lundberg Laboratory for Diabetes Research, University of Gothenburg, Sweden.

**Background and aims:** Adipose tissue dysfunction is thought to be an important player in the development of type 2 diabetes. We investigated adipocyte hypertrophy, impaired adipocyte differentiation, inflammation, remodeling and adipose tissue fibrosis in healthy, non-obese, genetically predisposed subjects compared with control subjects with no known genetic predisposition for type 2 diabetes.

**Materials and methods:** We recruited 17 healthy, non-obese first degree relatives (FDR) of persons with type 2 diabetes and 17 control subjects. Groups were matched for gender and BMI. Glucose tolerance was determined by an OGTT and insulin sensitivity was calculated using HOMA-IR. Blood samples were collected and subcutaneous abdominal adipose tissue biopsies obtained for gene expression analysis and adipocyte cell size measurement.

**Results:** In spite of similar age, gender, BMI or fat percent in the groups, FDR displayed higher waist/hip ratio, fasting serum insulin levels, HOMA-IR and serum triglycerides, as well as adipocyte hypertrophy (all  $p$ -values  $< 0.05$ ). Adipocyte hypertrophy in the FDR group, but not among the controls, was

associated with measures of impaired glucose metabolism. There was an increased wnt-signaling activity in the subcutaneous adipose tissue of the FDR and the gene expression of CCND2, Tcf7L2 and FN1 were significantly up-regulated. Cytokines involved in inflammation (TNF $\alpha$ , IL1 $\beta$  and IL10) showed an increased expression in adipose tissue among the FDR, as well as markers of macrophage infiltration (CD68 and MCP1). There were also signs of adipose tissue remodeling (MMP2) and fibrosis (CTGF and ACTA2) among the FDR.

**Conclusion:** Genetic predisposition for type 2 diabetes is associated with impaired glucose metabolism and adipose tissue dysfunction, including inflammation, differentiation and remodeling. Reduced ability to maintain adipose tissue functionality may be a major susceptibility factor for later development of type 2 diabetes.

### Evidence for the presence of the phagocytic machinery in adipose tissue

L. Boutens, J. van der Reest, A. Helmke, R. Stienstra;  
Wageningen University, Netherlands.

**Background and aims:** The chronic inflammatory state that develops in adipose tissue (AT) during obesity is generally considered to promote insulin resistance (IR) and Type 2 Diabetes (DMII). Obese, inflamed AT is characterized by the presence of dead hypertrophic adipocytes surrounded by inflammatory macrophages, forming so-called Crown-like structures (CLS). Contrary, in lean AT hardly any dead adipocytes and inflammatory macrophages can be identified. Immunologically silent clearance of dead cells by macrophages is known to be crucial for maintaining homeostasis in many tissues. The presence of CLS in obese, inflamed AT suggests that the clearance of dead adipocytes is disrupted during the development of obesity and might contribute to AT inflammation. We therefore aim to unravel the metabolic and immunologic (dys)regulation within AT macrophages (ATM) related to their phagocytic trait, in order to find new leads for therapeutic targets and strategies for obesity-induced AT inflammation and subsequent IR and DMII.

**Materials and methods:** In vivo, C57Bl/6 mice were fed a Low Fat diet (LFD) or a High fat diet (HFD) to promote IR and DMII. Phagocytosis was studied *ex vivo* using a co-culture system of labelled macrophages and dead adipocytes followed by staining for lipids and subsequent analysis using Flow Cytometry. The effect of AT-derived factors on the phenotype of the macrophages was examined using a co-culture system with AT explants. Quantitative PCR, Western Blotting, ELISA and Microarray were used to determine the immunological and metabolic state of macrophages.

**Results:** Microarray analysis of AT depots isolated from mice on a LFD or HFD revealed differential regulation of multiple genes that are known to play crucial roles in phagocytosis (Mertk, Gas6, Mfge8, Lrp, Gulp1, Elmo1 and Ucp2) upon the development of obesity, accompanied by changes in the expression of apoptosis- (Caspases, Bax) and inflammation-related (IL-1 $\beta$ , Nlrp3) genes. *In vitro* analysis demonstrated a profound increase in lipids in macrophages that were co-cultured with dead adipocytes (using Flow Cytometry), suggestive of phagocytosis of adipocytes by macrophages. Upon the phagocytosis of dead adipocytes, genes involved in fatty acid oxidation (FAO; Ppara, Pgc1 $\alpha$ ) were higher expressed and the macrophages were skewed towards a predominant anti-inflammatory phenotype, marked by higher expression and secretion levels of IL-10 and decreased expression and secretion of TNF $\alpha$ . Interestingly, macrophages that were co-cultured with AT explants from lean mice had a twofold higher phagocytic capacity than macrophages that were cultured without AT explants. An increased expression of genes involved in phagocytosis (Mertk, Gas6, Ucp2) in these macrophages was accompanied by higher expression levels of genes involved in FAO (Cpt1 $\beta$ , Acad, Pgc1 $\beta$ ) and anti-inflammatory cytokines (IL-10); closely mimicking the phenotypic changes that were found in macrophages that have phagocytosed dead adipocytes.

**Conclusion:** Our data suggest that the phagocytic machinery is present in AT and is differentially regulated in obese, inflamed AT. Interestingly, macrophages are capable of phagocytosing dead adipocytes *ex vivo* and their phagocytic capacity is enhanced by AT-derived factors.

## 756

### Local biocommunication between peripancreatic adipose tissue and pancreatic beta cell: characterisation of factors involved in beta cell dysfunction

E. Sidot, C. Guzman, M. Tournier, A.-D. Lajoix, S. Peraldi-Roux;  
EA 7288, Montpellier, France.

**Background and aims:** In metabolic syndrome, pancreatic beta-cell is able to compensate for the insulin resistance by increasing beta-cell mass and function which allows to maintain the normoglycaemia. During the transition from pre-diabetes/obesity to type 2 diabetes (T2D), beta-cell is subjected to metabolic and inflammatory stress, that gradually lead to secretory dysfunction. In obesity, factors secreted by visceral adipose tissue may influence beta-cell mass and function. Moreover, increased visceral adiposity is associated to the development of peripancreatic adipose tissue (PPAT), which penetrates the pancreas and establishes direct contact with islets of Langerhans. Rebuffat et al (Endocrinology, 2012) showed in a model of obesity and insulin resistance that factors secreted by the PPAT modulate the proliferation of beta-cells. This is in favor of a local biocommunication between PPAT and beta-cell. Our goal is to characterize the PPAT in terms of immune cells and inflammatory factors secreted during the onset of type 2 diabetes (T2D) and determine how these factors are able to influence beta-cell compensation and decompensation in response to insulin resistance and metabolic syndrome.

**Materials and methods:** Our study was performed in the Zucker fa/fa rats/ZDF rats model of obesity and T2D. Three groups of animals were studied, pre-obese rats (6 weeks old) obese/pre-diabetic rats (10 weeks old) and diabetic rats (12 week olds). The presence of immune cells infiltrating the PPAT was investigated by immunohistochemistry using the macrophage marker ED1. The expression profile of peripancreatic fat-derived factors was analyzed by antibodyarray (Chemiarrray, RD System) and proteomic technology. A comparison of each group of rats allowed us to identify modifications in adipose tissue-derived factors and to correlate these changes to the metabolic status of the animals.

**Results:** An increase in macrophages infiltrating the PPAT was observed in obese/pre-diabetic animals (10 weeks old). Using chemiarray technology, we observed changes in cytokines and chemokines profiles secreted by PPAT in the ZDF rat model. While in the early stages of the disease we observed an increase in pro-inflammatory cytokines and chemokines secreted by PPA (such as, CINC- 1, 2, 3, IL-1 $\beta$ , LIX, TIMP-1, and MIP- 1 $\alpha$ ), surprisingly and unexpectedly, the expression profile of these factors changed and their levels decreased, when animals become diabetic (12 weeks ZDF rats). Proteomic profile also varies during the onset of the disease.

**Conclusion:** Therefore, our results showed that in obese/pre-diabetes rats, PPAT adipose tissue expression of inflammatory cytokines and chemokines are modified and thus could (i) induce and perpetuate inflammation by attracting immune cell in tissue and (ii) contribute to progressive beta-cell dysfunction occurring in T2D.

## 757

### The metabolic and anti-inflammatory effects of long-term resveratrol intake; a randomised clinical trial

T.N. Kjær, M.M. Poulsen, M.J. Ornstrup, J. Jørgensen, B. Richelsen, S.B. Pedersen;  
Aarhus University Hospital, Denmark.

**Background and aims:** Low-grade inflammation due to macrophage infiltration and hypoxia in adipose tissue (AT) is thought to be the link between obesity and the metabolic syndrome (MS). Resveratrol (RV) is a natural anti-inflammatory compound found in e.g. grape-skin that reduces inflammation and normalizes both insulin sensitivity and lifespan of diet induced obese rodents. Sirt1 enzymes, thought to mediate the RV-effects in rodents, are present in human AT. *In vitro*, RV stimulates human AT to increase lipolysis, reduce secretion of the macrophage-attracting MCP1 and reduce inflammation. Furthermore, hypoxia induced inflammation in AT is completely reverted when exposed to RSV. In clinical trials the effects of RV are inconclusive. A previous short term cross over study has shown that RV lowered systolic blood pressure, hepatic liver fat, and plasma triglycerides, leptin, TNF- $\alpha$ , leukocytes, alanine transaminase (ALT) and HOMA index in healthy obese humans. However, we and others have not been able to verify these findings. We aim to investigate the anti-inflammatory effects of long term RV intake and it's potential to ameliorate aspects of MS.

**Materials and methods:** A placebo controlled double blind clinical trial. 76 males with MS were randomized to treatment with high dose RV (HD) 500 mg x 2 or low dose RV (LD) 75 mg x 2 daily or placebo (PL) for 4 months. Before and after treatment, biopsies from skeletal muscle, adipose tissues were obtained for analysis of gene expression. MR and DEXA-scans were used to quantify changes in body fat amount and body composition respectively. Clinical blood pressure (BP) measurement, blood tests and urine samples were obtained at day 0, 30, 60 and 120 to follow BP, inflammation, lipid profile, liver function, insulin sensitivity (HOMA).

**Results:** 76 were randomized for the trial and 66 completed the four months of treatment. At baseline the subjects were well matched for BMI, age and waist circumference. However lean mass was significantly greater in LD compared to HD ( $p=0.048$ ) and systolic BP was significantly higher in the PL group compared to LD group ( $p=0.05$ ). Plasma biochemistry: At baseline there was a positive correlation between severity of metabolic syndrome and IL-6 level ( $p<0.03$ ). Metabolic effects: There were no significant effects of RV treatment on total cholesterol, high-density lipoprotein (HDL), triglyceride, ALT, insulin, glucose (or HOMA-IR). Anti-inflammatory effects: There were no changes in hs-CRP, IL-6, soluble urokinase-type plasminogen activator receptor (suPAR) in plasma, and there were no significant changes of IL-6 and TNF- $\alpha$  gene expression in AT or muscle tissue between the groups. Body composition: There was no difference in BMI, total lean mass, total fat mass, total fat percentage, subcutaneous adipose tissue, visceral adipose tissue, liver fat or extra/intra myocellular lipid between the groups. BP was unchanged between the groups.

**Conclusion:** Increasing severity of metabolic syndrome is associated with higher IL-6 plasma levels. However, RV did not affect IL-6 levels. So neither long term HD or LD treatment affects low-grade inflammation, or parameters of the MS. RV does not change body composition or AT depot size irrespective of dose. We conclude that RV has no role in reducing low-grade inflammation as seen in MS and shows no promise in ameliorating any aspects of the MS.

### Elevated glucose concentrations induce Prep1 overexpression through epigenetic modifications

M. Ciccarelli<sup>1</sup>, V. Vastolo<sup>2</sup>, L. Albano<sup>1</sup>, A. Desiderio<sup>1</sup>, M. Lecce<sup>1</sup>, D. Conza<sup>1</sup>, G.L. Russo<sup>3</sup>, F. Beguinot<sup>1</sup>, P. Ungaro<sup>2</sup>;

<sup>1</sup>DiSMET, University of Naples Federico II, <sup>2</sup>CNR-IEOS, Naples, <sup>3</sup>CNR-ISA, Avellino, Italy.

**Background and aims:** Changes in epigenetic regulation of gene expression represent potentially important pathogenic mechanisms behind complex diseases such as diabetes. High glucose concentrations that mimics diabetic conditions can induce *in vivo* chromatin remodeling and histone modifications to allow increased binding of key transcription factors, such as the nuclear factor  $\kappa$ -B (NF- $\kappa$ B), regulating inflammatory and diabetes-related genes. *Prep1*, a homeodomain transcription factor essential in embryonic development, has a role in glucose and energy metabolism. Adult *Prep1*-hypomorphic mutant mice (*Prep1<sup>hi</sup>*), which express 2 to 3% of *Prep1* mRNA and up to 10% of the protein, exhibit enhanced sensitivity to insulin action and are protected from developing streptozotocin-induced diabetes. Consistent with these findings overexpression of the wild-type *Prep1* cDNA in L6 cells determined a >70% inhibition of insulin-stimulated 2-DG uptake by these cells and a similar decline in the expression of GLUT4 protein and mRNA. However, how the environment affect *Prep1* gene remains unknown. The aim of this study is to evaluate whether and how a diabetic condition such as high glucose can dysregulate *Prep1* gene expression by inducing epigenetic changes through NF- $\kappa$ B recruitment to its promoter.

**Materials and methods:** We mimicked diabetic condition by culturing L6 skeletal muscle cells in High Glucose (25 mM) relative to Normal glucose (5.5 mM). *Prep1* and NF- $\kappa$ B expression were analyzed by Real-Time PCR and western blot analysis. Chromatin Immunoprecipitation assays have been performed to identify histone marks and histone-associated proteins.

**Results:** L6 cells cultured in HG for 72 hours show a significant increase of *Prep1* mRNA and protein levels compared to NG cultured cells. Time course experiments of HG showed an increase of *Prep1* expression both at mRNA and protein levels yet at four hours of HG incubation with the maximum effect reached at 48 and 72 hours of high glucose incubation. This effect was specific to glucose since equimolar amounts of xylose (osmolarity control) and 2-DG had no effect. As expected *Glut4* mRNA levels decreased in re-

sponse to HG. In parallel, HG incubation induced nuclear translocation and binding to *Prep1* promoter of the transcription factor NF- $\kappa$ B p65 that in turn enhanced the binding of the histone methyltransferase SET7/9 and histone acetyl-transferase p300 to *Prep1* promoter. This event coincided with an increase in lysine 4 dimethylation and lysine 9 and 14 acetylation on histone H3 (two marks of active transcription). Co-incubation of L6 cells with HG plus JSH-23, an NF- $\kappa$ B inhibitor, prevented HG-induced p65 binding, histone modifiers recruitment and histone modifications on *Prep1* promoter and restored HG-induced *Prep1* overexpression.

**Conclusion:** Elevated glucose concentrations alter the epigenetic state of *Prep1* gene resulting in an increase of its expression levels. These findings might have clinical relevance as preliminary evidence in our lab indicates that *Prep1* gene is overexpressed in euglycemic offspring of type 2 diabetic patients, suggesting that *Prep1* overexpression may provide an early contribution to disease in these individuals. Clarify *Prep1* epigenetic regulation can yield new insights into the physiopathology of glucose homeostasis and uncover potential targets for diabetes treatment and prevention.

## 759

### Palmitate challenged muscle cells attract monocytes through TLR4-dependent release of ATP

N.J. Pillion<sup>1</sup>, Y.E. Li<sup>1</sup>, P.J. Bilan<sup>1</sup>, J.T. Brozinick<sup>2</sup>, A. Klip<sup>1</sup>;

<sup>1</sup>Cell Biology Program, The Hospital for Sick Children, Toronto, Canada,

<sup>2</sup>Eli Lilly and Company, Indianapolis, USA.

**Background and aims:** Obesity and type 2 diabetes are associated with chronic activation of the immune system, and insulin-resistance arises by both lipotoxicity and low-grade inflammation. In response to high fat diet, the fat tissue attracts immune cells that cause low, sustained inflammation responsible for making the body resistant to insulin. Although inflammation is clearly recognized in adipose tissue, recent studies show that high fat-feeding is also responsible for a significant increase in pro-inflammatory cytokine expression in muscle. Yet, it is unknown whether there is a cause-effect relationship between muscle inflammation and whole body insulin resistance. Strikingly, muscle contains resident macrophages and we and others have recently detected infiltrating pro-inflammatory macrophages in muscle from type 2 diabetic individuals or from high fat-fed mice. Beyond this, little is known about the interplay between immune and muscle cells in the context of hyperlipidic environment, and a key unresolved issue is whether and how muscle cells themselves are capable of attracting monocytes.

**Materials and methods:** Skeletal muscle is composed primarily of muscle fibers and satellite myoblasts, but also encompasses blood and lymph vessels, nerves and immune cells. As each of these cell types can potentially respond to a high fat environment *in vivo*, we chose a cell culture approach to investigate the specific crosstalk between muscle cells and macrophages in the context of fatty acid exposure. This strategy enables us to control individual variables, to determine vectorial communication, and to explore separately the responses of each cell type. Medium collected from L6 myotubes (conditioned media, CM) exposed to saturated or unsaturated fatty acids (palmitate vs palmitoleate) was tested for its ability to attract monocytes. Secreted factors in the CM and inflammatory pathway activation in myotubes were analyzed using western blot, qPCR, nucleotide degradation strategies and gene knockdown.

**Results:** CM from L6 myotubes treated with palmitate - but not palmitoleate - induced THP1 monocyte migration across transwells. Palmitate caused both myotube lipotoxicity and inflammation. Although ceramide levels rose, they were not required for monocyte chemoattraction. Palmitate activated the TLR4-NF $\kappa$ B pathway in myotubes and elevated cytokine expression, but the monocyte chemoattracting agent in CM was not a polypeptide. Instead, nucleotide degradation eliminated the chemoattracting properties of CM. Moreover, palmitate induced the expression and activity of pannexin-3 channels in myotubes, mediated by TLR4-NF $\kappa$ B. Importantly, TLR4-NF $\kappa$ B inhibition or pannexin-3 knockdown in myotubes prevented monocyte chemoattraction by CM.

**Conclusion:** These findings constitute proof of concept that high levels of saturated fats may promote monocyte migration towards skeletal muscle *in vivo*, promoting the macrophage infiltration of this tissue that arises with fatty diets. They also predict that targeting chemokine production may be insufficient to reduce macrophage infiltration of muscle, as other factors such as nucleotides may significantly contribute to immune cell chemoattraction. Moreover, this study identifies pannexin-3 as an interesting target to taper the arrival and contribution of tissue inflammatory macrophages to metabolic disease.

#### Serum omentin is associated with lipid levels, but not with glucose tolerance and type 2: KORA F4 study

C. Herder<sup>1,2</sup>, M. Carstensen<sup>1,2</sup>, D.M. Ouwens<sup>3,4</sup>, B. Kowall<sup>5</sup>, A. Peters<sup>6,7</sup>, W. Rathmann<sup>5</sup>, M. Roden<sup>1,2</sup>, B. Thorand<sup>6,7</sup>;

<sup>1</sup>Institute for Clinical Diabetology, German Diabetes Center, Düsseldorf,

<sup>2</sup>German Center for Diabetes Research, Düsseldorf, <sup>3</sup>Institute for Clinical Biochemistry and Pathobiochemistry, German Diabetes Center, Düsseldorf,

<sup>4</sup>Department of Endocrinology, Ghent University Hospital, Belgium,

<sup>5</sup>Institute for Biometrics and Epidemiology, German Diabetes Center,

Düsseldorf, <sup>6</sup>Institute of Epidemiology II, Helmholtz Zentrum Muenchen, Neuherberg, <sup>7</sup>German Center for Diabetes Research, Neuherberg, Germany.

**Background and aims:** Circulating omentin levels are positively correlated with adiponectin. Although several studies suggested that omentin - like adiponectin - may be inversely associated with obesity and insulin resistance (HOMA-IR), data from population-based studies are not available so far. Therefore, we investigated in the population-based KORA F4 survey from Augsburg/Germany (i) whether serum levels of omentin were associated with prediabetes, type 2 diabetes (T2D) and continuous T2D risk factors and (ii) whether associations between omentin, prediabetes, T2D and related risk factors were mediated by BMI.

**Materials and methods:** Serum levels of omentin were measured by ELISA in 1089 participants (48% male; age range 61–82 years; BMI 29±4 kg/m<sup>2</sup>; NGT: n=576, IFG: n=56, IGT: n=186, IFG/IGT: n=46; newly diagnosed T2D: n=66, known T2D: n=159). Associations between serum omentin, glucose tolerance and continuous risk factors of T2D were assessed using logistic and linear regression models, respectively.

**Results:** We found no inverse association between serum omentin and prediabetes or diabetes ( $P > 0.05$  for unadjusted comparison of categories of glucose tolerance) and no significant associations with glucose tolerance status after adjustment for age, sex, BMI, lifestyle factors, lipids, hypertension and history of myocardial infarction. After adjustment for multiple confounders, serum levels of omentin were associated with blood lipids (HDL cholesterol:  $\beta = -0.04$ ,  $P < 0.001$ ; ln(triglycerides):  $\beta = -0.04$ ,  $P = 0.02$ ), but not with BMI ( $P = 0.4$ ), parameters of glucose metabolism (fasting and 2-hr glucose, fasting insulin, HOMA-IR, HbA1c;  $P$  between 0.1 and 1.0) and systolic or diastolic blood pressure ( $P = 0.9$  and  $0.09$ , respectively). Associations between omentin and lipids were explained by adiponectin.

**Conclusion:** In conclusion, our data indicate that omentin is associated with lipid levels, but does not represent a novel biomarker of prediabetes and T2D. *Supported by: DZD e.V., DFG (RA 459/3-1)*

#### The novel adipokine / hepatokine betatrophin is increased in women with gestational diabetes mellitus

T. Ebert<sup>1,2</sup>, U. Wurst<sup>1,2</sup>, M. Stumvoll<sup>1</sup>, A. Tönjes<sup>1,2</sup>, M. Fasshauer<sup>1,2</sup>, S. Kralisch<sup>1,2</sup>;

<sup>1</sup>Department of Endocrinology and Nephrology, University of Leipzig,

<sup>2</sup>IFB AdiposityDiseases, Leipzig University Medical Center, Germany.

**Background and aims:** Betatrophin has recently been introduced as a novel adipokine/ hepatokine which promotes pancreatic  $\beta$  cell proliferation and improves glucose tolerance in mouse models of insulin resistance. However, regulation of betatrophin in women gestational diabetes mellitus (GDM), as well as its association with markers of obesity, glucose and lipid metabolism, inflammation, and renal function, have not been elucidated.

**Materials and methods:** Circulating betatrophin was quantified in 74 women with GDM and 74 healthy, pregnant, age-, body mass index-, and gestational age-matched controls by enzyme-linked immunosorbent assay. In a subset of the study population comprising of 85 patients (41 previous controls, 44 previous women with GDM), postpartum betatrophin levels were measured in a follow-up study.

**Results:** Median [interquartile range] serum betatrophin levels were higher in women with GDM (1.80 [0.53]  $\mu\text{g/l}$ ) as compared to non-diabetic pregnant controls (1.58 [0.44]  $\mu\text{g/l}$ ) ( $p = 0.003$ ) during pregnancy. In multivariate analysis, GDM status was an independent and positive predictor of circulating betatrophin ( $p < 0.05$ ). Furthermore, high density lipoprotein cholesterol and leptin were independently and positively associated with betatrophin ( $p$

$< 0.05$ ). Moreover, betatrophin levels were significantly higher during gestation (1.69 [0.53]  $\mu\text{g/l}$ ) as compared to postpartum levels (1.55 [0.66]  $\mu\text{g/l}$ ) ( $p = 0.029$ ).

**Conclusion:** Circulating betatrophin is increased in women with GDM and remains a positive predictor of GDM status. Betatrophin levels during gestation are significantly higher as compared to postpartum concentrations. Further studies need to elucidate the pathophysiological significance of betatrophin upregulation in GDM and during pregnancy.

#### Plasma chemerin is a strong and independent predictor of cardiovascular event risk

A. Leihner<sup>1,2</sup>, A. Muendlein<sup>1</sup>, P. Rein<sup>3</sup>, K. Geiger<sup>1</sup>, P. Fraunberger<sup>4</sup>, H. Drexel<sup>3,5</sup>, A. Vonbank<sup>3</sup>, C.H. Saely<sup>3,2</sup>;

<sup>1</sup>VIVIT Institute, Feldkirch, Austria, <sup>2</sup>Private University of the Principality

of Liechtenstein, Triesen, Liechtenstein, <sup>3</sup>Academic Teaching Hospital

Feldkirch, Austria, <sup>4</sup>Medical Central Laboratory, Feldkirch, Austria,

<sup>5</sup>Drexel University College of Medicine, Philadelphia, USA.

**Background and aims:** Associations of the adipokine chemerin with the metabolic syndrome (MetS) and with chronic kidney disease (CKD), two important indicators of increased cardiovascular event risk, have been described. However, the power of chemerin to predict cardiovascular events has not been investigated so far and is addressed in the present study.

**Materials and methods:** We measured plasma chemerin in a high-risk cohort of 495 patients undergoing coronary angiography for the evaluation of suspected or established coronary artery disease (CAD) in which cardiovascular events were prospectively recorded over 3.5±1.1 years. Significant baseline CAD was diagnosed in the presence of coronary artery stenoses  $\geq 50\%$ .

**Results:** At baseline, plasma chemerin was significantly higher in patients with the MetS as defined by the current harmonized consensus definition ( $n = 147$ ) than in non-MetS subjects (201±71 ng/ml vs. 163±62 ng/ml  $p < 0.001$ ) and was inversely correlated with estimated glomerular filtration rate (eGFR;  $r = -0.33$ ,  $p < 0.001$ ). During follow-up, chemerin significantly predicted cardiovascular events ( $n = 82$ ) univariately, after adjustment for age, gender, BMI, and eGFR, and also after additional adjustment for the presence of significant baseline CAD, with standardized hazard ratios of 1.83 [1.19–2.83],  $p = 0.006$ ; 1.77 [1.12–2.80],  $p = 0.015$ ; and 1.69 [1.07–2.67],  $p = 0.024$ , respectively.

**Conclusion:** From this first prospective evaluation of the cardiovascular event risk associated with chemerin we conclude that chemerin is strongly predictive of cardiovascular events independently from standard risk factors, from the MetS, and from the baseline presence of CAD.

### 763

#### Secreted frizzled-related protein 4 is up-regulated in type 2 diabetes and interferes with hepatic insulin signalling

M. Bekaert<sup>1</sup>, P. Fahlbusch<sup>2</sup>, S. Colenbie<sup>1</sup>, T. Doktorova<sup>3</sup>, Y. Van Nieuwenhove<sup>4</sup>, T. Vanhaecke<sup>3</sup>, J.B. Ruige<sup>1</sup>, D.M. Ouwens<sup>1,2</sup>;

<sup>1</sup>Endocrinology, Ghent University Hospital, Belgium, <sup>2</sup>Institute for Clinical

Biochemistry and Pathobiochemistry, German Diabetes Center, Düsseldorf,

Germany, <sup>3</sup>Toxicology, Center for Pharmaceutical Research VUB, Brussels,

<sup>4</sup>Abdominal surgery, Ghent University Hospital, Belgium.

**Background and aims:** Accumulating evidence implicates secreted regulators of the Wnt signaling pathway to metabolic control. For example, the inflammation-induced up-regulation of the Wnt inhibitor secreted frizzled-related protein 4 (Sfrp4) associates with impaired glucose-induced insulin secretion in type 2 diabetes. Importantly, Sfrp4 is also expressed in adipose tissue. The current study investigated whether the expression of Sfrp4 in visceral adipose tissue is altered in morbid obesity and type 2 diabetes, and whether Sfrp4 affects the expression of key rate-limiting gluconeogenic enzymes.

**Materials and methods:** Gene expression levels of Sfrp4 were determined by real-time PCR in subcutaneous and visceral adipose tissue biopsies from morbidly obese men ( $n = 45$ , of which 20 had type 2 diabetes) and control men ( $n = 22$ ) undergoing abdominal surgery. The effects of recombinant Sfrp4 (100 ng/ml) on the mRNA expression of phosphoenolpyruvate carboxykinase (PEPCK), glucose-6-phosphatase (G6P) and fructose-1,6-bisphosphatase 1 (FBP1) were studied in the human hepatocyte cell line HepaRG after glucose starvation in the presence and absence of 100 nM insulin.

**Results:** In visceral adipose tissue, expression of Sfrp4 was 2.3-fold higher in patients with type 2 diabetes either versus patients with morbid obesity only or controls ( $P<0.002$ ). There were no differences in Sfrp4 expression among these groups in subcutaneous adipose tissue. In vitro, in the absence of insulin, Sfrp4 reduced FBPI expression by 33% ( $P<0.05$ ), while having no effect on G6P- and PEPCK-levels in HepaRG cells. Insulin exposure reduced the expression of PEPCK, G6P and FBPI by 2.1-, 2.8-, and 2.7-fold, respectively (all  $P<0.001$ ). Exposing HepaRG cells to Sfrp4 further impaired the suppression of FBPI- and PEPCK-levels by insulin by 30% and 35%, respectively. In contrast, Sfrp4 did not affect the suppression of G6P levels by insulin. However, Sfrp4 reduced the insulin-mediated phosphorylation of Akt- and FOXO1, which has been implicated in the suppression of PEPCK expression, by 25% and 35%, respectively (both  $P<0.05$ ).

**Conclusion:** These data show that the expression of the Wnt regulator Sfrp4 is selectively increased in visceral adipose tissue from patients with type 2 diabetes. In vitro, Sfrp4 interferes with the suppression of the expression of rate-limiting regulators of hepatic gluconeogenesis by insulin.

### Wnt1 inducible signalling pathway protein 1 (WISP1) is a novel marker of obesity regulated by high fat diet

C. Tacke<sup>1,2</sup>, V. Murahovschi<sup>1,2</sup>, F. Keyhani-Nejad<sup>1,2</sup>, O. Pivovarova<sup>1,2</sup>, I. Ilkavets<sup>3</sup>, M. Kemper<sup>1,2</sup>, S. Hornemann<sup>1,2</sup>, R. Dmitrieva<sup>4</sup>, A. Conradi<sup>4</sup>, S. Dooley<sup>5</sup>, A.F.H. Pfeiffer<sup>1,2</sup>, N. Rudovich<sup>1,2</sup>;

<sup>1</sup>German Institut for Nutrition Science, Nuthetal, <sup>2</sup>Charité University Medicine, Berlin, <sup>3</sup>University Medical Centre Mannheim, University of Heidelberg, Mannheim, Germany, <sup>4</sup>Almazov Federal Medical Research Centre, Saint Petersburg, Russian Federation.

**Background and aims:** The Wnt signaling is involved in several processes such as proliferation, adhesion, apoptosis and differentiation. WISP1 (WNT1 inducible signaling pathway protein 1) is a target protein of canonical Wnt signaling and it belongs to the secreted extracellular matrix associated proteins of the CCN family. Recently, we showed that WISP1 expression is associated with signs of insulin resistance and low-grade inflammation in humans. We tested here the acute effect of insulin on WISP1 expression in vivo in subcutaneous adipose tissue (SAT). Additionally, the effect of high fat diet induced obesity on regulation of WISP1 gene expression in mice.

**Materials and methods:** Body weight matched, twelve-week-old male C57Bl/6J mice were kept on either a control diet D12450B (1) containing 10kcal-%fat, 20kcal-% protein, 70 kcal-% carbohydrate, 3.85kcal/g or a high fat diet D12492; (2) containing 60kcal-% fat, 20 kcal-% protein, 20 kcal-%carbohydrate, 5.24 kcal/g for 6 weeks. Body weight and composition was determined by magnetic resonance spectroscopy in conscious mice. Overnight fasted mice were sacrificed and epididymal white adipose tissue, liver and gastrocnemius muscle tissue were collected. Human mesenchymal stem cells (n=3) were differentiated in vitro into adipocytes. Differentiated adipocytes were incubated with 100nM insulin for 4h. Healthy, moderately obese male subjects (n=14) underwent one or three of the following procedures: 1) isotonic saline-infusion (n=11); 2) hyperinsulinemic-euglycemic clamp (EC) for 4 h with continuous infusion of 40•mU•m<sup>2</sup> of the body surface•min<sup>-1</sup> human insulin at a steady state capillary plasma glucose concentration of 4,4 mmol/l (80 mg/dl) (n=10); 3) hyperinsulinemic-hyperglycemic clamp (HC) for 4 h with continuous infusion of 40•mU•m<sup>2</sup> of the body surface•min<sup>-1</sup> human insulin at a steady state capillary plasma glucose concentration of 7,8 mmol/l (140 mg/dl) (n=8). Healthy, obese male subjects (n=10) underwent 1) isotonic saline-infusion and 2) intralipid/heparin -infusion. SAT biopsies were obtained before and after infusion. WISP1 gene expression was measured in human differentiated adipocytes, human SAT, in mice in epididymal white adipose tissue, in liver and gastrocnemius muscle tissue.

**Results:** WISP1 gene expression increased in human differentiated adipocytes after stimulation with 100nM insulin, but no significant difference was observed in SAT after HC and EC. The high fat diet-fed mice had increased body weight, fat mass and lean mass compared with control group and up-regulated WISP1 expression in adipose and muscle tissues. We couldn't observe any acute effect on WISP1 expression in human SAT after intralipid/heparin -infusion.

**Conclusion:** Insulin increased WISP1 expression in vitro, but has no acute effect in overweight subjects in vivo. High-fat diet induced obesity increased WISP1 gene expression in mice, however intralipid infusion hasn't any acute effect in overweight subjects in vivo.

## 765

### Wnt1 inducible signalling protein 1 (WISP1) is a novel adipokine linked to inflammation and insulin resistance in adipose tissue

V. Murahovschi<sup>1,2</sup>, O. Pivovarova<sup>1,2</sup>, I. Ilkavets<sup>3</sup>, R. Dmitrieva<sup>4</sup>, S. Döcke<sup>1</sup>, M. Kemper<sup>1</sup>, Ö. Gögebakan<sup>1,2</sup>, M. Osterhoff<sup>1,2</sup>, N. Klötting<sup>5</sup>, A. Conradi<sup>4</sup>, S. Dooley<sup>5</sup>, C. von Loeffelholz<sup>6,2</sup>, M. Blüher<sup>5</sup>, A.F.H. Pfeiffer<sup>1,2</sup>, N. Rudovich<sup>1,2</sup>;

<sup>1</sup>German Institut for Nutrition Science, Nuthetal, <sup>2</sup>Charité University Medicine, Berlin, <sup>3</sup>University Medical Centre Mannheim, University of Heidelberg, Mannheim, Germany, <sup>4</sup>Almazov Federal Medical Research Centre, Saint Petersburg, Russian Federation, <sup>5</sup>University of Leipzig, <sup>6</sup>Jena University Hospital, Germany.

**Background and aims:** WISP1 (Wnt1 inducible signaling pathway protein 1) belongs to the secreted extracellular matrix associated proteins of the CCN family and is a target gene of canonical Wnt signaling pathway. Here we show that WISP1 is released from adipocytes and circulating WISP1 levels correlate with weight reduction and signs of insulin resistance.

**Materials and methods:** The mRNA expression of WISP1 was studied 1) in paired samples of visceral (VAT) and subcutaneous adipose tissue (SAT) from healthy glucose-tolerant subjects (n=75); 2) in paired VAT, SAT and liver tissue samples from subjects with/without NAFLD (n=47); 3) in overweight subjects underwent weight reduction by caloric restriction (n=49); 4) in SAT of overweight subjects (n=14) in the euglycemic-hyperinsulinemic (EC) and hyperglycemic-hyperinsulinemic (HC) clamp test; 5) in human mesenchymal stem cells (MSC) derived adipocytes and in human GM-macrophages. WISP1 protein levels were measured in overweight subjects underwent weight reduction and in cell culture medium adipocytes during differentiation. Expression and release of TNF $\alpha$ , IL-6, IL-10, IL-1 $\beta$  was measured in differentiated adipocytes and in GM-macrophages after stimulation with 0,5 $\mu$ g/ml WISP1 for 24h. 3T3-L1 differentiated adipocytes were treated with 100nmol/L insulin with/without LY294002 (25 $\mu$ M, preincubation 30 min) and with/without PD 098059 (30 $\mu$ M, preincubation 30 min) for 4h.

**Results:** WISP1 protein release and WISP1 expression increase in cell culture medium during adipocytes differentiation. Expression and release of IL-6, IL-10, IL-1 $\beta$ , TNF $\alpha$  in GM-makrophage was significantly enhanced after stimulation with 0,5 $\mu$ g/ml WISP1 for 24h. WISP1 expression was increased in differentiated 3T3-L1 cells after stimulation with 100nM insulin for 4h. This effect was abolished by incubation with LY294002 and PD098059. In human studies: 1) we found a correlation between insulin sensitivity, macrophages infiltration, adiponectin levels and WISP1 gene expression in samples of VAT and SAT; 2) WISP1 expression is higher in (VAT) rather than in (SAT); 3) hepatic WISP1 expression has no association with ectopic fat accumulation in obesity; 4) weight reduction decreases WISP1 expression in SAT as well as circulating WISP1 levels in plasma.

**Conclusion:** Our data shows that WISP1 is a novel adipokine but no hepatokine that is substantially overexpressed in visceral fat from obese subjects and reflects insulin resistance and adipose tissue inflammation. Weight changes regulate circulating WISP1 levels and WISP1 expression in adipose tissue. Therefore, we propose that WISP1 is a novel biomarker and a potential link between obesity and the metabolic syndrome.

## 766

### FABP5 is an essential modulator of fatty acid-induced GIP secretion in enteroendocrine K cells

K. Shibue<sup>1,2</sup>, S. Yamane<sup>1</sup>, N. Harada<sup>1</sup>, A. Hamasaki<sup>1</sup>, K. Suzuki<sup>1</sup>, E. Joo<sup>1</sup>, K. Iwasaki<sup>1</sup>, D. Nasteska<sup>1</sup>, T. Harada<sup>1</sup>, Y. Adachi<sup>3</sup>, Y. Owada<sup>4</sup>, R. Takayanagi<sup>2</sup>, N. Inagaki<sup>1</sup>;

<sup>1</sup>Department of Diabetes, Endocrinology and Nutrition, Graduate School of Medicine, Kyoto University, <sup>2</sup>Department of Medicine and Bioregulatory Science, Graduate School of Medical Sciences, Kyushu University, Fukuoka, <sup>3</sup>Department of Anatomy, School of Medicine, University of Occupational and Environmental Health, Fukuoka, <sup>4</sup>Department of Organ Anatomy, Yamaguchi University Graduate School of Medicine, Japan.

**Background and aims:** Fatty acid-binding protein 5 (FABP5) is a 15-kDa cytosolic-protein with high affinity to long chain fatty acids (LCFA). It has been known as an intracellular chaperon that transports LCFA into various organelles and has been reported to be involved in insulin resistance in white adipose tissue (WAT). Using microarray analysis, we demonstrated that FABP5 is expressed exclusively in murine enteroendocrine GIP-producing K-cells. We investigated the physiological function of FABP5 in K-cells.

**Materials and methods:** Immunostaining for FABP5 and GIP was performed in murine samples of small intestine for confirmation of specific expression of FABP5 in K-cells. To evaluate the acute GIP secretory response in FABP5<sup>-/-</sup> mice, lard (10ml/kg) and glucose were injected orally; plasma glucose and serum levels of GIP, GLP-1 and insulin were measured. Using K-cells isolated from newly-generated GIP-GFP knock-in hetero (GIPgfp/+)-FABP5<sup>+/+</sup> and GIPgfp/+ -FABP5<sup>-/-</sup> mice, quantitative real-time PCR (qPCR) for GIP expression and measurement of GIP content were performed to determine whether or not FABP5 is involved in GIP biosynthesis. To assess potential effects of FABP5-deficiency on body weight and composition, mice were fed a high fat diet (HFD) for 10 weeks. Whole body CT scans of HFD-fed wild-type (WT), FABP5<sup>-/-</sup>, GIPgfp/gfp-FABP5<sup>+/+</sup> and GIPgfp/gfp-FABP5<sup>-/-</sup> mice were compared. Using WAT taken from HFD-fed WT and FABP5<sup>-/-</sup> mice, mRNA expression levels of lipid metabolism-related genes were evaluated by qPCR.

**Results:** Immunostaining of intestinal mucosa showed that GIP-positive cells were totally merged with FABP5-positive cells and that 90% of FABP5-positive cells were merged with GIP-positive cells. Although plasma GIP levels after lard injection were significantly lower in FABP5<sup>-/-</sup> mice compared to those in WT mice, there were no significant differences in the results of OGTT. Plasma glucose, insulin and GLP-1 levels after both glucose and lard administration were similar in WT mice and FABP5<sup>-/-</sup> mice. There was no significant difference in GIP mRNA expression or GIP content in K-cells from GIPgfp/+ -FABP5<sup>+/+</sup> and GIPgfp/+ -FABP5<sup>-/-</sup> mice. Under HFD feeding conditions, FABP5<sup>-/-</sup> mice exhibited significantly decreased body weight gain compared to WT control, but there was no significant difference in body weight between GIPgfp/gfp-FABP5<sup>+/+</sup> and GIPgfp/gfp -FABP5<sup>-/-</sup> mice, in which GIP expression is genetically deleted. Whole body CT scan showed that body fat mass was significantly reduced in FABP5<sup>-/-</sup> mice compared to that in WT mice and that body fat mass in GIPgfp/gfp -FABP5<sup>+/+</sup> and GIPgfp/gfp -FABP5<sup>-/-</sup> mice was comparable. qPCR of WAT revealed no significant change in mRNA expression levels of hormone sensitive lipase, PPAR $\delta$ , aP2 or GIP-receptor between HFD-fed WT and FABP5<sup>-/-</sup> mice.

**Conclusion:** Our results show that FABP5 is involved in fatty acid-induced acute GIP secretion and that it contributes to the development of HFD-induced obesity in a GIP-dependent manner.

## 767

### NOV/CCN3: a new adipokine involved in obesity-associated insulin resistance?

B. Feve<sup>1</sup>, C. Martinerie<sup>1</sup>, M. Fesatidou<sup>1</sup>, P.-O. Marchal<sup>1</sup>, C. Kazazian<sup>1</sup>, M. Buysse<sup>1</sup>, H. Do Thi Tu<sup>1</sup>, B. Antoine<sup>1</sup>, T. Ladent<sup>1</sup>, M.-P. Garcia<sup>1</sup>, H. Koseki<sup>2</sup>, C. Chadjichristos<sup>3</sup>, R. Denis<sup>4</sup>, S. Luquet<sup>4</sup>;

<sup>1</sup>Faculté de Médecine Pierre et Marie Curie, CDR St-Antoine UMR\_S938 INSERM/UPMC, Paris, France, <sup>2</sup>Chiba University Graduate School of Medicine, Chiba, Japan, <sup>3</sup>Hôpital Tenon, UMR\_S 702 INSERM/UPMC, <sup>4</sup>Université Paris Diderot-Paris7, CNRS EAC 4413, Paris, France.

**Background and aims:** The pathophysiology of obesity is far to be elucidated. Identification of new adipokines represents a major challenge to decipher the mechanisms of adipose tissue development and metabolism. Our recent results suggest that NOV/CCN3, a multifunctional matricellular protein, is synthesized and secreted by adipose tissue, with plasma levels correlated with body mass index and fat mass, and down-regulated following bariatric surgery (Pakradouni et al.). NOV has been involved previously in tissue repair, fibrotic and inflammatory diseases, and cancer. However, its role in adipose tissue and energy homeostasis remains unknown.

**Materials and methods:** The aim of our work was to investigate the metabolic phenotype of NOV knockout mice fed a standard or high fat diet (HFD) **Results:** Weight gain was similar between wild type (WT) and NOV<sup>-/-</sup> mice fed a chow diet. Strikingly, the weight of NOV<sup>-/-</sup> mice fed a HFD was markedly lower than that of WT animals. This was related to a sharp decrease in fat mass, whereas lean mass was preserved. Accordingly, NOV<sup>-/-</sup> mice fed a HFD displayed an improved glucose tolerance and insulin sensitivity. No significant changes were detected for food intake, energy expenditure, or locomotor activity. Importantly, the absence of NOV was associated with a marked decrease in adipose tissue expression of several proinflammatory cytokines and chemokines. Conversely, exposure of 3T3-L1 mature adipocytes to NOV led to an induction of these cyto-/chemokines.

**Conclusion:** Altogether, these results show that NOV is a new adipokine that could be involved in obesity-associated insulin resistance

### The mRNA expression and release of (pro)-inflammatory and angiogenic factors in perivascular fat cells is influenced by fetuin-A via different signalling pathways

D.I. Siegel-Axel<sup>1,2</sup>, S. Ullrich<sup>1,2</sup>, N. Stefan<sup>1,2</sup>, K. Rittig<sup>1</sup>, F. Gerst<sup>1,2</sup>, U. Schmidt<sup>1</sup>, B. Schreiner<sup>1</sup>, H.-E. Schaller<sup>3</sup>, H.-U. Haering<sup>1,2</sup>;

<sup>1</sup>Department of Internal Medicine, Medical Clinic IV, Division of Endocrinology, Diabetology, Angiology, Nephrology and Clinical Chemistry, <sup>2</sup>Institute for Diabetes Research and Metabolic Diseases of the Helmholtz Centre Munich at the University of Tuebingen and German Center for Diabetes Research <sup>3</sup>Department of Plastic, Hand and Reconstructive Surgery, BG-Trauma-Center, Tuebingen, Germany.

**Background and aims:** Our previous in vitro and in vivo studies showed that fetuin-A exerts effects on perivascular fat cells (PVFC) and vascular cells which may influence cardiovascular diseases, predominantly effects on (pro)- inflammatory and angiogenic factors. Analysis of underlying pathways demonstrated that fetuin-A/palmitate (fet/palm) stimulates IL-6 and -8 expression via TLR4 receptor signalling. In contrast, the inhibition of the potent angiogenic protein HGF was mediated via the well known insulin-dependent receptor tyrosine kinase pathway. In order to elucidate pathways downstream TLR4 receptor activation, in this study fet/palm induced signalling pathways were studied in PVFC more detailed using several kinase inhibitors.

**Materials and methods:** PVFC were isolated from fat specimens around arm arteries of patients from our trauma center. Cells were treated with or without the JNK inhibitor SP500125 (10  $\mu$ mol/L), the p38MAPkinase inhibitor SB203580 (10  $\mu$ mol/L), the MEK1/2 inhibitor PD98059 (10  $\mu$ mol/L) and the NF $\kappa$ B inhibitor BAY11-7082 (1  $\mu$ mol/L) 2 h prior to the addition of fet (600  $\mu$ mol/L) and palm (50  $\mu$ mol/L). After 24 h protein release was quantitated by ELISA technology and mRNA expression by realtime PCR.

**Results:** The expression of IL-8, IL-6 and MCP-1 was upregulated by fet and this effect was potentiated significantly by the addition of palm. Additional incubation with the NF $\kappa$ B inhibitor abrogated these effects significantly. JNK inhibition caused a partial blockade of the fet/palm induced stimulatory effects on interleukins whereas MEK1/2 and p38MAPkinase inhibition had only slight influence on the potent stimulatory effects of fet/palm. In contrast to the TLR4-mediated stimulatory effects on interleukins, the expression of the strong angiogenic factor HGF was potently inhibited by fet/palm and this effect could not be abrogated by the NF $\kappa$ B inhibitor and only partially by the other MAPkinase inhibitors. However, the angiogenic factor bFGF was not inhibited but slightly stimulated by fet/palm and this was predominantly influenced by the JNK inhibitor and slightly by NF $\kappa$ B inhibitor. Finally, fet/palm exerted nearly no effects on the angiogenic factor VEGF.

**Conclusion:** Fet/palm caused strong stimulatory effects on (pro)inflammatory proteins. However, the observed effects on several potent angiogenic factors were diverse: bFGF was stimulated slightly, VEGF remained nearly unchanged and HGF was even inhibited significantly. Treatment with several signalling pathway inhibitors showed that fet acts via different pathways downstream TLR4 receptor activation, such as JNK or NF $\kappa$ B signalling but to a lesser extent on other MAPkinases, such as MEK1/2 and p38. Nevertheless, the diverse inhibitory effect of fet/palm on the potent angiogenic factor HGF seems to be mediated at least partially by another - TLR4-independent - pathway.

**Background and aims:** Nicotinamide phosphoribosyltransferase (NAMPT), also known as visfatin, was claimed to be secreted predominantly from visceral adipose tissue and to exert insulin-like action. It has been reported that NAMPT induced the release of inflammatory cytokines, cholesterol accumulation and the formation of macrophage foam cells in cultured cells. So there may be some association with atherosclerosis due to its role in inflammation and lipid accumulation. However, the impact of NAMPT on atherosclerosis

remained to be systematically investigated. To determine the role of NAMPT in the development of atherosclerosis, we have determined whether NAMPT knockdown can improve insulin resistance and formation of atherosclerotic lesions by using a loss-of-function approach (adenovirus-mediated RNAi) to inhibit NAMPT expression in the liver in C57BL/6J and apoE KO mice on a high fat diet. More importantly, we discussed the molecular mechanisms of NAMPT-knockdown in the regulation of cholesterol metabolism and the development of atherosclerosis.

**Materials and methods:** In vivo, NAMPT-knockdown C57BL/6J and apoE KO mice by a adenovirus-mediated RNAi was used to assessed the effects of NAMPT knockdown on metabolic parameters on a standard chow diet or a high fat diet; Euglycemic- hyperinsulinemic clamps were performed to assess glucose kinetics by tracer dilution methodology. An in vivo reverse cholesterol transport (RCT) assay that traces  $^3\text{H}$ -cholesterol derived from macrophages loaded with cholesterol ex vivo was performed. In vitro, assays testing effects of Ad-GFP or Ad-*sh*Visfatin treatment on cholesterol efflux from  $^3\text{H}$ -cholesterol-loaded RAW264.7 cells to lipoprotein acceptors was conducted. The expressions of hepatic genes related to cholesterol metabolism were analyzed by qRT-PCR and western blots; MK886, a selective inhibitor of PPAR $\alpha$  was used to analyze the mechanisms by which NAMPT knockdown leads to increased cholesterol efflux and RCT.

**Results:** HFD-fed C57BL/6J mice with reduced hepatic NAMPT content showed no alterations in all tested metabolic parameters, except for elevated HDL-C and slightly decreased LDL-C levels without statistical significance compared to littermates fed HFD; However, plasma HDL-C levels in HFD-fed ApoE KO mice treated with Ad-*sh*NAMPT were significantly increased and hepatic TC contents were decreased compared to littermates fed HFD; Analysis of lipoproteins by FPLC showed an increase in cholesterol content in the HDL fractions of Ad-*sh*NAMPT-treated mice compared with control mice; RCT assay showed that higher HDL levels in response to NAMPT knockdown increased cholesterol transport from peripheral macrophages to the liver. In cultured RAW264.7 cells, HDL-mediated  $^3\text{H}$ -cholesterol efflux was increased by NAMPT knockdown; NAMPT knockdown upregulated mRNA and protein expression involved in cholesterol efflux and RCT; MK886 abolished NAMPT knockdown-induced ABCA1/G1 and LXR $\alpha$  expressions in Hepa1-6 and RAW264.7 cells.

**Conclusion:** NAMPT knockdown exerted antiatherogenic effects by promoting cholesterol efflux and macrophage RCT through the PPAR $\alpha$ - LXR $\alpha$ -ABCA1/G1 pathway in vitro or in vivo.

### Dietary fat intake in low-carbohydrate diets and subsequent mortality and weight change in type 2 diabetes

J.W.J. Beulens<sup>1</sup>, M.J.E. Campmans-Kuijpers<sup>1</sup>, I. Sluijs<sup>1</sup>, U. Nöthlings<sup>2</sup>, H. Freisling<sup>3</sup>, K. Overvad<sup>4</sup>, H. Boeing<sup>5</sup>, A.M. May<sup>1</sup>, on behalf of the EPIC consortium;

<sup>1</sup>Julius Center for Health Sciences and Primary Care, University Medical Center Utrecht, Netherlands, <sup>2</sup>Department of Food Sciences and Nutrition, University of Bonn, Germany, <sup>3</sup>International Agency for Research on Cancer (IARC-WHO), Lyon, France, <sup>4</sup>Department of Epidemiology School of Public Health, Aarhus University, Denmark, <sup>5</sup>Department of Epidemiology, German Institute of Human Nutrition, Potsdam-Rehbrücke, Germany.

**Background and aims:** The replacement of carbohydrates with fat in a diet for type 2 diabetes patients is still debated. This study aimed to investigate the association between dietary carbohydrate intake and replacement with different types of fat with all-cause and cardiovascular (CVD) mortality risk and 5-year weight change in patients with type 2 diabetes.

**Materials and methods:** The study included 6,192 patients with type 2 diabetes from 15 cohorts of the European Prospective Investigation into Cancer and Nutrition (EPIC). Dietary intake was assessed at baseline with country-specific food-frequency questionnaires. Cox regression was used to estimate whether replacement of carbohydrates with different types of fat was associated with cardiovascular mortality adjusted for diabetes risk factors and dietary factors. Linear regression was used for associations with weight change.

**Results:** After a mean follow-up of  $9.2 \text{ y} \pm \text{SD } 2.3 \text{ y}$ , 791 (13%) participants had died, of which 268 (4%) due to CVD. The risk of all-cause mortality increased when 10 gram or 5 energy % of carbohydrates was replaced by total fat (HR 1.07 [1.02-1.13]), or SFAs (HR 1.25 [1.11-1.40]) and decreased when replaced by MUFAs (HR 0.89 [0.77-1.02]). CVD mortality risk increased when carbohydrates were substituted with SFAs (HR 1.22 [1.00-1.49]) or PUFAs (HR 1.29 [1.02-1.63]). The 5-year weight change decreased when carbohydrates were substituted with total fat or MUFAs, and increased when substituted by SFAs. After adjusting for 5-year weight change, the associations for (CVD) mortality lost significance.

**Conclusion:** In diabetes patients, substitution of carbohydrates with total fat or SFAs increased mortality risk. Replacement of carbohydrates with MUFAs was associated with lower mortality risk and weight change. Dietary guidelines should focus on replacement of carbohydrates by fat-subtypes, especially replacement of SFAs by MUFAs seems beneficial.

771

### Differential acute postprandial effects to isocaloric meals with different macronutrient content in subjects with type 2 diabetes and healthy controls

L. Belinova<sup>1</sup>, H. Kahleova<sup>1</sup>, H. Malinska<sup>1</sup>, O. Topolcan<sup>2</sup>, J. Vrzalova<sup>2</sup>, O. Oliyarnyk<sup>1</sup>, L. Kazdova<sup>1</sup>, M. Hill<sup>3</sup>, T. Pelikanova<sup>1</sup>;

<sup>1</sup>Department of Diabetes, Institute for Clinical and Experimental Medicine, Prague, <sup>2</sup>University Hospital in Pilsen,

<sup>3</sup>Institute of Endocrinology, Praha, Czech Republic.

**Background and aims:** Dietary guidelines for treatment of diabetes focus mainly on carbohydrate counting. Evidence suggests that postprandial metabolic response is also modified by other macronutrient content of meals and their effect on various gastrointestinal hormone release. We aimed to investigate the effects of two standardized isocaloric meals: a processed hamburger meat meal rich in protein and saturated fat (M-meal) and a vegetarian sandwich meal rich in carbohydrates (V-meal) in terms of postprandial glucose, lipids and insulin levels, gastrointestinal hormone (GIH) response and oxidative stress markers.

**Materials and methods:** In a randomized crossover study, 50 patients with type 2 diabetes (T2D) and 50 healthy subjects underwent two 3-hour meal tolerance tests. For statistical analyses, repeated-measures ANOVA was used.

**Results:** The M-meal resulted in a higher postprandial increase in lipids in both groups ( $p < 0.001$ ) and persistent postprandial hyperinsulinemia in diabetics. The plasma glucose levels were significantly higher after the V-meal only at the peak level. The GIH concentrations were higher (glucose-dependent insulinotropic peptide (GIP):  $p < 0.001$ ; peptide tyrosine-tyrosine (PYY):  $p < 0.05$ ; pancreatic polypeptide (PP):  $p < 0.01$ ) and the ghrelin concentration

was lower ( $p < 0.05$ ) after the M-meal in healthy subjects. In contrast, the GIH concentrations were significantly higher after the V-meal in T2D patients (glucagon-like peptide-1:  $p < 0.001$ ; GIP:  $p < 0.001$ ; PYY:  $p < 0.05$ ; PP:  $p < 0.05$ ). Compared with the V-meal, the M-meal was associated with a larger increase in lipoperoxidation in T2D patients (thiobarbituric acid reactive substances:  $p < 0.05$ ).

**Conclusion:** Our results suggest that the diet composition and the energy content, rather than the carbohydrate count, should be important considerations for dietary management and demonstrate that differences in isocaloric meals composition led to differences in postprandial gastrointestinal hormone response and oxidative stress.

## 772

### Dietary protein intake in low-carb diets and subsequent weight change and mortality in type 2 diabetes

M.J.E. Campmans-Kuijpers<sup>1</sup>, I. Sluijs<sup>1</sup>, U. Noethlings<sup>2</sup>, H. Freisling<sup>3</sup>, K. Overvad<sup>4</sup>, E. Weiderpass<sup>5</sup>, G. Fagherazzi<sup>6</sup>, P.H.M. Peeters<sup>1</sup>, J.W.J. Beulens<sup>1</sup>; <sup>1</sup>Julius Center, University Medical Center Utrecht, Netherlands, <sup>2</sup>Department of Food Sciences and Nutrition, University of Bonn, Germany, <sup>3</sup>International Agency for Research on Cancer (IARC-WHO), Lyon, France, <sup>4</sup>Department of Epidemiology School of Public Health, Aarhus University, Denmark, <sup>5</sup>Department of Community Medicine, Faculty of Health Sciences, University of Tromsø, Norway, <sup>6</sup>Institut Gustave-Roussy, Villejuif, France.

**Background and aims:** Dietary replacement of carbohydrates with protein for patients with type 2 diabetes is still debated. This study aimed to investigate the association between dietary carbohydrate intake and replacement with (animal and plant) protein, with 5-year weight change and all-cause and cardiovascular (CVD) mortality risk in patients with type 2 diabetes.

**Materials and methods:** The study included 6,192 patients with type 2 diabetes from 15 cohorts of the European Prospective Investigation into Cancer and Nutrition (EPIC). Usual dietary intake was assessed at baseline with country-specific food-frequency questionnaires. Different methods to adjust for energy intake were used.

**Results:** Annual weight-loss of participants was 0.17 (SD 1.24)kg. After a mean follow-up of 9.2 (SD 2.3)y, 791 (13%) participants had died, of which 268 (4%) due to CVD. Substitution of dietary carbohydrate intake with plant protein was associated with reduced risk of all-cause mortality (HR 0.71 [0.61–0.89]) and CVD mortality (HR 0.68 [0.53–0.89]). Substitution with total protein or animal protein was not associated with total or CVD mortality risk. Five-year weight change increased by substitution with total protein ( $\beta$  151 [39–262] g) and animal protein ( $\beta$  156 [39–271]g), but not by substitution with plant protein ( $\beta$  279 [-102–660]g). Five-year waist circumference change was not associated with any substitution of carbohydrates with protein. After adjustment for 5-year weight change, the association with CVD mortality was attenuated and became non-significant, but remained the same for all-cause mortality.

**Conclusion:** In diabetes patients, replacement of dietary carbohydrates with total protein and animal protein was associated with weight gain, but not with total and CVD mortality risk. Substitution of carbohydrates with plant protein may reduce the risk of total and CVD mortality.

## 773

### Does excessive consumption of high fructose corn syrup, aspartame or rebaudioside A affect insulin sensitivity and regulatory genes in liver and muscles?

P.B. Jeppesen<sup>1</sup>, M. Elseøe<sup>1</sup>, C. Laustsen<sup>2</sup>;

<sup>1</sup>Dept. of Clinical Medicine, Aarhus University Hospital, Aarhus Sygehus

THG, <sup>2</sup>Dept. of Clinical Medicine, The MR Research Centre, Aarhus University Hospital, Denmark.

**Background and aims:** Added sugar is believed to play a critical role in the epidemic of welfare diseases and in particular, fructose, has been shown to be directly diabetogenic. Furthermore, intake of the added sweetener high-fructose corn syrup (HFCS), consistently correlates with increased risk for developing lifestyle diseases. The little information regarding non-caloric sweeteners such as Rebaudioside A and Aspartame. The aim of this study is to investigate the effects of long-term high-fructose (HF) feeding on Development of insulin resistance (IR), steatosis and dyslipidaemia in rats; and to

examine the effects of intervention sweetener diets post the HF feeding e.g excessive daily intake of HFCS, Rebaudioside A and Aspartame.

**Materials and methods:** 48 healthy male Wistar rats were randomly assigned to four groups. One control group and three intervention groups received a diet of 60% fructose for 16 weeks. Post HF feeding the three groups instead received water sweetened with HFCS, Rebaudioside A or Aspartame for 8 weeks. Development and progression of IR, steatosis, dyslipidaemia and hypertension was monitored and tissues were analyzed after termination.

**Results:** The fructose diet led to a significant increase in insulin resistance, fasting levels of TG, total- and LDL-cholesterol. No differences in weight were observed. When compared with control group the daily intake of HFCS resulted in large increases in fasting blood TG levels ( $0.71 \pm 0.04$  vs  $1.53 \pm 0.14$  mM;  $p < 0.005$ ); Total cholesterol ( $1.45 \pm 0.05$  vs  $1.87 \pm 0.12$  mM;  $p < 0.05$ ); development of IR HOMA-IR: ( $55.55 \pm 10.69$  vs  $28.20 \pm 21.67$ ;  $p < 0.01$ ) and a 43 % increased storage of lipids in liver and muscle tissue (MR-scanning). Furthermore, HFCS markedly changes the gene expression profile of key regulatory genes as Srebp-1, FAS in the liver and FAS and GLUT 4 as well as PGC1A in muscle tissue. Rebaudioside A or Aspartame did not change any of the above shown data significantly when compared with control group.

**Conclusion:** HF feeding and excessive daily intake of HFCS had a negative physiological impact in this study. Switching to Rebaudioside A or aspartame reversed the hypercholesterolaemia induced fructose feeding and improved insulin sensitivity. Excessive HFCS-intake caused IR within 8 weeks and increased lipid storage in liver and muscle tissue.

### A low-dose whey protein preload slows gastric emptying and improves post-prandial glycaemia in type 2 diabetes

L.E. Mignone, T. Wu, M.J. Bound, K.L. Jones, M. Horowitz, C.K. Rayner; Discipline of Medicine, University of Adelaide, Australia.

**Background and aims:** We previously reported that a 55g whey protein 'preload', taken 30 minutes before a meal, reduced postprandial glycaemia in patients with type 2 diabetes, related in part to slowing of gastric emptying. A smaller preload that could be taken a lesser interval before the meal would be advantageous in terms of cost, reduction in additional energy intake, and compliance. We therefore evaluated the effects of a low-dose 20g whey protein preload, formulated with 5g guar, on post-prandial glycaemia and gastric emptying.

**Materials and methods:** Seven subjects with type 2 diabetes [4 males and 3 females; age  $64.6 \pm 0.4$  years; body mass index:  $29.3 \pm 2.0$  kg/m<sup>2</sup>; HbA1c  $6.8 \pm 0.4\%$  ( $50.4 \pm 3.9$  mmol/mol); duration of known diabetes  $4.8 \pm 0.8$  years], managed by diet or metformin only, were each studied on 2 occasions in randomised order. On each day, a 150 mL preload drink containing either 20 g whey plus 5 g guar, or similarly flavoured placebo, was consumed 15 minutes before a 13C-octanoic acid-labelled mashed potato meal. Gastric emptying (breath test) and blood glucose (glucometer) were evaluated. Data are means  $\pm$  SEM.

**Results:** The half-emptying time (T50) of the potato meal was greater ( $199.7 \pm 20.8$  vs.  $167.4 \pm 16.0$  min,  $P = 0.004$ ) after the whey protein preload than placebo. Fasting blood glucose did not differ between the two study days, and was not altered by either preload prior to the meal ( $t = -15$  to 0 min). After the meal ( $t = 0$  to 240 min), blood glucose concentrations were lower after whey protein than placebo ( $P < 0.001$  for treatment x time interaction, with significant differences at  $t = 30$  and 90 min after the meal,  $P < 0.05$  for each).

**Conclusion:** A low-dose whey protein preload can slow gastric emptying and improve postprandial glycaemic excursions in patients with type 2 diabetes who have relatively good glycaemic control. It may represent a promising nutritional strategy to optimise postprandial glycaemia in this group.

## 775

**Two weeks of adaptation to a high-protein hypercaloric high-fat-diet changes the postprandial carbohydrate and fat response after a mixed meal**A. Rietman<sup>1</sup>, J. Schwarzl<sup>1</sup>, E. Siebelink<sup>1</sup>, F.J. Kok<sup>1</sup>, D. Tomé<sup>2</sup>, M. Mensink<sup>1</sup>;<sup>1</sup>Human Nutrition, Wageningen University, Netherlands,<sup>2</sup>Nutrition Physiology and Ingestive Behavior, AgroParisTech, INRA, UMR914, Paris, France.

**Background and aims:** We and others previously showed changes in fasting lipid metabolism after adaptation to a high-protein diet. To further explore these changes we evaluated the effect of a two week short-term adaptation to a high protein diet on postprandial carbohydrate and lipid metabolism in healthy human subjects, by applying a meal challenge (MC).

**Materials and methods:** A randomized crossover trial with a parallel control group was performed. After a 2-week-run-in period, participants were assigned to either the control-diet for 4 weeks (CD-group; n=10; 27.8 En% fat; 16.9 En% protein; 55.3 En% carbohydrates), or a hypercaloric high-fat diet (HD-group; n=17; + 2 MJ per day), with in random order two periods of 2 weeks, with either a high protein (HP; 37.7 En% fat; 25.7 En% protein; 36.6 En% carbohydrates) or a normal protein content (NP; 39.4 En% fat; 15.4 En% protein; 45.2 En% carbohydrates). The MC (Liquid meal, 40 En% fat; 15 En% protein and 45 En% carbohydrate) was performed after 2 weeks and 4 weeks of intervention. Blood samples were drawn regularly during 6 hours postprandial for metabolite analyses.

**Results:** No significant differences were observed between NP and HP in fasting glucose ( $5.04 \pm 0.08$  vs.  $5.05 \pm 0.09$  mmol/L) and insulin ( $4.21 \pm 0.62$  vs.  $3.95 \pm 0.63$   $\mu$ U/L) levels. However, during the MC, subjects who were adapted to the HP diet showed a significantly higher iAUC of glucose as compared to subjects adapted to the NP diet (NP:  $377.4 \pm 14.1$  vs. HP:  $408.2 \pm 13.2$  mmol/L\*60min;  $p=0.03$ ), without clear differences in insulin iAUC (NP:  $2583.9 \pm 383.7$  vs. HP:  $2984.8 \pm 496.9$  mU/L\*60 min;  $p=0.38$ ). Fasting triglyceride (TG) concentration tended to be lower on the HP compared to the NP condition (NP:  $0.77 \pm 0.05$  vs. HP:  $0.65 \pm 0.03$  mmol/L;  $p=0.07$ ). Also during the MC subjects adapted to the HP diet showed a lower iAUC of TG as compared to subjects adapted to the NP diet (NP  $67.1 \pm 5.6$  vs. HP  $57.9 \pm 4.4$  mmol/L\*60min;  $p=0.11$ ).

**Conclusion:** Adaptation to a high protein hypercaloric high-fat diet resulted in a decreased clearance of carbohydrates after the MC as indicated by the increased glucose iAUC, without changes in plasma insulin response compared to adaptation to a normal protein hypercaloric high-fat diet. Additionally, adaptation to the HP diet was associated with an improved lipid metabolism, as indicated by a lower level of circulating TG in fasted state as well as during the MC. Additional metabolomics data are anticipated to be present at the time of the meeting.

## 776

**Differential islet, incretin and glucose prandial responses after high caloric breakfast vs isocaloric dinner in type 2 diabetic patients**D. Jakubowicz<sup>1</sup>, O. Froy<sup>2</sup>, Y. Bar-Dayana<sup>1</sup>, H. Rabinovitz<sup>2</sup>, Z. Landau<sup>1</sup>, J. Wainstein<sup>1</sup>;<sup>1</sup>Diabetes Unit, E.Wolfson Medical Center, Holon,<sup>2</sup>Institute of Biochemistry, Food Science and Nutrition, Rehovot, Israel.

**Background and aims:** It was shown in type 2 diabetic (T2D) individuals that a high-calorie (HC) that a diet with high-calorie (HC) breakfast (B) with reduced dinner (D), resulted in a significant decrease in HbA1c, and was more beneficial than isocaloric diet with HCD and reduced B in improving glucose, lipids and hunger scores. Whether it is related to a potential diurnal pattern of incretin secretion and  $\beta$ -cell responsiveness to incretins after Iso HCB vs HCD has however, not been studied in T2D. We assessed in T2D postprandial early AUC30, late AUC 60-180 and AUC180 min response for plasma insulin, glucose, intact (i) and total (t) glucagon-like peptide-1 (GLP-1) and hunger scores after HCB vs isocaloric HCD

**Materials and methods:** In a randomized crossover design 18-T2D (8 males), aged 57  $\pm$  83 yrs; BMI:  $28.11 \pm 2.92$  kg/m<sup>2</sup>; HbA1c:  $7.55 \pm 0.42\%$ , undergone HCB meal test on day with HCB diet: B: 700 kCal; % of CH: protein: fat: 50:30:20%; lunch (L) (500 kCal, 20:45:25%) and D (200 kCal, 13:40:47%). Another day HCD meal test was done on HCD diet: B : (200 kCal, 13:40:47%), L: (500 kCal, 20:45: 25%) and D (700 kCal, 50:30:20%).

**Results:** Glucose peak was lower after HCB:  $230 \pm 24$  vs. HCD:  $285 \pm 25$  mg/dl, ( $p<0.001$ ). Similarly, AUC180 for glucose was reduced after HCB:  $31255 \pm 1375$  vs HCD:  $40899 \pm 3007$  mg/dl\*min, ( $p<0.001$ ). AUC 60-180 for late insulin secretion was not different ( $p<0.11$ ), in contrast AUC30 for early insulin response was significantly greater (almost 2-fold) after HCB:  $526 \pm 109$  vs. HCD:  $247 \pm 47$  mIU/ml\*min, ( $p<0.001$ ). Postprandial AUC180 response after HCB vs after HCD was higher by  $29 \pm 9.7\%$  for tGLP-1 ( $p<0.001$ ) and by  $20.7 \pm 7\%$  for iGLP-1 ( $p<0.001$ ) and reduced by  $44.2 \pm 11\%$  for hunger scores ( $p<0.001$ ). AUC30 for tGLP-1 and iGLP-1 were strongly and positively associated with AUC30 early insulin response ( $r=0.32$ ,  $p<0.0001$ ); whereas negatively associated with the postprandial AUC180 for plasma glucose ( $r=0.18$ ,  $p<0.0001$ ).

**Conclusion:** HCB induced more rapid early (30-min) insulin response associated with greater total and intact GLP-1, lower glucose excursion and greater hunger suppression. It suggests that high caloric intake in the breakfast with reduced intake at dinner might be a beneficial alternative for the management of type 2 diabetes.

Clinical Trial Registration Number: NCT01977833

## 777

**The effects of a high egg diet in people with type 2 diabetes mellitus: a three-month randomised controlled trial**N.R. Fuller<sup>1</sup>, I.D. Caterson<sup>1</sup>, G. Denyer<sup>2,1</sup>, A. Sainsbury<sup>1</sup>, T.P. Markovic<sup>1</sup>;<sup>1</sup>Sydney Medical School,<sup>2</sup>Faculty of Sciences, The University of Sydney, Australia.

**Background and aims:** The effects of high egg consumption in people with Type 2 Diabetes Mellitus (T2DM) are controversial, due to many confounding factors in previously published research. This randomised, controlled study aimed to determine whether a high egg diet (two eggs per day on six days per week) leads to improved lipid profiles (increased high density lipoprotein cholesterol; HDL-C) in people with pre-diabetes or T2DM, compared to a low egg diet (less than two eggs per week).

**Materials and methods:** 140 subjects with pre-diabetes or T2DM were randomised to either a low or high egg diet as part of a weight maintenance study. Subjects attended the clinic monthly and were given a written guide as to the specific types of foods and quantities that could be consumed, with particular emphasis on improving management of T2DM, and replacing foods containing saturated fats with foods containing monounsaturated fats and polyunsaturated fats. Outcome measures were collected at screening and three months.

**Results:** There was no significant difference in the change in HDL-C from screening to three months between the two groups; mean difference (95% confidence interval (CI)) for the high egg versus low egg group:  $+0.02$  mmol/L ( $-0.03$ ,  $0.08$ );  $P=0.38$ . There was a within group trend towards an improvement in HDL-C in the high egg group:  $+0.034$  mmol/L (95% CI:  $-0.003$ ,  $0.071$ );  $P=0.07$ . No between group differences were found at three months for total cholesterol, low density lipoprotein cholesterol, triglycerides, or glycaemic control. Both groups were matched for protein intake, yet the high egg group reported less hunger and greater satiety post meal. Both diets were well accepted, with the high egg group reporting a significantly greater enjoyment of foods, less boredom, and more satisfaction with the diet.

**Conclusion:** Eggs do not have an adverse effect on lipid levels in those with T2DM and hence at high risk of cardiovascular outcomes. Moreover, it is associated with better appetite control. These findings suggest that a high egg diet can be included as part of the dietary management of T2DM.

**Assessment of caffeine dose and time of administration required for resetting of insulin sensitivity in high-sucrose rats**J.F. Sacramento<sup>1</sup>, J.C. Coelho<sup>1</sup>, B.F. Melo<sup>1</sup>, M.P. Guarino<sup>1,2</sup>, S.V. Conde<sup>1</sup>;<sup>1</sup>CEDOC, Faculdade Ciências Médicas, Universidade Nova de Lisboa,<sup>2</sup>UIS- Unidade de Investigação em Saúde- Escola Superior de Saúde de Leiria- Instituto Politécnico de Leiria, Portugal.

**Background and aims:** Several epidemiological studies have described beneficial effects of chronic coffee intake on type 2 diabetes and metabolic syndrome. Our group has previously shown that chronic caffeine intake (1g/L over 15 days) prevents the development of insulin resistance (IR) and hypertension in diet-induced IR rats. The aim of this work was to investigate the

therapeutic dose of caffeine that restores insulin sensitivity and normalizes blood pressure in diet-induced IR rats. The time required for the reversion of IR was also evaluated.

**Materials and methods:** All experiments were performed in 8–13 weeks Wistar rats of both genders (250–450g). Two groups of rats were used: a high-sucrose diet-group (HSu) and a control group. The HSu insulin-resistant model was obtained by submitting the animals to a 35% sucrose diet during 28 days. A dose-response curve for chronic caffeine intake (0.25–1g/L) on insulin sensitivity was performed both in HSu and control groups. Caffeine was administered in drinking water after the first 28 days of control or HSu diet and maintained during 13 weeks. The insulin sensitivity was evaluated by an insulin tolerance test in conscious animals. Plasma glucose and insulin were monitored each 2 weeks. At the end of the experimental period, rats were anaesthetized with pentobarbitone (60mg/Kg) and blood pressure was measured in the femoral artery. Blood was collected by heart puncture and skeletal muscle collected for Glut4, Insulin receptor and AMPK $\alpha$ 1 quantification by Western-blot.

**Results:** Administration of HSu diet during 28 days decreased insulin sensitivity to  $2.81 \pm 0.29$  %glucose/min (KITT control =  $4.70 \pm 0.28$  %glucose/min). Chronic administration of 0.5 and 1g/L of caffeine did not modify insulin sensitivity. In the HSu group, 3 weeks after chronic administration of 1g/L of caffeine, insulin sensitivity was restored (KITT =  $4.70 \pm 0.299$  %glucose/min). The insulin sensitivity in this group was maintained during the following weeks. In the HSu rats submitted to chronic administration of 0.5g/L caffeine insulin sensitivity start to increase (30%) after 5 weeks of administration and it was completely restored after 9 weeks (KITT =  $4.75 \pm 0.669$  %glucose/min).

**Conclusion:** Chronic caffeine administration in all concentrations tested restores insulin sensitivity. The period of time to restore insulin sensitivity is positively related with caffeine concentration.

**Background and aims:** The beneficial effects of fish and n-3 polyunsaturated fatty acids (PUFA) consumption on atherosclerosis have been reported in numerous epidemiological studies. However, to the best of our knowledge, the effects of a fish-based diet intervention on endothelial function have not been investigated. Therefore, we studied these effects in postmenopausal women with type 2 diabetes mellitus (T2DM).

**Materials and methods:** Twenty-three postmenopausal women with T2DM were assigned to two four-week periods of either a fish-based diet (n-3 PUFA  $\approx$  3.0 g/day) or a control diet in a randomized crossover design. Endothelial function was measured with reactive hyperemia using strain-gauge plethysmography and compared with the serum levels of fatty acids and their metabolites. Endothelial function was determined with peak forearm blood flow (Peak), duration of reactive hyperemia (Duration) and flow debt repayment (FDR). Serum lipid compositions and eicosanoids were measured with tandem mass spectrometry (LCMS).

**Results:** A fish-based dietary intervention improved Peak by 63.7%, Duration by 27.9% and FDR by 70.7%, compared to the control diet. Serum n-3 PUFA levels increased after the fish-based diet period and decreased after the control diet period, compared with the baseline period (1.49 vs. 0.97 vs. 1.19 mmol/l,  $p < 0.0001$ ). There was no correlation between serum n-3 PUFA levels and endothelial function. Eicosanoids were measured with LCMS and 7 / 86 metabolites were significantly changed after a fish-based diet intervention. Interestingly, the ratio of epoxyeicosatrienoic acid (EET, known as the vasodilator) / dihydroxyeicosatrienoic acid (the inactive metabolites of EET) was increased after a fish-based diet intervention.

**Conclusion:** A fish-based dietary intervention improves endothelial function in postmenopausal women with T2DM. The improvement of endothelial function was not associated with serum n-3 PUFA concentration. These data suggests that the vasoactive metabolites such as EET, may contribute to this phenomenon.

### 780

#### Incretin hormones are released in healthy subjects by both diet oil and olive oil while short chain fatty acids have no effect on secretion

M.J. Mandoe<sup>1,2</sup>, K.B. Hansen<sup>3</sup>, B. Hartmann<sup>2</sup>, J.J. Holst<sup>2</sup>, H.S. Hansen<sup>4</sup>;

<sup>1</sup>Department of Clinical Physiology and Nuclear Medicine, Glostrup

Hospital, <sup>2</sup>NNF Center for Basic Metabolic Research, Department of

Biomedical Sciences, University of Copenhagen, <sup>3</sup>Department of

Endocrinology, Rigshospitalet, <sup>4</sup>Department of Drug Design and

Pharmacology, University of Copenhagen, Copenhagen, Denmark.

**Background and aims:** Diet oil (1,3-di-buteryl-2-oleoyl-glycerol) consists of two short chain fatty acids and 2-oleoyl-glycerol (2-OG), the latter being a naturally occurring ligand for the G protein-coupled receptor GPR119. Intestinal 2-OG causes release of the incretin hormone, glucagon-like peptide-1 (GLP-1), in healthy subjects and diet oil does the same in patients with type 2 diabetes. This study evaluated tributyrin, which in mouse studies may increase GLP-1 release, and a new form of diet oil with medium chain fatty acids (1,3-di-octanoyl-2-oleoylglycerol or "C8-diet oil") on GLP-1 and glucose-dependent insulinotropic polypeptide (GIP) secretion. Octanoic acid may not significantly activate known fatty acid receptors.

**Materials and methods:** C8-diet oil, tributyrin, olive oil and carrot were administered orally to 12 Caucasian healthy male subjects (age:  $24 \pm 0.6$  years (mean  $\pm$  SEM), body mass index:  $22. \pm 0.6$  kg/m<sup>2</sup>; HbA1c:  $30.45 \pm 0.67$  mmol/mol) in a randomised, single-blinded cross-over study. The subjects were given four meals on four different days: 200 g grated carrot + 6.53 g tributyrin; 200 g grated carrot + 13.15 g diet oil; 200 g grated carrot + 19 g olive oil or 200 g grated carrot. All lipids amounted to 0.0216 mol, and theoretically, the C8-diet oil and olive oil regimens both result in formation of 0.0216 mol 2-OG during digestion. Primary outcomes were total GLP-1 and GIP in plasma.

**Results:** C8-diet oil and olive oil resulted in ( $p \leq 0.01$ ) greater postprandial GLP-1 and GIP responses [GLP-1: incremental area under curve 583 and 538 pmol/l $\times$ 120 min,  $p=0.733$ ; GIP: 1674 and 3293 pmol/l $\times$ 120 min,  $p=0.002$ ] compared to both tributyrin (GLP-1: 94 pmol/l $\times$ 120 min and GIP: 403 pmol/l $\times$ 120 min) and the carrot meal (GLP-1: 126 pmol/l $\times$ 120 min and GIP: 423 pmol/l $\times$ 120 min)

**Conclusion:** C8-diet-oil and olive oil enhanced secretion of GLP-1 and GIP significantly compared to tributyrin and carbohydrate. Tributyrin had no effect. Olive oil liberates not only 2-OG but in addition 2 oleic acid molecules, which may also stimulate incretin secretion. However, the previous reported effect of diet oil and the present effect of C8-diet oil giving the same full GLP-1 response as olive oil, suggests that it is mediated by 2-OG and not by fatty acids.

#### Glucose spikes of eating vegetables before carbohydrates with snacks at mid-afternoon are lower than that of eating carbohydrates before vegetables without snacks

S. Imai<sup>1</sup>, M. Fukui<sup>2</sup>, N. Ozasa<sup>3</sup>, S. Kajiyama<sup>4,5</sup>;

<sup>1</sup>Graduate School of Comprehensive Rehabilitation, Osaka Prefecture

University, <sup>2</sup>Graduate School of Medical Science, Kyoto Prefectural

University of Medicine, <sup>3</sup>Graduate School of Medicine, Kyoto University,

<sup>4</sup>Kajiyama Clinic, Kyoto, <sup>5</sup>Kyoto Prefectural University of Medicine, Japan.

**Background and aims:** Postprandial plasma glucose and glucose spikes are associated with cardiovascular diseases in patients with diabetes. An appropriate diet is needed to reduce postprandial hyperglycemia and minimize hypoglycemic events in addition to improving mean blood glucose. However, a compliance of diet in patients with diabetes is low, partly as a result of eating snacks. We evaluated whether eating order without snacks and with snacks at different time of the day could change the postprandial glucose values assessed by continuous glucose monitoring system (CGMS) in Japanese patients with type 2 diabetes mellitus (T2DM).

**Materials and methods:** This was a randomized, controlled, four-treatment, crossover study. Thirteen patients with T2DM ( $69.1 \pm 6.7$  yrs, HbA1c  $7.5 \pm 1.2\%$ : mean  $\pm$  SD) were assigned to use CGMS (Medtronic Minimed Gold) for 8 days (4-day each) either (1) eating vegetables first or (2) carbohydrates first and (3) eating vegetables first with additional snacks (biscuits 18 g, 75

kcal, carbohydrate 13.5 g, protein 1.2g, fat 1.8 g) at 12:30 and (4) 15:30. The test meals consist of rice/bread, meat/fish, 500 g of vegetables, and contain 21 g of dietary fiber: the energy ratio was 60, 16, and 24% from carbohydrates, protein, and fat, respectively. First, at 12:00 of the 1st day, each participant wore a CGMS at the clinic, and consumed the test meals at 7:00, 12:00, and 19:00 at home on the 2nd and the 3rd day, and at noon of the 4th day a CGMS was removed at the clinic. The patients consumed the first dish of vegetables for 5 min, then the main dishes for 5 min, and rice or bread for 5 min of the test meals or eating vice versa. Next, the patients ate vegetables before carbohydrates of the test meals at the same time and consumed snacks at 12:30 and 15:30 on the 2nd and the 3rd day. The daily glucose parameters were compared between four treatments.

**Results:** Mean blood glucose increased 0.67 mmol/L by adding snacks. Eating vegetables before carbohydrates with snacks at 15:30 resulted in lower incremental glucose peak (IGP) and incremental area under the glucose curve (IAUC) 0–3h of lunch and dinner compared with eating carbohydrates before vegetables without snacks (Figure).

**Conclusion:** Glucose spikes of eating vegetables before carbohydrates with snacks at mid-afternoon were significantly lower than that of eating carbohydrates before vegetables without snacks in patients with T2DM.

**Figure 783** IGP and glucose IAUC of lunch and dinner were reduced when the patients with T2DM consumed vegetables before carbohydrates with snacks at mid-afternoon compare to consuming carbohydrates before vegetables without snacks. Data are mean  $\pm$  SD. \*\*\* $p < 0.001$ , \*\* $p < 0.01$ .

### Dietary carbohydrates predict maternal hyperinsulinaemia and cord blood visfatin levels in pregnancy compared to total daily caloric intake, fat and proteins

G. Valsamakis<sup>1</sup>, D. Papatheodorou<sup>1</sup>, Z. Papadimitriou<sup>1</sup>, G. Landis<sup>2</sup>,

E. Kapantais<sup>3</sup>, A. Thomopoulos<sup>1</sup>, G. Mastorakos<sup>3</sup>;

<sup>1</sup>Endocrine Unit, Aretaieion University Hospital,

<sup>2</sup>Endocrine Unit, Evgenideion University Hospital,

<sup>3</sup>Diabetes Obesity Metabolism, Metropolitan Hospital, Athens, Greece.

**Background and aims:** Maternal diet affects insulin resistance and fetal growth-metabolism during pregnancy. Hyperinsulinemia is a marker of insulin resistance. There is still ongoing debate regarding the effect of maternal diet composition and caloric intake into maternal hyperinsulinemia and fetal metabolism. The effect of maternal dietary nutrients (carbohydrates, proteins, fat) and total daily caloric intake into maternal hyperinsulinemia, fetal metabolism and birthweight was assessed during normal pregnancy

**Materials and methods:** A prospective, non interventional study, 50 pregnant non diabetic women (mean  $\pm$  SD) pre-pregnancy BMI 24.2  $\pm$  4 kg/m<sup>2</sup> and age 29.3  $\pm$  4.3 years were randomly assessed with validated quantitative food frequency questionnaire and a 7 day dietary diary for nutrient and total daily caloric intake (kcal) during the second trimester (24th–26th week). A 75gr oral glucose tolerance test was performed and maternal glucose and insulin levels measured at 0,5,15,30,60,90,120 min. 3 cases diagnosed with gestational diabetes were removed from the study. The delta area under the curve ( $\Delta$ AUCInsulin) for maternal hyperinsulinemia was calculated by trapezoidal rule. During delivery cord blood levels for visfatin, adiponectin, leptin, glucose and insulin were measured. Birth weight was measured.

**Results:** Dietary analysis revealed a diet composition of 20% protein, 40% carbohydrates and 40% fat. Mean birthweight was 3132  $\pm$  125 gr. Mean weight gain was 16  $\pm$  3 kg. There was no association between mean maternal total caloric intake and dietary nutrients with birth weight or maternal weight. Carbohydrates and caloric intake were negatively and positively associated

with cord blood visfatin ( $r = -0.91$ ,  $p = 0.002$ ) ( $r = 0.72$ ,  $p = 0.037$ ) respectively. Backwards multiple regression analysis showed carbohydrates ( $p = 0.015$ ,  $\beta = -1.28$ ) being the best predictors of maternal  $\Delta$ AUCInsulin of the second trimester and cord blood visfatin levels ( $p = 0.009$ ) compared to dietary fat, proteins and mean total daily caloric intake.

**Conclusion:** Maternal carbohydrate intake is the best predictor of hyperinsulinemia among protein, fat and total caloric daily intake. Furthermore carbohydrate intake seems to affect the insulinomimetic secretion of adipocytokine visfatin of the fetus. Further studies need to assess the effect of maternal diet composition into fetal metabolism and growth.

## 783

### Vitamin D supplementation might increase the benefits of weight loss on insulin sensitivity in obese individuals with hypovitaminosis D

C. Conte, C.M.A. Cefalo, C. Policola, V.A. Sun, S. Moffa, G.P. Sorice,

T. Mezza, A. Giaccari;

Catholic University of the Sacred Heart, Rome, Italy.

**Background and aims:** Hypovitaminosis D is highly prevalent in the general population, and particularly among obese individuals. It has been suggested that, besides being associated with obesity, vitamin D insufficiency might have an independent role in the pathogenesis of insulin resistance. Healthy dietary habits and weight loss are the mainstay for the prevention of type 2 diabetes mellitus in overweight/obese individuals. Vitamin D supplementation might increase the benefits of these lifestyle interventions. Here we present the preliminary results of a currently ongoing double blind, placebo controlled randomised study. The aim of the study is to assess whether vitamin D supplementation in conjunction with a weight-loss dietary regimen has a greater impact on insulin sensitivity as compared to weight loss alone in obese subjects with hypovitaminosis D.

**Materials and methods:** 12 obese volunteers (8/4 F/M; mean age  $\pm$  SD: 40.4  $\pm$  12.4 yrs; BMI: 38.3  $\pm$  6.3 kg/m<sup>2</sup>) with hypovitaminosis D [serum 25(OH)D: 14.8  $\pm$  7.8 ng/ml] were enrolled in this study after providing signed informed consent. Subjects were randomised (1:1) to hypocaloric diet + either oral cholecalciferol 25,000 I.U./week (VIT) or placebo (PLA) for 3 months. Anthropometric assessments, a standard 2-hr OGTT and a hyperinsulinaemic euglycaemic clamp (HEC) for the measurement of insulin sensitivity (M value) were performed at baseline and at study end.

**Results:** Baseline anthropometric characteristics, insulin sensitivity and 25(OH)D levels were comparable in the two groups. After 3 months of hypocaloric diet + cholecalciferol or placebo, body weight was significantly reduced in both groups (-6.3% and -9.3% for VIT and PLA, respectively;  $p < 0.05$  for both;  $p$  for interaction = 0.195). 25(OH)D levels increased only in the VIT group (13.5  $\pm$  6.2 vs. 29.1  $\pm$  6.2 ng/ml;  $p = 0.007$ ), and did not change in the PLA group (16.2  $\pm$  9.5 vs. 16.1  $\pm$  5.3 ng/ml;  $p = ns$ ;  $p$  for interaction = 0.019). No significant differences from baseline were observed in glucose and insulin areas under the curve during the OGTT in either group. Insulin sensitivity, as assessed with the HEC, significantly improved only in the VIT group (M pre vs. post: 5.2  $\pm$  2.4 vs. 7.3  $\pm$  3.2 mg  $\cdot$  kg<sup>-1</sup>  $\cdot$  min<sup>-1</sup>,  $p = 0.046$  and 4.4  $\pm$  2.6 vs. 4.7  $\pm$  2.2 mg  $\cdot$  kg<sup>-1</sup>  $\cdot$  min<sup>-1</sup>,  $p = 0.84$  for the VIT and PLA groups, respectively). However, the increase in insulin sensitivity in the VIT group did not reach statistical significance vs. the PLA group ( $p$  for interaction = 0.161), possibly due to the relatively small number of subjects.

**Conclusion:** Vitamin D supplementation might potentiate the effects of weight loss on insulin sensitivity. Increasing the sample size could allow us to confirm these preliminary findings.

## 784

### Secondary metabolites from vintage vegetables improve the health status of patients with type 2 diabetes when compared to equivalent modern vegetables

A.C.S. Thorup<sup>1</sup>, H.L. Kristensen<sup>2</sup>, P.B. Jeppesen<sup>1</sup>;

<sup>1</sup>Department of Endocrinology and Internal Medicine,

Aarhus University Hospital,

<sup>2</sup>Department of Food Science, Aarhus University, Aarslev, Denmark.

**Background and aims:** Vegetables are an important part of the human diet and a major source of biologically active substances called secondary metabolites. These secondary metabolites contribute to the nutritional quality of food giving it a bitter and strong taste, but more importantly are their po-

tential health promoting effects. Aim: To determine if a high dietary intake of bitter and strong tasting vegetables have a beneficial impact on insulin resistance related to type 2 diabetes (T2D) when compared to equivalent intake of modern mild and sweet tasting vegetables.

**Materials and methods:** The study was a 3-month randomized controlled parallel intervention study involving 77 participants aged 35–70 years with T2D. The participants were randomized into 3 different diets; 1) consuming daily 500 g of bitter and strong tasting (BST) vegetables 2) 500 g daily of sweet and mild tasting (SMT) vegetables and 3) normal diet (control). Both vegetable diets (group 1 and 2) consisted of root vegetables and cabbages, but the seeds for the vegetables in the BST group originate from the Nordic gene bank collection. Additionally the vegetables were ensured a bitter and strong taste through modulation of the agronomic and postharvest storage practice. **Results:** Both diets high in vegetables did significantly reduce the participants BMI ( $p < 0.0001$ ), fasting plasma glucose ( $p < 0.05$ ), HbA1c ( $p < 0.001$ ), body fat composition ( $p < 0.01$ ), fasting insulin concentration ( $p < 0.05$ ) and HOMA-IR ( $p < 0.05$ ). Furthermore, in the BST group significant difference was also found regarding average blood pressure from 24-h measurements ( $p < 0.05$ ), iAUC from OGTT (insulin ( $p < 0.05$ ) and glucose ( $p < 0.01$ )) and plasma lipids ( $p < 0.05$ ).

**Conclusion:** The study shows that the vegetable diet with a high level of secondary metabolites hence the bitter and strong taste, have higher health promoting effects when compared to an equivalent diet with modern mild and sweet tasting vegetables. The results can be used to develop new recommendations to a healthier lifestyle and to prevent any further progression of these lifestyle diseases.

### Evaluation of the daily nutrient intake and accuracy of meal carbohydrate content estimation by type 1 diabetic patients under CSII and MDI

C. Schmid<sup>1</sup>, C. Krauß<sup>1</sup>, C. Kröner<sup>1</sup>, P. Buchwald<sup>2</sup>, C. Haug<sup>1</sup>, G. Freckmann<sup>1</sup>;

<sup>1</sup>Institut für Diabetes-Technologie Forschungs- und Entwicklungsgesellschaft GmbH an der Universität Ulm,

<sup>2</sup>Endokrinologikum Ulm, Germany.

**Background and aims:** Nutrition therapy is a key component in the treatment of people with diabetes. Carbohydrate counting is a prerequisite for making appropriate insulin therapy decisions even with the increasing use of automated bolus calculators. The goal of this study was to determine the total daily nutrient intake of carbohydrates (CHO), proteins (P) and fats (F) in conditions similar to real life. In addition, we evaluated the accuracy of meal carbohydrate estimation.

**Materials and methods:** Fifty type-1-diabetic patients, (26f, 24m, mean age 46 years, range: 20 to 68 years, HbA1c  $7.5\% \pm 1.1\%$ , duration of diabetes  $23 \pm 12$  years, BMI  $26.7 \pm 4.1$  kg/m<sup>2</sup>, insulin therapy: CSII 35, MDI 15) participated as inpatients in the study, which lasted for 8 days. They managed their own therapy and selected their meals freely from an ample buffet of typical food choices. The entire food intake was documented during the study and full 24h intake was available for four days. The weight of the food was determined by scale, and the intake of CHO, P, and F was calculated as percentage of total calories from the nutrition labelling of the package or a nutritional software (DGE-PC vers. 2.9.1.007). Individual accuracy of CHO estimation was evaluated for a subgroup of 39 patients. They were asked to estimate the CHO content of each meal in their preferred carbohydrate estimation unit. Ratios between estimated and actual CHO content were calculated.

**Results:** The mean meal composition for breakfast was: 43% CHO - 16% P - 41% F as percentage of total calories (570 kcal), for lunch: 37% CHO - 20% P - 43% F (760 kcal), for dinner: 36% CHO - 21% P - 43% F (697 kcal) and for the whole day: 39% CHO ranging from 24% to 49% (45–60% recommended), 17% P ranging from 12% to 23% (10–20% recommended), 45% F ranging from 36% to 63% (25–35% recommended) (2208 kcal). When compared as percentage of the calculated CHO content, the mean estimates of the subgroup of 39 patients were in total  $92.9\% \pm 13.0\%$  (median 92.4%, min. 60.3%, max. 128.8%), for breakfast  $99.9\% \pm 16.9\%$ , for lunch:  $93.8\% \pm 16.1\%$  and for dinner:  $87.2\% \pm 12.9\%$ .

**Conclusion:** Nutrient intake was different from current nutritional recommendations of the EASD. Especially daily carbohydrate intake was lower and fat intake was higher than recommended. In previous studies we found a similar macronutrient distribution reflecting current eating patterns and personal preferences. Currently, the establishment of more individualized

recommendations is discussed. In contrast to results of other studies, the type-1-diabetic patients in this study estimated the amount of carbohydrates in self-chosen meals accurately in conditions similar to real life. Most of these patients are very motivated and participate frequently in similar studies indicating that regular training is helpful to keep nutritional education at a high level.

## 786

### The increment of postprandial energy expenditure is associated with body weight reduction by dietary intervention in type 2 diabetes

D. Sanoyama, M. Nagao, Y. Nakajima, H. Sugihara, S. Oikawa;

Department of Endocrinology, Diabetes and Metabolism,

Graduate School of Medicine, Nippon Medical School, Tokyo, Japan.

**Background and aims:** Body weight change is determined by the balance between food intake and energy expenditure. Total energy expenditure is composed of basal metabolic rate (BMR), activity induced energy expenditure (AEE), and diet-induced thermogenesis (DIT). Although dietary energy restriction is an essential approach for diabetes management, the degree of body weight reduction varies between individuals. To clarify the determinants for the efficacy of dietary intervention in type 2 diabetes, we measured energy expenditure (EE) by indirect calorimeter during short-term hospitalization, and analyzed relationships between the EE and other metabolic parameters.

**Materials and methods:** A total of 63 subjects (21 females and 42 males) with type 2 diabetes admitted to our hospital for glycemic control were enrolled in this study. During the hospitalization ( $15.2 \pm 2.4$  days), the subjects received calorie-restricted diets (daily total energy intake was determined based on the recommendation of the Japan Diabetes Society;  $[\text{height (m)}]^2 \times 22 \times 27.5$  kcal/day) with restricted exercise. Clinical measurements were carried out after an overnight fast on the 2nd day of admission. Body weight was checked again on discharge. EE was evaluated at fasting (0900 h, FEE) and postprandial state (1500 h, PPEE) using an indirect calorimeter during the hospitalization, and the increment of PPEE over FEE ( $\Delta$ EE) was calculated. We analyzed correlations between the EE indices (FEE and  $\Delta$ EE) and the clinical measurements. All data are expressed as means  $\pm$  SD. Mean values were compared using Student's t test. Correlations between the EE indices and other continuous variables were examined by Pearson's correlation analysis.

**Results:** Body weight was reduced from  $67.2 \pm 15.8$  to  $65.0 \pm 15.3$  kg ( $p < 0.001$ ) during the hospitalization. PPEE was significantly higher than FEE ( $0.989 \pm 0.208$  and  $1.083 \pm 0.208$  kcal/min for FEE and PPEE, respectively;  $p < 0.001$ ).  $\Delta$ EE was  $0.094 \pm 0.142$  kcal/min. FEE was significantly higher in male ( $P < 0.001$ ) and positively correlated with height ( $r = 0.69$ ,  $p < 0.001$ ), initial body weight ( $r = 0.75$ ,  $p < 0.001$ ), body mass index ( $r = 0.53$ ,  $p < 0.001$ ), abdominal circumference ( $r = 0.52$ ,  $p < 0.001$ ), fasting serum C-peptide ( $r = 0.26$ ,  $p = 0.037$ ) and urinary C-peptide ( $r = 0.41$ ,  $p = 0.001$ ), whereas inversely correlated with age ( $r = -0.41$ ,  $p < 0.001$ ).  $\Delta$ EE showed a positive correlation with daily body weight reduction ( $r = 0.37$ ,  $p = 0.003$ ) and an inverse correlation with age ( $r = -0.25$ ,  $p = 0.047$ ). Multiple regression analysis with adjustment for covariates (age, gender, initial body weight, and HbA1c) revealed that  $\Delta$ EE is a potential independent predictor for daily body weight reduction ( $\beta = 0.449$ ,  $p = 0.038$ ).

**Conclusion:** The positive correlations of FEE with anthropometric and insulin secretion parameters suggest that FEE is related to insulin resistance. On the other hand,  $\Delta$ EE showed a positive correlation with body weight reduction during the short-term dietary energy restriction. Under the sedentary lifestyle like hospitalization, since FEE is nearly equivalent to BMR,  $\Delta$ EE is supposed to reflect predominantly DIT. Taken together, these results indicate that  $\Delta$ EE, as a surrogate marker of DIT, may determine the efficacy of dietary intervention in type 2 diabetes.

## 787

**Relationships of serum 25-OH vitamin D and parathyroid hormone levels with all-cause mortality in type 2 diabetes**

E.H. Nystrom<sup>1</sup>, P. Jennersjö<sup>1</sup>, H. Guldbrand<sup>1</sup>, S. Björne<sup>1</sup>, T. Länne<sup>1</sup>, M. Fredriksson<sup>2</sup>, C. Östgren<sup>1</sup>;

<sup>1</sup>Department of Medical and Health Sciences, Faculty of Health Sciences,

<sup>2</sup>Department of Clinical and Experimental Medicine, Faculty of Health Sciences, Linköping, Sweden.

**Background and aims:** New and clinically useful markers of risk are of essence in high risk states such as Type 2 diabetes.

**Materials and methods:** We analyzed baseline data from 741 patients (489 men and 252 women) who participated in “Cardiovascular Risk factors in Patients with Diabetes - a Prospective study in Primary care” (CARDIPP). Participants of this prospective observational study were between 55–66 years old when recruited between the years 2005–2008 and they all had Type 2 diabetes. 25-OH-vitamin D and parathyroid hormone levels (PTH) were analyzed using electrochemo-luminescence on a Cobas® e602 unit (Roche Diagnostics Scandinavia AB, Bromma, Sweden). Carotid-femoral pulse wave velocity (PWV) was measured with applanation tonometry (SphygmoCor® system, AtCor Medical, Sydney, Australia) and intima-media thickness of the carotid arteries (IMT) was evaluated using B-mode ultrasound (ATL HDI 5000, Bothell, WA, USA). The participants were followed for all-cause mortality until December 31, 2012, using the Swedish Cause of Death Registry.

**Results:** There was a negative linear relationship between vitamin D levels with waist circumference ( $r = -0.147$ ,  $p < 0.0001$ ) in the total cohort. During the follow up period 24 men and 9 women died. When entering major risk factors in Cox regression vitamin D levels were negatively related to all-cause mortality in men, independently of age, PTH, HbA<sub>1c</sub>, waist circumference, mean 24-hour systolic ambulatory blood pressure (ABP) and apolipoprotein B levels ( $p = 0.049$ ). This finding of increased mortality related to low levels of vitamin D in men was also statistically significant when PWV and IMT were added to the equations in men ( $p = 0.028$  Hazard ratio of 0.97, CI from 0.95 to 0.997 for each nmol/l of vitamin D). The figure below shows mortality in men of the lower and higher tertiles of vitamin D levels, respectively. In women, on the other hand, levels of PTH ( $p = 0.016$  without PWV and IMT) were positively related with all-cause mortality when performing the corresponding analyses ( $p = 0.006$  with PWV and IMT, Hazard ratio of 1.049, CI from 1.014 to 1.085 for each ng/l of PTH) while vitamin D levels were without statistical significance in the models ( $p = 0.9$ ).

**Conclusion:** Our data show that information about the levels of serum vitamin D in men and of PTH in women add prognostic information in terms of total-mortality that goes beyond traditional risk factors and that also adds information independently of the levels of systolic ABP, IMT and PWV.

## 788

**Oral glucose has no effect on appetite and satiety sensations compared to isoglycaemic i.v. glucose in healthy subjects**

M. Gyldenløve<sup>1</sup>, A.E. Junker<sup>2</sup>, L. Skov<sup>1</sup>, T. Vilsbøll<sup>2</sup>, F.K. Knop<sup>2</sup>;

<sup>1</sup>Department of Dermato-Allergology,

<sup>2</sup>Diabetes Research Division, Department of Medicine, Gentofte Hospital, University of Copenhagen, Hellerup, Denmark.

**Background and aims:** Oral glucose ingestion is thought to elicit release of satiety-promoting gastrointestinal (GI) hormones. However, the effect of glucose stimulation of the GI tract on appetite per se has been difficult to separate from the satiety-inducing effect of elevated plasma glucose concentrations. We aimed to evaluate the GI-independent effect of glycaemic excursions following OGTT on appetite and satiety sensations in healthy volunteers.

**Materials and methods:** Hunger, satiety, fullness, prospective food consumption, thirst, well-being, and nausea were assessed by 100-mm visual analogue scales in 20 healthy subjects (7 females; age (mean±SEM): 54±3 years; BMI: 27.0±0.6 kg/m<sup>2</sup>; HbA<sub>1c</sub> 5.4±0.1%) every 20 minutes during a 3h 50g-OGTT and an isoglycaemic i.v. glucose infusion (IIGI), respectively. Overall appetite score (OAS) was calculated as (satiety + fullness + (100 - hunger) + (100 - prospective food consumption)) / 4. Gastrointestinal-mediated glucose disposal (GIGD) was calculated as the difference in glucose amounts used during OGTT and IIGI related to the amount used during OGTT ( $GIGD = 100\% \times (\text{glucose}_{\text{OGTT}} - \text{glucose}_{\text{IIGI}}) / \text{glucose}_{\text{OGTT}}$ ).

**Results:** Isoglycaemia during the oral and i.v. glucose stimuli was achieved in all subjects. As expected, glucose stimulation of the GI tract had a strong impact on glucose disposal from the blood reflected by a mean±SEM GIGD of 57±2%. No significant differences in baseline appetite and satiety sensations were observed between the two experimental days. Overall, appetite sensations increased whereas satiety sensations decreased during both glucose stimuli. There were no significant differences in hunger, satiety, fullness, prospective food consumption, thirst, well-being, nausea or OAS.

**Conclusion:** Our findings show that glucose stimulation of the GI tract has little or no effect on appetite and satiety sensations independently of plasma glucose levels. This suggests that the collective effect of GI factors triggered by oral glucose is of minor importance for appetite and satiety sensations in healthy subjects.

## PS 059 Metformin

#### Effectiveness of add-on glucose-lowering drugs for early glycaemic control in users of metformin: population-based cohort study

R.W. Thomsen<sup>1</sup>, L.M. Baggesen<sup>1</sup>, L. Pedersen<sup>1</sup>, E.S. Buhl<sup>2</sup>, C.L. Haase<sup>2</sup>, E. Svensson<sup>1</sup>, M.L. Svendsen<sup>1</sup>, M. Søgaard<sup>1</sup>, H. Nørrelund<sup>1</sup>, S.P. Johnsen<sup>1</sup>;  
<sup>1</sup>Department of Clinical Epidemiology, Aarhus University Hospital,  
<sup>2</sup>Novo Nordisk Scandinavia AB, Copenhagen, Denmark.

**Background and aims:** We examined the association of different add-on glucose-lowering drugs with achieved quality of early glycaemic control in a large population-based cohort of incident metformin users.

**Materials and methods:** We included all individuals with a first-time prescription for metformin in Northern Denmark between 2000 and 2012 who had their treatment intensified with another glucose-lowering drug within the first year. We obtained individual-level data on glycated hemoglobin (HbA1c) measurements, comorbidities, and medications from population-based medical databases.

**Results:** We identified 25,631 T2D patients with a first metformin prescription. Of these, 3,898 (15%) received an add-on glucose-lowering drug within the first year following metformin start, of which 3,089 had a baseline HbA1c measured before their add-on drug. A number of 1,888 patients (61%) received a sulfonylurea (SU) add-on, 648 (21%) received a DPP4 inhibitor, 132 (4%) a GLP-1 receptor analogue, 125 (4%) another oral hypoglycemic agent (OHA), and 296 (10%) started insulin in addition to metformin. Median patient age at time of add-on was 60 years, 59% were males, and the median HbA1c before add-on was 7.9% (inter quartile range 7.0–9.2%). Patients with SU add-on had a median age of 61 y, a median HbA1c of 7.8% at baseline, and 23% had hospital-diagnosed comorbidity. The corresponding values were similar for patients with DPP4 inhibitor add-on (59 y, 7.7%, and 21%); for GLP-1 add-on (55 y, 8.0%, and 15%); and for other OHA add-on (59 y, 7.9%, and 18%). Insulin add-on patients tended to have worse glycaemic control and more comorbidity (56 y, 9.6%, and 29%). Within 3–6 months after add-on therapy start, 2,357 T2D patients (76%) had a control HbA1c measurement recorded. Overall, the median HbA1c dropped from 7.9% at baseline to 6.7%, corresponding to a reduction of 1.2 percentage points (pp). Absolute reductions were 1.2 pp (from 7.9 to 6.7) for sulfonylurea add-on, 1.0 pp (7.7 to 6.7) for DPP4 inhibitors, 1.5 pp (8.0 to 6.5) for GLP-1 receptor analogues, 1.1 pp (8.0 to 6.9) for other OGDs, and 2.7 pp (9.7 to 7.0) for insulin add-on. Overall, 61% of all metformin users who had add-on therapy attained an HbA1c target of <7% within 3–6 months, while 36% attained an HbA1c target of <6.5%. In the largest group with SU add-on, the proportions attaining an HbA1c target of <7% were 83%, 55%, and 45% for the 3 different baseline HbA1c levels displayed in Figure 1. In comparison, a target of <6.5% was attained by 56%, 27%, and 26%. Target attainments for other treatment groups are shown in Figure 1.

**Conclusion:** This study provides data on glycaemic control in real-world metformin users who are started with different add-on glucose-lowering drugs. Overall, more than one third did not attain an HbA1c target of <7% within 6 months, and close to two thirds did not attain a target of <6.5%.

#### Cardiovascular safety of metformin and sulphonylureas in type 2 diabetes patients

S. Ioacaru<sup>1,2</sup>, M. Roden<sup>3</sup>, C. Guja<sup>4,2</sup>, C. Ionescu-Tirgoviste<sup>4,2</sup>, A. Reghina<sup>1,2</sup>, O. Georgescu<sup>1</sup>, S. Fica<sup>1,2</sup>;  
<sup>1</sup>“Elias” University Emergency Hospital, <sup>2</sup>“Carol Davila” University of Medicine and Pharmacy, Bucharest, Romania, <sup>3</sup>Institute for Clinical Diabetology, German Diabetes Center, Düsseldorf, Germany,  
<sup>4</sup>“I. Pavel” Outpatient Clinic, Bucharest, Romania.

**Background and aims:** To investigate the impact of the exposure to the oral glucose lowering drugs (OGLD) metformin and sulphonylureas, on cardiovascular mortality in type 2 diabetes patients.

**Materials and methods:** All consecutive diabetes patients residing in a major urban area were screened at their first diabetes outpatient visit between 01/01/2001–12/31/2008 (n=79869). Baseline was defined at 6 months after screening (n=78714). Exclusion criteria at baseline were: insulin treatment (n=15515), not on monotherapy with metformin or sulphonylurea (n=32257), and age <40 or ≥65 years (n=14128). All 16814 patients (46.9% females) were followed-up until (i) death, based on death certificate and National Institute of Statistics data, or (ii) first insulin exposure, or (iii) end of follow-up on 12/31/2011. Data on gender, age, time-dependent daily dose and number of concomitant OGLD were available. Time-dependent competing risk regression analysis, with daily updates of treatment modalities was performed. Simultaneous use of cumulative exposure and ever exposed term of the available treatment options, a “fixed” cohort, and cumulative exposure limited to that attained one year prior to death (reverse causation) completed the evaluation.

**Results:** Mean baseline age was 55±6 years, with a mean follow-up of 6.0±2.9 years. During 101418 person-years exposure time, there were 968 cardiovascular deaths (328 myocardial infarction; 223 stroke) and 889 deaths from other causes (competing events), with an overall mortality rate 183 per 1000 person-years. Cumulative time exposure (one year increments) (sub) hazards (SHR) for cardiovascular death showed: male gender 1.850 (95% CI 1.618–2.115, p<0.001), age at baseline 1.083 (95% CI 1.070–1.096, p<0.001), metformin 0.979 (95% CI 0.975–0.983, p<0.001), glimepiride 0.975 (95% CI 0.968–0.983, p<0.001), gliclazide 0.978 (95% CI 0.973–0.984, p<0.001), glipizide 0.984 (95% CI 0.977–0.992, p<0.001), glibenclamide 0.985 (95% CI 0.979–0.991, p<0.001), repaglinide 0.982 (95% CI 0.970–0.995, p=0.005). There was no significant impact of pioglitazone, rosiglitazone, and concomitant number of OGLD. Cumulative dose exposure (one gram increments) results were comparable, with the exception of repaglinide 0.450 (95% CI 0.192–1.051, p=0.065) and pioglitazone 0.866 (95% CI 0.751–0.998, p=0.047). Similar results were obtained with myocardial infarction or stroke death as end-point. Future exposure to sulphonylureas in patients on metformin monotherapy at baseline (n=7546) was associated with a decrease in cardiovascular mortality. Patients originally on sulphonylurea (n=9268) and subsequently exposed to metformin did not experience significant changes in cardiovascular hazards (all SHR p values >0.05). Cumulative exposure limited to that attained one year prior to death and “fixed” cohort analysis did not affect the original results.

**Conclusion:** Exposure to oral glucose lowering drugs in type 2 diabetes patients originally on monotherapy with metformin or sulphonylurea is safe in terms of cardiovascular mortality. Subsequent exposure to metformin in patients treated with sulphonylurea at baseline was not associated with increased cardiovascular mortality.

#### Polymorphism of OCT2 and MATE1 improve glucose-lowering effect of metformin via influencing its pharmacokinetics in Chinese type 2 diabetic patients

W.L. Hou<sup>1</sup>, D.D. Zhang<sup>1</sup>, W. Lu<sup>1</sup>, T.S. Zheng<sup>1</sup>, L.L. Wan<sup>2</sup>, Q. Li<sup>1</sup>, F. Liu<sup>1</sup>, W.P. Jia<sup>1</sup>;

<sup>1</sup>Department of Endocrinology and Metabolism, Shanghai Clinical Medical Center of Diabetes, Shanghai Key Clinical Center of Metabolic Diseases,  
<sup>2</sup>Department of Pharmacy, Department of Pharmacy, Shanghai, China.

**Background and aims:** This study aims to investigate the potential impact of organic cation transporter 2 (OCT2) nucleotide polymorphism at site 808 (G→T) and multidrug and toxin extrusion protein 1 (MATE1) on metformin pharmacokinetics and long-term antidiabetic effect.

**Materials and methods:** A total of 220 newly diagnosed type 2 diabetes patients taking oral metformin were recruited, genotyped and divided into three groups by SLC22A2 genotypes (G/G, G/T, T/T), as well as three groups by SLC47A1 genotypes (G/G, G/A, A/A). Six to ten patients in each group were randomly selected and undertaken metformin pharmacokinetic study. A one-year follow up randomized cohort study was performed to clarify metformin pharmacodynamics.

**Results:** After one year, the falling range of HbA1c level was significantly greater in subjects with heterozygous variant genotype (GT and AA) than wild type homozygote (-1.28% in GT vs -1.01% in GG, -2.32% in AA vs -1.07% in GG, both  $P < 0.05$ ) after adjustment for baseline HbA1c levels in each group. There were also differences in pharmacokinetic parameters of metformin between reference and variant forms of OCT2 and MATE1. Multivariate analysis further revealed that OCT2 exon 808 polymorphism, SLC47A1 genotype and gender were independent influencing factors for urine excretion of metformin ( $P < 0.05$ ).

**Conclusion:** Except for gender, the glucose-lowering efficacy of metformin can be enhanced by SLC22A2 808 G>T variants and SLC47A1 rs2289669 G>A variants through delaying its transportation and renal clearance in Chinese type 2 diabetes populations.

### Long term effects of metformin on plasma concentrations of C-peptide in insulin-treated type 2 diabetes patients: a placebo controlled trial

W.M.C. Top<sup>1,2</sup>, A. Kooy<sup>1,2</sup>, P. Leher<sup>3</sup>, C.D.A. Stehouwer<sup>4</sup>;

<sup>1</sup>Internal Medicine, Bethesda Hospital Care Group Leveste Middelveld, Hoogeveen, <sup>2</sup>Bethesda Diabetes Research Centre, Hoogeveen, Netherlands, <sup>3</sup>Statistical Department, Louvain University, Belgium,

<sup>4</sup>Internal Medicine, Maastricht University Medical Centre, Netherlands.

**Background and aims:** Type 2 diabetes (T2D) is characterized by beta cell failure and varying degrees of insulin resistance, both being targets of treatment. While metformin is known to improve insulin sensitivity, its effects on beta cell function are assumed to be neutral. Because beta cell mass decreases over time, improvement of beta cell function may be more difficult to obtain in advanced T2D. In this study, the effects of metformin on beta cell function were evaluated in patients with advanced, insulin-treated T2D during a follow-up of 4.3 years.

**Materials and methods:** To evaluate the effect of metformin on endogenous insulin secretion, we analysed the plasma concentrations of C peptide (immuno-assay) at baseline, after 4 months and yearly for 4 years in a placebo-controlled, randomized trial in insulin-treated patients with T2D (N=390, mean age 61.3 years, mean diabetes duration 13.1 years, mean baseline HbA1c 7.9%, 54% men). A linear model was performed on logtransformed values because of a skewed distribution of the data, and with adjustment for baseline values.

**Results:** Unadjusted mean C-peptide levels decreased from 0.52 (+/- 0.38) to 0.47 (+/- 0.34) nmol/l in the placebo group, and increased from 0.47 (+/- 0.40) to 0.55 (+/- 0.47) nmol/l in the metformin group. For the final visit, regression analysis showed a significant treatment effect (difference, 5.8% (95% CI, 1.0-11.5),  $P = 0.034$ ). The summary mean in the placebo group was 0.52 (+/- 0.35) and in the treatment group 0.53 (+/- 0.40) nmol/l. No statistically significant treatment effect was found on the summary mean (difference, 2.7% (95% CI, -0.5-5.9),  $P = 0.101$ ). As a measure for steady state beta cell function, we calculated the fasting C-peptide/fasting glucose index (C-peptide/glucose x 100). This ratio decreased from 5.4 (+/- 4.1) to 5.0 (+/- 3.9) in the placebo group, and increased from 4.9 (+/- 4.0) to 5.9 (+/- 4.7) in the metformin group. Regression analysis showed a significant treatment effect both for the final visit (difference 0.9 (95% CI, 0.2-1.6),  $P = 0.010$ ) and for the summary mean (difference 0.9 (95% CI, 0.5-1.4),  $P < 0.001$ ). The greater part of this effect (71% (95% CI, 44-86)) was not mediated by changes in HbA1c.

**Conclusion:** Our study shows that beta cell function in advanced T2D can be improved by the addition of metformin in insulin-treated patients. This improvement is only partially explained by a reduction in HbA1c. In insulin-treated patients not treated with metformin a slight decrease in beta cell function was observed during a follow-up of 4.3 y.

Clinical Trial Registration Number: NCT00375388

## 793

### Glucose-lowering effect of metformin resides in the gut not the circulation. A 12-week placebo-controlled double-blind randomised trial

M. Fineman<sup>1</sup>, R.A. DeFronzo<sup>2</sup>, J. Rosenstock<sup>3</sup>, J. Buse<sup>4</sup>, T. Kim<sup>1</sup>, C. Burns<sup>1</sup>, S. Skare<sup>1</sup>, A. Baron<sup>1</sup>;

<sup>1</sup>Elcelyx Therapeutics, San Diego, <sup>2</sup>UT Health Science Center, San Antonio,

<sup>3</sup>Dallas Diabetes and Endocrine Center,

<sup>4</sup>UNC School of Medicine, Chapel Hill, USA.

**Background and aims:** Metformin delayed release (Met DR) is formulated to deliver Met directly to the lower bowel where absorption is poor, resulting in low plasma Met exposure. In previous studies, the same dose of Met DR and Met immediate release (IR) comparably lowered fasting (FPG) and postprandial plasma glucose and augmented GLP-1 and PYY release but plasma Met was reduced by approximately 50% with Met DR compared to IR. Maintained glucose-lowering efficacy with reduced plasma exposure may allow for removal of the renal impairment contraindication due to reduced Met plasma exposure and subsequent lower risk of Met-associated lactic acidosis.

**Materials and methods:** The randomized, blinded, 12-week study compared 3 doses of Met DR (600, 800, 1000 mg) to placebo (PBO) in subjects with T2DM (n = approximately 40/group, mean age 52 years, mean BMI 33 kg/m<sup>2</sup>), screening mean FPG 144 mg/dl, and mean A1C 7.2%. Subjects were on diet and exercise (11%) or washed off previous Met (89%, average dose ~1400 mg) and/or DPP-4i for 2 weeks prior to randomization. Two open-label groups of Met extended release (XR 1000, 2000 mg) were also included as a reference.

**Results:** FPG decreased within the first week of treatment in all groups and was stable after 4 weeks. The mean 4-12 week change in FPG from baseline was -13.5, -12.3 and -18.0 mg/dl for 600, 800 and 1000 mg Met DR, respectively, vs. -1.2 mg/dl for PBO (all  $p < 0.05$ , median change). The mean FPG for Met XR 1000 mg (-13.3 mg/dl,  $p < 0.05$  vs. PBO) was similar to 600/800 mg Met DR, despite 4-9 fold higher fasting Met plasma concentrations (515 vs. 56 and 119 ng/ml, respectively). Met XR 2000 mg reduced FPG by 26.5 mg/dl ( $p < 0.05$  vs PBO) with a fasting Met plasma concentration of 912 ng/ml. The similar glucose-lowering effect of 600 mg Met DR and 1000 mg Met XR represents an approximately 40% shift in the dose response for Met DR, consistent with the gut being the primary site of metformin action. At Week 12, mean A1C rose by 0.45% for PBO, reflecting withdrawal of oral agents, and remained unchanged in the DR groups and 1000 mg Met XR. The mean A1C change was -0.21% for 2000 mg Met XR. GI tolerability was similar among all Met groups.

**Conclusion:** Maintenance of efficacy at lower doses and markedly reduced plasma Met exposure with gut restricted Met DR confirms that Met works chiefly in the gut. Importantly, Met DR could be useful to reduce risk of lactic acidosis in patients with renal impairment.

Clinical Trial Registration Number: NCT01819272

## 794

**Effects of metformin on fuel metabolism, energy expenditure and body composition in human subjects and rats**

I. Tokubuchi<sup>1</sup>, Y. Tajiri<sup>1</sup>, S. Iwata<sup>1</sup>, K. Hara<sup>1</sup>, K. Yamada<sup>1</sup>, H. Mifune<sup>2</sup>;  
<sup>1</sup>Division of Endocrinology and Metabolism, <sup>2</sup>Department of Animal Experiment, Kurume University School of Medicine, Japan.

**Background and aims:** Metformin is widely used to treat obese diabetics because of its beneficial effects on body weight, energy intake, and glucose regulation. Metformin phosphorylates AMP-activated protein kinase (AMPK) and exerts its effects on hyperglycemia and insulin resistance through a blockade of gluconeogenesis in the liver and an enhancement of fat oxidation in the skeletal muscle. However, results regarding effects on energy expenditure (EE), respiratory quotient (RQ) and body composition have been rather controversial. In the present study, we investigated this unsolved issue separately during either fasting or post-prandial state in both human subjects and rats.

**Materials and methods:** All data were expressed as means±S.D. In human study, metformin hydrochloride (1500 mg/day) was administered either 23 healthy subjects (group C: 16 males, 26±3 years old, BMI 22.0±3.4) or 13 type 2 diabetic patients (group DM: 7 males, 44±17 years old, BMI 30.9±6.2) for 2 weeks. Meal tolerance test (592 kcal, 75 g of carbohydrate, 28.5 g of fat) was performed in the morning before and after 2 weeks administration of metformin. Blood samples were collected before and 1, 2, 3 hours after the ingestion of meal, and plasma concentrations of glucose (G), triglyceride (TG), lactate (LA) and pyruvate (PA) were measured. Simultaneously expired gas analysis was performed for the measurements of EE and RQ. In animal study, male Sprague Dawley rats (13 weeks old) were fed 10 g of standard chow twice daily (at 8AM and 7PM), and drinking water either with or without metformin hydrochloride (2.5 mg/ml) was given for 2 weeks. At 15 weeks old, EE and RQ were measured in a chamber equipped with expired gas analysis system, body compositions were measured by CT scan, then they were sacrificed in either fasting or post-prandial state and blood samples were collected.

**Results:** In human study, by the administration of metformin for 2 weeks significant decreases of G (P<0.01) and TG (P<0.05) were observed at all points in DM and a significant decrease of G after 2 hours (P<0.01) in C compared to values before administration. In DM, LA and PA after meal ingestion were significantly (P<0.05) increased by metformin administration. Although EE did not change, RQ decreased before meal (C: 0.8±0.06→0.78±0.05, P<0.05; DM: 0.73±0.03→0.71±0.02, P<0.05) and conversely increased 2 hours after meal ingestion (C: 0.77±0.05→0.8±0.07, P<0.05; DM: 0.71±0.04→0.74±0.04, P<0.05). In animal study, LA and PA were significantly (P<0.05) increased in both fasting and post-prandial state by the treatment of metformin for 2 weeks. RQ decreased during fasting state in metformin-treated rats compared to control rats (0.8±0.02 vs. 0.82±0.03, P<0.05) in spite of comparable EEs in both groups. Total fat volume was significantly decreased by the treatment of metformin (19.5±2.3 vs. 25.5±4.1%, P<0.05) while body weight did not differ between both groups.

**Conclusion:** Long-term administration of metformin brought about a shift of fuel resource, especially fat oxidation during fasting state was noted in both human and animal experiments. Concomitantly, a significant decrease of fat volume was noted in animal experiment in reflection of a dominant fat utilization. Precise molecular mechanisms for these beneficial effects of metformin are now under exploration.

## 795

**Metformin-associated prevention of weight gain in insulin-treated type 2 diabetic patients cannot be explained by decreased energy intake**

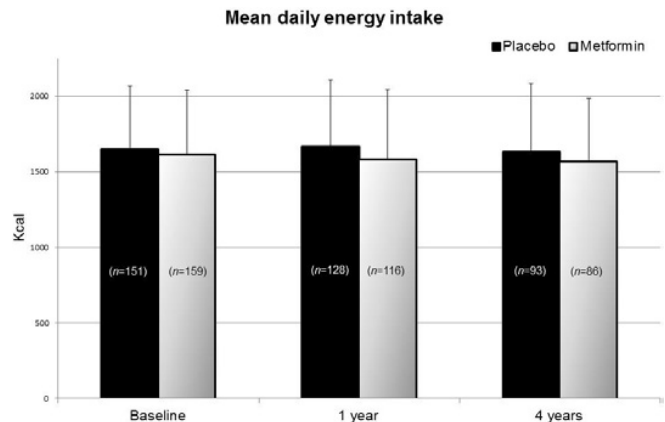

M. Out<sup>1,2</sup>, I. Miedema<sup>3</sup>, H.A. Jager-Wittenaar<sup>3</sup>, C.P. van der Schans<sup>3</sup>, W.P. Krijnen<sup>3</sup>, P. Leher<sup>4</sup>, C.D.A. Stehouwer<sup>5</sup>, A. Kooy<sup>1,2</sup>;  
<sup>1</sup>Bethesda Hospital, <sup>2</sup>Bethesda Diabetes Research Center, Hoogeveen, <sup>3</sup>Research and Innovation Group in Health Care and Nursing, Hanze University of Applied Sciences Groningen, Netherlands, <sup>4</sup>Department of Statistics, Louvain Academy, Mons, Belgium, <sup>5</sup>Maastricht University Medical Centre, Netherlands.

**Background and aims:** Metformin is known to prevent weight gain in patients with type 2 diabetes (T2D). However, the mechanisms involved are still unknown. Less energy intake, malabsorption and metabolic effects may play a role.

**Materials and methods:** We analysed energy intake in the HOME trial, a placebo-controlled, randomised trial (RCT) conducted in 3 hospitals in insulin-treated T2D patients (N=390, mean age 61.3 years, mean diabetes duration 13.1 years, mean baseline HbA1c 7.9%, 54% men). Dietary intake was assessed at baseline, after 1 year and after 4 years by four trained registered dietitians. For dietary assessment, patients were asked about their intake during the preceding week according to the dietary history method. Mean energy intake per day (kcal) was calculated using food calculation software (Becel Institute Nutrition Software). All analyses were based on intention to treat. For statistical analysis, we used a general linear model (ANCOVA) and a Linear Mixed Model (LMM) to determine the robustness of our results.

**Results:** Dietary assessments were available from 2 hospitals, resulting in inclusion of 310 patients of the 390 patients randomised in the original study. Of the 310 participants, 179 completed (93 placebo and 86 metformin) all three dietary assessments. Body weight of the patients in the placebo group increased 4.9 kg (SD 4.9) in 4 years and increased significantly more than in the metformin group (+ 1.1 kg, SD 5.2; p<0.001). Mean daily energy intake after 4 years decreased from 1649 (SD 419) to 1632 kcal (SD 453) in the placebo group and from 1613 (SD 426) to 1567 kcal (SD 419) in the metformin group. ANCOVA did not detect a significant difference after 4 years (-71.0 kcal/day in metformin compared to placebo; 95% CI -199.4 to +54.5, p=0.28). The outcome remained non-significant after additional adjustment for gender, age, duration of diabetes and smoking, and was confirmed by a LMM (F-value 1.803, df=415, p = 0.18). LMM failed to detect a significant effect of energy intake as explanation for the difference in weight gain between the groups (F-value 0.054, df=1, p = 0.82).

**Conclusion:** In this long-term RCT in T2D patients treated with insulin, metformin treatment was not associated with a change in energy intake as compared to placebo. Therefore, the prevention of weight gain by metformin could not be explained by a lower energy intake. Further research is needed to investigate whether other mechanisms like malabsorption, changes in intestinal glucose metabolism or effects through the GLP-1 system are involved in the favourable effect of metformin on weight development.

Clinical Trial Registration Number: NCT00375388

## 796

**Are sulfonylurea and insulin therapies associated with a larger risk of cancer than metformin therapy? A retrospective database analysis**

B. Kowall<sup>1</sup>, K. Kostev<sup>2</sup>, W. Rathmann<sup>1</sup>;  
<sup>1</sup>German Diabetes Center, Düsseldorf, Germany,  
<sup>2</sup>IMS Health, Frankfurt am Main, Germany.

**Background and aims:** Several meta-analyses of observational studies suggested that metformin use reduces, while sulfonylurea use increases cancer risk in type 2 diabetes. However, studies of the effects of drugs are prone to bias. Recently, Suissa (2012) claimed that 23 published observational studies on the effects of metformin on cancer incidence were afflicted with time related bias like immortal time bias, bias from time lag and latency. As the few RCTs published so far have failed to confirm the results of the observational studies, the reduced cancer risk in metformin users may be put into question. Our aim is to compare cancer incidence in users of sulfonylurea, insulin and other diabetes medication, respectively, with cancer incidence in metformin users, and to avoid time related biases.

**Materials and methods:** In a retrospective observational study, we used the German Disease Analyzer database which includes patient data from general

practices throughout Germany. Practices anonymously report all diagnoses (ICD-10), prescriptions (ATC), hospital admissions, and laboratory test results on an ongoing basis. The study sample included 22,556 patients who received a diagnosis of type 2 diabetes during the index period used for this study (January 2000 to December 2012), and who did not have cancer before diagnosis of diabetes. The outcome measure was cancer incidence (ICD-10: all, breast, colon, and prostate cancer). The median follow-up time was 4.8 years. 1,446 (6.4%) patients developed cancer. In an intention-to-treat type analysis, patients with sulfonylurea (or insulin, or other antidiabetic medications) as their first diabetes medication were compared to patients with metformin as their first antidiabetic drug prescription. In a second type of analysis, patients with a monotherapy of sulfonylurea, insulin, or other medications, respectively, were compared to patients with a metformin monotherapy. For these analyses, time 0 was the time one year (three years in a sensitivity analysis) after the first prescription of the respective medication. Cox regression models were fitted, and hazard ratios (HR) and 95% confidence intervals (CI) were calculated to compare users of sulfonylurea, insulin, and other medications with users of metformin.

**Results:** Compared to patients with metformin as first diabetes medication, no increased risks of cancer of all sites were found in patients with other first diabetes medication. In models adjusted for age, sex, obesity, hypertension, hyperlipidemia, duration of diabetes, and Charlson comorbidity index, the corresponding HRs were 1.02 (95%-CI: 0.89 - 1.17) for sulfonylurea, 1.09 (95%-CI: 0.86 - 1.37) for insulin, and 0.91 (95%-CI: 0.74 - 1.12) for other diabetes medication. In the analogous analyses for the comparison of monotherapies, similar results were obtained. In additional analyses with a latency time of three years, and in analyses for some selected cancer sites (breast, colon, and prostate cancer), no decreased cancer risk was found in metformin users.

**Conclusion:** In a retrospective database analysis, taking into account potential time related biases, no different cancer risk was found in metformin, sulfonylurea and insulin users. This finding is in line with few other observational studies using time-dependent analyses. To clarify the association between antidiabetic drug use and cancer risk, there is a strong need for further well-designed observational studies and RCTs.

### The suppression mechanism of metformin on the tumour death ratio accelerated by a high calorie diet in the RasH2 mouse: a model for evaluating tumour prevention or regression

O. Shuichi;

Department of Internal Medicine, Kurume University, Kurume, Japan.

**Background and aims:** The objective of the current study was to investigate whether Metformin intake changed the rate of tumor death under different diet conditions in the rasH2 transgenic mouse, a model for evaluating and designing tumor prevention or regression therapies.

**Materials and methods:** Male rasH2 transgenic mice at 8 weeks of age were divided into 2 groups (n=4 per group): one fed a high calorie diet of 592 kcal/100 g and drinking water *ad libitum*; and the other fed the same high calorie diet with Metformin added to the drinking water from initiation until 32 weeks. Metformin was administered at a small dose of 25 mg/kg body weight per day. Then all mice were sacrificed and examined under microarrays analysis (SurePrint G3 Mouse GE microarrays kit 8x60K, Agilent) and then quantitative PCR.

**Results:** Body weights of the rasH2 transgenic mice fed a high calorie diet with or without Metformin were almost the same from the age of 10 weeks until 32 weeks (76.5 ± 17.6 g vs. 76.5 ± 17.6 g). The human ras gene expression of liver, lung, kidney, spleen and visceral fat were not significantly different between the 2 groups. The lifespan of mice fed a high calorie diet with Metformin (n = 15; 75.3 ± 17.4 weeks) was longer than those fed a high calorie diet without Metformin (p < 0.05), regardless of no differences in weekly body weights. However, At autopsy, multiple occurrences of tumors in the lung, liver, spleen, digestive organs and kidney were found in all groups and malignancy was considered as the cause of death. Based on the results of microarrays analysis, we identified that Ddit4 gene, which plays an important role in responses to cellular energy levels and cellular stress, including responses to hypoxia and DNA damage, was a possible cause for this phenomenon. Our quantitative PCR experiments showed that the Ddit4 gene expression of mice with Metformin significantly decreased compared with that of mice without Metformin in kidney (0.90 ± 0.38 vs. 1.91 ± 0.49, p=0.037, n=4, respectively). Other organs showed tendency to decrease (liver: 0.35 ± 0.14 vs. 0.89 ± 0.14, p=0.09; lung: 1.43 ± 1.19 vs. 1.74 ± 2.89, p=0.64, n=4, respectively).

**Conclusion:** Findings from the current study demonstrate that a constitutional predisposition to tumor may be enhanced by diet, and that high incidence of tumor death may be suppressed by a small dose of orally administered Metformin acting on ameliorating genes, including Ddit4 gene, in mice fed a high calorie diet. We hope this Metformin research will act as a stepping stone for making an effective drug for the anti-cancer effects especially among diabetic patients.

## PS 060 SGLT2 inhibitors: safety

798

### Long-term renal safety with dapagliflozin treatment

A. Ptaszynska<sup>1</sup>, T. Mansfield<sup>1</sup>, E. Johnsson<sup>2</sup>, S. Parikh<sup>3</sup>, Y. Yavin<sup>1</sup>, J.F. List<sup>1</sup>;<sup>1</sup>Bristol-Myers Squibb, Princeton, USA, <sup>2</sup>AstraZeneca, Mölndal, Sweden,<sup>3</sup>AstraZeneca, Wilmington, USA.

**Background and aims:** Dapagliflozin (DAPA) reduces hyperglycaemia by inhibiting renal glucose reabsorption. Because of this mechanism of action renal safety has been monitored closely throughout the DAPA clinical development programme.

**Materials and methods:** Renal safety was assessed in data pooled from 13 placebo (PBO)-controlled trials lasting up to 24 weeks (short-term [ST] dataset), 9 PBO-controlled trials lasting up to 102 weeks (ST + long-term [LT] dataset), and from all 21 phase 2b/3 trials, including an active-controlled study up to 208 weeks (all Ph2b/3 dataset) in type 2 diabetes mellitus (T2DM) patients. Frequency of adverse events (AEs), serious AEs, and abnormal laboratory tests were summarised.

**Results:** Among a total of 9339 patients in the all Ph2b/3 dataset, estimated glomerular filtration rate (eGFR) at baseline (BL) was  $\geq 60$  mL/min/1.73 m<sup>2</sup> in 8268 (88.5%) patients and  $\geq 30$  to  $< 60$  mL/min/1.73 m<sup>2</sup> in 1070 (11.5%) patients. With DAPA, in the ST+LT dataset, after a small initial decrease at week 1 (mean change from BL: -4.2 vs 0.5 mL/min/1.73 m<sup>2</sup> [DAPA 10 mg vs PBO]) mean eGFR returned toward baseline by week 24 (mean change from BL: -1.4 vs -0.7 mL/min/1.73 m<sup>2</sup> [DAPA 10 mg vs PBO]) and was stable to week 102. In the ST and ST+LT datasets, AEs related to renal function were more frequent with DAPA (Table); most were small, reversible changes in serum creatinine. In both PBO- and DAPA-treated subjects, these AEs occurred  $> 10$  times more frequently over 24 weeks, and 6–8 times more frequently over 102 weeks, in subjects with eGFR  $\geq 30$  to  $< 60$  mL/min/1.73 m<sup>2</sup> at BL (moderate renal impairment) compared with those with eGFR  $\geq 60$  mL/min/1.73 m<sup>2</sup> at BL (Table). Serious AEs (SAEs) related to renal function were balanced across treatments and were recorded in 0.15% of patients in both DAPA and control groups in the all Ph2b/3 dataset (DAPA, 9 of 5936; control, 5 of 3403) and there were no instances of acute tubular necrosis or acute nephritis. Marked laboratory abnormalities were uncommon and similar between groups; for example, serum creatinine  $\geq 2.5$  mg/dL was observed in 3 (0.2%) of both DAPA- and PBO-treated patients at week 102, but in no patient with eGFR  $\geq 60$  mL/min/1.73 m<sup>2</sup> at BL. Shifts between categories of albuminuria (normal, micro, and macro) at week 24 in the ST dataset were similar for DAPA and PBO; overall, albuminuria did not worsen in either group. Renal safety data with DAPA were similar in a 4-year active-controlled trial (N=816).

**Conclusion:** Pooled data from 21 phase 2b/3 trials in T2DM patients, including 13 ST and 9 LT studies, show that DAPA 10 mg is associated with a slight excess of renal AEs, mostly transient creatinine changes, but not of renal SAEs, compared with PBO. The difference is driven primarily by the

subgroup of patients with eGFR  $\geq 30$ – $< 60$  mL/min/1.73 m<sup>2</sup> at BL. There is no indication of renal toxicity with DAPA. These data provide further evidence of a good renal safety profile for DAPA in the treatment of T2DM.

Table. Renal AEs in placebo-controlled studies up to 24 weeks and 102 weeks

| Data shown are n (%), including data after rescue            | Studies up to 24 weeks (13 studies, ST dataset)    |          |   |          |   |           |
|--|--|----------|---|----------|---|-----------|

### Efficacy and safety of canagliflozin (CANA) in patients with type 2 diabetes mellitus (T2DM) who progressed to stage 3A chronic kidney disease during treatment

R. Roussel<sup>1</sup>, D. de Zeeuw<sup>2</sup>, G. Law<sup>3</sup>, G. Meininger<sup>3</sup>;<sup>1</sup>Hôpital Bichat, Paris, France, <sup>2</sup>University of Groningen, Netherlands,<sup>3</sup>Janssen Research & Development, LLC, Raritan, USA.

**Background and aims:** CANA, an SGLT2 inhibitor, has provided reductions in HbA1c, body weight (BW), and systolic blood pressure (SBP) across Phase 3 studies of patients with T2DM. CANA was also associated with transient reductions in estimated glomerular filtration rate (eGFR) that stabilized or attenuated over the treatment period. This analysis evaluated the impact of decreases in eGFR on the efficacy and safety of CANA in patients with T2DM.

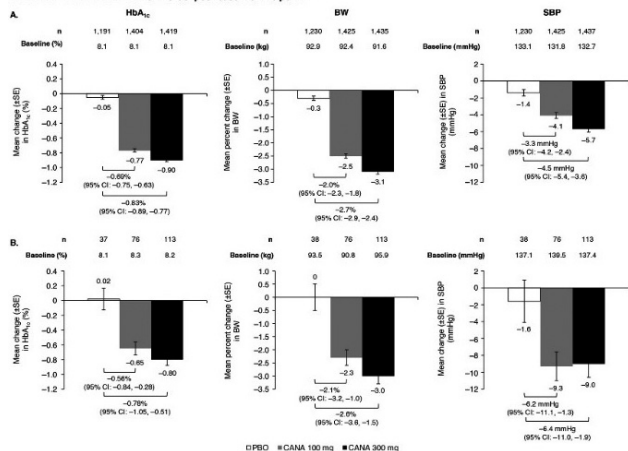

**Materials and methods:** Changes from baseline in HbA1c, BW, and SBP were assessed in the subset of patients with eGFR  $\geq 60$  mL/min/1.73 m<sup>2</sup> at baseline who had a reduction in eGFR to  $\geq 45$  and  $< 60$  mL/min/1.73 m<sup>2</sup> at the last post-baseline time point based on pooled data from 6 randomised, double-blind, placebo (PBO)-controlled studies over 18 or 26 weeks (N = 262/4,158; 6.3%). Safety analyses, including the incidence of adverse events (AEs), were conducted in those who had a reduction in eGFR from  $\geq 60$  mL/min/1.73 m<sup>2</sup> to  $\geq 45$  and  $< 60$  mL/min/1.73 m<sup>2</sup> at the last time post-baseline in a broader pooled population from 8 randomised, double-blind, PBO- and active-controlled studies over 26 or 52 weeks (N = 664/9,439; 7.0%).

**Results:** Among patients who had a reduction in eGFR from  $\geq 60$  to  $\geq 45$  and  $< 60$  mL/min/1.73 m<sup>2</sup> (mean baseline eGFR 67.3 mL/min/1.73 m<sup>2</sup>), mean eGFR at the last post-baseline time point was 54.6, 54.8, and 55.9 mL/min/1.73 m<sup>2</sup> with CANA 100 and 300 mg and PBO (mean change from baseline of -12.7, -12.6, and -11.5 mL/min/1.73 m<sup>2</sup>). In these patients, CANA 100 and 300 mg provided PBO-subtracted reductions (95% confidence interval) in HbA1c (-0.56% [-0.84, -0.28] and -0.78% [-1.05, -0.51]), BW (-2.1% [-3.2, -1.0] and -2.6% [-3.6, -1.5]), and SBP (-6.2 mmHg [-11.1, -1.3] and -6.4 mmHg [-11.0, -1.9]). Changes in HbA1c and BW in patients who had eGFR reductions were similar to those in the overall efficacy population; changes in SBP with CANA were greater in those with eGFR reductions compared with the overall population (Figure). eGFR reductions were reversible once patients discontinued CANA treatment. In the broad dataset used for safety analyses, the incidence of overall AEs in patients whose eGFR decreased to  $\geq 45$  and  $< 60$  mL/min/1.73 m<sup>2</sup> was 62.7%, 64.2%, and 58.6% with CANA 100 and 300 mg and non-CANA; rates of AE-related discontinuations were 6.0%,

8.1%, and 6.4% and serious AEs were 12.4%, 10.0%, and 7.9%. The incidence of volume depletion-related AEs was 4.5%, 4.6%, and 2.0% with CANA 100 and 300 mg and non-CANA; discontinuations and serious AEs related to volume depletion were infrequent across groups.

**Conclusion:** Among patients with T2DM with reductions from eGFR  $\geq 60$  mL/min/1.73 m<sup>2</sup> at baseline to eGFR  $\geq 45$  and  $< 60$  mL/min/1.73 m<sup>2</sup> during treatment, CANA 100 and 300 mg provided reductions in HbA<sub>1c</sub>, BW, and SBP, consistent with the overall population. CANA was generally well tolerated, with a low incidence of volume depletion-related AEs across groups.

**Figure.** Changes in HbA<sub>1c</sub>, BW, and SBP (A) in the overall population and (B) in patients with baseline eGFR  $\geq 60$  mL/min/1.73 m<sup>2</sup> and reduction to  $\geq 45$  and  $< 60$  mL/min/1.73 m<sup>2</sup> at the last post-baseline time point.\*

BW, body weight; SBP, systolic blood pressure; eGFR, estimated glomerular filtration rate; SE, standard error; PBO, placebo; CANA, canagliflozin; CI, confidence interval; LS, least squares. \*PBO-extracted differences in LS means and associated 95% CIs are shown below graphs.

### Diuresis-related safety and tolerability of dapagliflozin in type 2 diabetes mellitus over 24 weeks

E. Johnsson<sup>1</sup>, K.M. Johnsson<sup>1</sup>, T.A. Mansfield<sup>2</sup>, A. Apanovitch<sup>2</sup>, Y. Yavin<sup>2</sup>, A. Ptaszynska<sup>2</sup>, S.J. Parikh<sup>3</sup>, J.F. List<sup>2</sup>;

<sup>1</sup>AstraZeneca, Mölndal, Sweden, <sup>2</sup>Bristol-Myers Squibb, Princeton, USA, <sup>3</sup>AstraZeneca, Wilmington, USA.

**Background and aims:** Dapagliflozin lowers blood glucose in Type 2 diabetes mellitus by increasing urinary glucose excretion, which is accompanied by mild osmotic diuresis.

**Materials and methods:** This placebo-controlled short-term pool comprised 13 double-blind core phase IIb/III studies of up to 24 weeks' duration (dapagliflozin 10 mg N=2360; placebo N=2295).

**Results:** The incidence of volume depletion events (events of hypotension, dehydration or hypovolaemia) was 1.1% with dapagliflozin and 0.7% with placebo. Most events were reported by investigators as being mild in intensity (0.7% and 0.4% respectively). Events in 3 dapagliflozin patients and 1 placebo patient were reported as severe by the investigator. Volume depletion events led to discontinuation in 2 dapagliflozin and 1 placebo recipient, and study drug interruption in 1 dapagliflozin and 0 placebo recipients. Events were slightly more frequent for both dapagliflozin and placebo in patients using antihypertensive therapies including diuretics, loop diuretics and angiotensin converting enzyme inhibitors/angiotensin II receptor blockers, in older patients and in patients with baseline estimated GFR  $\geq 30$ - $< 60$  mL/min/1.73m<sup>2</sup> (Table). Orthostatic hypotension was measured in 13.1% of dapagliflozin recipients and 11.3% of placebo recipients, but reported as an adverse event in only 0.1% and 0.3%, respectively. Pollakiuria was reported in 2.1% and 0.7% of dapagliflozin and placebo recipients, respectively, and polyuria in 0.9% and 0.2% of patients, respectively.

**Conclusion:** Volume depletion events and urinary volume events were slightly more common with dapagliflozin than placebo, predominantly in at-risk subjects, but were mostly mild and did not lead to study discontinuation.

### Empagliflozin, a selective SGLT2 inhibitor, ameliorated hyperglycaemia and insulin resistance, while preserving the integrity of pancreas and kidney in CRDH rats

F.M. Younis<sup>1</sup>, Z. Abassi<sup>2</sup>, E. Mayoux<sup>3</sup>, K.S. Hollander<sup>1</sup>, L. Rath-Wolfson<sup>4</sup>, T. Rosenthal<sup>1</sup>;

<sup>1</sup>Physiology and Pharmacology Dept., Sackler School of Medicine, Tel Aviv University, <sup>2</sup>Physiology and Biophysics, Ruth & Bruce Rappaport Faculty of Medicine, Haifa, Israel, <sup>3</sup>Research Division, Boehringer Ingelheim Pharma GmbH & Co.KG, Biberach an der Riss, Germany, <sup>4</sup>Pathology, Hasharon Hospital, Tel Aviv, Israel.

**Background and aims:** Empagliflozin (EMPA), a selective sodium glucose cotransporter 2 inhibitor, in development for the treatment of diabetes, lowers blood glucose independently of  $\beta$ -cell function and insulin resistance via urinary glucose excretion (UGE). The aim of this study was to evaluate its prophylactic effects on hyperglycemia and insulin resistance in diabetic hypertensive rat model (CRDH rats).

**Materials and methods:** Cohen-Rosenthal diabetic hypertensive (CRDH) rats (n=36) were divided into 3 groups: sugar diet (SD) + EMPA (Empa), SD + vehicle (Veh), regular chow + vehicle (Cont). Treatment + SD were introduced concomitantly to animals 6-8 weeks old for 18 weeks. Treatment was added to drinking water and adjusted for drinking volume and body weight; daily dose of 10 mg/kg. Hyperglycemia and insulin were monitored and IP-

GTT was performed at day 80 and 120 of treatment. Immunofluorescence analysis of nephrin in the renal cortex and H&E in the pancreas was performed in the different experimental groups.

**Results:** Empa treatment enhanced significant ( $P<0.05$ ) glucose excretion and associated urine volume as expected in comparison to control, reaching ( $>2000$  vs. Veh  $<200$  mg/dl, and  $32.6 \pm 3.9$  vs.  $15.1 \pm 4.7$  ml  $P<0.01$ ), respectively. Post prandial and fasting hyperglycemia was significantly improved by Empa treatment, ( $P<0.05$ ). Fasting insulin levels did not differ between groups however, a significant decrease ( $P<0.05$ ) in obtained HOMA-IR was seen in the EMPA treated group vs. Veh and Cont groups. Empagliflozin reduced AUC of glucose during IPGTT at 80 and 120 days of treatment. At the end of treatment, EMPA preserved nephrin integrity in the kidney associated with a reduction of proteinuria but also prevented diabetes induced impairment of diaphragm structure. Pancreas H&E staining in empagliflozin treated group revealed an impressive decrease in fatty infiltration and atrophy in comparison to control.

**Conclusion:** In CRDH rat model, empagliflozin treatment was shown to reduce hyperglycemia, to improve insulin resistance and ameliorate diabetic induced kidney and pancreatic damage.

### Long-term empagliflozin treatment preserves beta cell function in ageing ZDF rats

E. Pepin<sup>1</sup>, T. Sulpice<sup>1</sup>, M. Mark<sup>2</sup>, E. Mayoux<sup>2</sup>, T. Alquier<sup>1,3</sup>, V. Poutout<sup>1,3</sup>,  
<sup>1</sup>Betagenex Inc., Laval, Canada, <sup>2</sup>Boehringer-Ingelheim, Biberach, Germany,  
<sup>3</sup>Montreal Diabetes Research Center, CRCHUM and Department of Medicine, Université de Montréal, Canada.

**Background and aims:** Type 2 diabetes (T2D) development is characterized by a progressive decline in  $\beta$ -cell function. Pharmacological interventions aimed at decreasing blood glucose levels by stimulating insulin secretion generally fail to prevent the decline of  $\beta$ -cell function and disease progression. With a mode of action independent of insulin secretion, SGLT2 inhibitors (SGLT2i) may interrupt the vicious cycle of  $\beta$ -cell exhaustion and delay or prevent the deterioration of  $\beta$ -cell function during the progression of T2D. The Zucker diabetic fatty (ZDF) rat is a preclinical T2D model exhibiting a rapid progression of the disease associated with early hyperinsulinemia followed by a decline in  $\beta$ -cell function leading to hypoinsulinemia and hyperglycaemia. We investigated whether empagliflozin, a potent and selective SGLT2i, could impact the disease progression of aging diabetic ZDF rats.

**Materials and methods:** 7-week-old ZDF rats were treated daily with empagliflozin (10mg/kg per os) or vehicle for 6 or 14 weeks. Baseline values were established in 7-week-old untreated ZDF rats. Body weight, 2h-fasted glycaemia, insulinemia and HbA1c were measured at baseline and then weekly during the 6 or 14 weeks of treatment (treated rats). Hyperglycemic clamps were performed at baseline and after 5 and 13 weeks of treatment.

**Results:** Plasma glucose and HbA1c levels increased from  $7.3 \pm 0.2$  mM ( $n=10$ ) and  $3.0 \pm 0.0$  % ( $n=10$ ), respectively, to  $27.8 \pm 0.9$  mM ( $n=9$ ;  $p<0.001$ ) and  $10.7 \pm 0.5$  % ( $n=9$ ;  $p<0.001$ ) over the 14 weeks study duration in vehicle-treated ZDF rats. In contrast, plasma glucose and HbA1c did not significantly increase in empagliflozin-treated rats (blood glucose:  $8.0 \pm 0.3$  mM at 14 weeks vs.  $7.0 \pm 0.2$  mM at 7 weeks,  $n=6$ , NS; HbA1c:  $4.1 \pm 0.2$  % at 14 weeks vs.  $3.0 \pm 0.1$  % at 7 weeks,  $n=6$ , NS). Insulin levels declined greatly in the vehicle-treated group from  $229 \pm 33$  to  $48 \pm 4$  uU/mL ( $n=6$ ,  $p<0.001$ ), while the decline was less pronounced in the empagliflozin group (from  $237 \pm 38$  to  $116 \pm 21$  uU/mL,  $n=6$ ,  $p<0.001$ ). During hyperglycemic clamps after 14 weeks treatment, plasma insulin levels (AUC) and maximal insulin release in response to arginine (AIRmax) were significantly higher in empagliflozin- vs. vehicle-treated groups (AUC:  $174 \pm 20$  vs.  $47 \pm 4$ ,  $n=4$  and  $5$ ,  $p<0.001$ ; AIRmax:  $130 \pm 10$  vs.  $22 \pm 4$  ng/mL,  $n=4$  and  $5$ ,  $p<0.001$ ). Accordingly, C-peptide levels during the clamp were higher in empagliflozin-treated rats ( $5.6 \pm 0.3$  vs.  $2.7 \pm 0.3$  nmol/L,  $n=4$  and  $5$ ,  $p<0.001$ ).

**Conclusion:** Empagliflozin treatment delays the onset of hyperglycaemia in the aging ZDF rats by preserving insulin secretory capacity. This suggests that this new mode of action to decrease plasma glucose levels may prove beneficial for T2D patients by preserving  $\beta$ -cell function during the progression of the disease.

### LX4211, a dual inhibitor of SGLT1/SGLT2, reduces postprandial glucose in patients with type 2 diabetes mellitus and moderate to severe renal impairment

P. Lapuerta, A. Sands, I. Ogbaa, P. Strumph, D. Powell, P. Banks, B. Zambrowicz;  
 Lexicon Pharmaceuticals, Inc., The Woodlands, USA.

**Background and aims:** The prevalence of renal impairment (RI) in type 2 diabetes mellitus (T2DM) is  $\geq 20\%$ . Since selective sodium-glucose co-transporter 2 (SGLT2) inhibitors target only the kidney, they have reduced efficacy in T2DM patients with RI. Because LX4211 blocks both SGLT2-mediated renal glucose reabsorption and SGLT1-mediated gastrointestinal glucose absorption, it should benefit patients with T2DM and RI by significantly reducing postprandial glucose (PPG) levels.

**Materials and methods:** The primary objective was to evaluate the effect of LX4211 on 4-hour PPG AUC change from baseline to Day 7 in patients with T2DM and baseline renal function (eGFR)  $\geq 15$  and  $\leq 59$  mL/min/1.73 m<sup>2</sup> (calculated by MDRD). Patients (N=31) were randomly assigned to receive LX4211 (400 mg, n=16) or placebo (n=15) 15 minutes before a standard breakfast on 7 consecutive days. Glucose and GLP-1 were measured 15 minutes prior to breakfast and 1, 2, 2.5, 3, and 4 hours post breakfast at baseline and on Day 7.

**Results:** LX4211 significantly reduced mean PPG AUC<sub>(-15min - 4hr)</sub> by  $169.3$  mg•hr/dL compared to placebo in all treated patients,  $p=0.003$ . In patients with baseline eGFR values  $<45$  mL/min/1.73 m<sup>2</sup>, the LX4211-treated patients (N=5) had a  $259.6$  mg•hr/dL mean PPG reduction compared to the placebo patients (N=9),  $p=0.002$ . Compared to placebo, LX4211 also showed significant elevations in the mean change in incremental AUC between baseline and Day 7 for total GLP-1 of  $9.7$  pmol•hr/L ( $p=0.017$ ) and for active GLP-1 of  $4.7$  pmol•hr/L ( $p=0.042$ ) in all patients. There were no serious adverse events (SAEs) and no discontinuations due to AEs. There were 3 mild cases of hypoglycemia reported as treatment-emergent adverse events during the trial: 1 in the LX4211-treated patients and 2 in placebo patients.

**Conclusion:** These results indicate that LX4211 may enhance glycemic control in patients with moderate to severe RI.

## 804

### Dapagliflozin, a selective sodium-glucose cotransporter-2 inhibitor, does not increase risk of fractures

K.M. Johansson<sup>1</sup>, A. Ptaszynska<sup>2</sup>, T.A. Mansfield<sup>2</sup>, A. Apanovitch<sup>2</sup>, E. Johansson<sup>1</sup>, S.J. Parikh<sup>3</sup>, J.F. List<sup>2</sup>;  
<sup>1</sup>AstraZeneca, Mölndal, Sweden, <sup>2</sup>Bristol-Myers Squibb, Princeton,  
<sup>3</sup>AstraZeneca, Wilmington, USA.

**Background and aims:** Observational studies have shown a higher risk of fractures in patients with type 2 diabetes mellitus (T2DM), and a higher incidence of fractures versus comparator has been reported for the sodium-glucose cotransporter-2 inhibitor (SGLT2) inhibitor canagliflozin. Dapagliflozin is a highly specific SGLT2 inhibitor improving glycaemic control in T2DM by reducing renal glucose reabsorption. Here we assess frequency of fractures across the dapagliflozin clinical trial programme.

**Materials and methods:** Data on fractures were pooled across 21 double-blind, core phase IIb/III T2DM studies of up to 208 weeks' duration (dapagliflozin N=5936; placebo N=3403). Long-term data from a placebo-controlled subset of this pool were also analyzed, overall and in the subgroups of patients at risk: with renal impairment (estimated GFR [eGFR] using modification of diet in renal disease [MDRD]  $<60$  mL/min/1.73m<sup>2</sup>), older patients, and women over 50 years old.

**Results:** Proportion of patients with fractures was numerically the same or lower in the dapagliflozin arms in all pools including patients at higher risk (Table). A dedicated study of patients with moderate renal impairment (eGFR by MDRD  $<60$  mL/min/1.73m<sup>2</sup>) had an imbalance in fractures (8 in dapagliflozin 10 mg arm vs 0 in placebo arm). This was not confirmed in the pooled data set of patients with renal impairment.

**Conclusion:** Consistent with the lack of effect on bone mineral density previously reported, in these pooled clinical data analyses dapagliflozin therapy was not associated with an increase in fractures overall or in subgroups at risk (i.e. older patients, postmenopausal women and patients with renal impairment).

| Table: Proportion of patients with fractures overall and in higher risk subgroups |                                |                           |

### Two-year efficacy and safety of dapagliflozin for patients with type 2 diabetes mellitus and a history of cardiovascular disease

I. Gause-Nilsson<sup>1</sup>, T.W. DeBruin<sup>2</sup>, J. Sugg<sup>3</sup>, S.J. Parikh<sup>2</sup>, E. Johnsson<sup>1</sup>, L.A. Leiter<sup>3</sup>

<sup>1</sup>AstraZeneca, Mölndal, Sweden, <sup>2</sup>AstraZeneca, Wilmington, USA,

<sup>3</sup>University of Toronto, Canada.

**Background and aims:** Dapagliflozin (DAPA) is a selective sodium-glucose co-transporter 2 inhibitor with glucuretic and osmotic diuretic effects. The benefit/risk profile of DAPA was evaluated in a double-blind, placebo (PBO)-controlled phase 3 study of patients (pts) with type 2 diabetes mellitus (T2DM) inadequately controlled on usual care and preexisting cardiovascular disease (CVD). Primary outcome results for 24 weeks (wks) plus a 28-wk extension were previously reported; here we report results for 104 wks.

**Materials and methods:** Pts (HbA1c 7%-10%) were randomised 1:1 to receive 10 mg/d DAPA or PBO for 24 weeks, followed by consecutive extension periods of 28 and 52 wks. Pts were stratified by age (< or ≥ 65 years [y]) and insulin (INS) use; INS doses were reduced by 25% at randomisation. Efficacy data for 104 wks (observed cases) are descriptive (mean [95% CI]); glycaemic end points exclude pts who received rescue therapy (DAPA, n=130 [27.5%]; PBO, n=245 [50.5%]).

**Results:** In the efficacy population (N=962), mean age was 64 y; 47% were ≥ 65 y. Mean T2DM duration was 13 y. CVD history was mainly CHD (76.5%); 93% of pts had a history of hypertension. Most pts reported using 1 (45.4%) or 2 (34.7%) oral antihyperglycemic agents; 60.5% of patients used INS, 20% as monotherapy. Of the 964 randomised pts, 157 (33.6%) and 162 (32.5%) in the DAPA and PBO groups, respectively, were eligible to continue into the 52-week extension period. Over 104 wks DAPA maintained reductions vs PBO for HbA1c, body weight (BW), systolic blood pressure (SBP), and fasting plasma glucose (FPG) (Table). Pts in the DAPA group showed a mean decrease of -8.7 IU/d in daily INS dose compared with PBO. A larger proportion of pts achieved a combined reduction of HbA1c ≥ 0.5%, BW ≥ 3% and SBP ≥ 3 mm Hg with DAPA compared with PBO (4.2% vs 1.1%); proportions were lower in both groups compared with earlier time points. In the safety population (N=965), for DAPA vs (vs) PBO, ≥ 1 adverse event was observed in 77.0% vs 72.5% of

pts, hypoglycaemic events in 30.7% (none major) vs 29.4% (2 major) of pts, and cardiac disorders in 10.0% vs 13.5% of pts, respectively. Events of genital infection were reported in 7.7% of DAPA vs 0.4% of PBO-treated pts; events of urinary tract infection were reported in 11.8% of DAPA vs 6.8% of PBO-treated pts. For DAPA vs PBO, mean percent changes were 3.6 vs -2.0 mg/dL in total cholesterol, 4.3 vs -1.3 mg/dL in HDL-C, and 5.5 vs -1.6 mg/dL in LDL-C, respectively.

**Conclusion:** When added to standard of care over 104 wks in older pts with advanced T2DM and preexisting CVD, DAPA treatment resulted in sustained reductions in HbA1c, FPG, SBP, and BW. Safety and tolerability were similar to PBO, except for a small excess of genital and urinary infections.

### Safety and tolerability of empagliflozin (EMPA) in phase III trials and their extension in patients with type 2 diabetes (T2DM)

M. Roden<sup>1</sup>, L. Merker<sup>2</sup>, A.V. Christiansen<sup>3</sup>, F. Roux<sup>4</sup>, S. Hantel<sup>5</sup>, A. Salsali<sup>6</sup>, G. Kim<sup>5</sup>, T. Meinicke<sup>5</sup>, S.S. Lund<sup>5</sup>, T. Hach<sup>5</sup>, H.J. Woerle<sup>5</sup>, U.C. Broedl<sup>5</sup>;

<sup>1</sup>Institute for Clinical Diabetology, German Diabetes Center, Leibniz Center for Diabetes Research, Düsseldorf, <sup>2</sup>Diabetes- und Nierenzentrum, Dormagen, Germany, <sup>3</sup>Boehringer Ingelheim Danmark A/S, Copenhagen, Denmark, <sup>4</sup>Boehringer Ingelheim France, Reims, France, <sup>5</sup>Boehringer Ingelheim, Ingelheim, Germany, <sup>6</sup>Boehringer Ingelheim Pharmaceuticals Inc., Ridgefield, USA.

**Background and aims:** Four 24-week randomized, double-blind, Phase III trials assessed the efficacy and safety of EMPA vs placebo (PBO) as monotherapy, add-on to metformin, add-on to metformin plus sulphonylurea, and add-on to pioglitazone ± metformin in patients with T2DM. Patients had the option to continue in 52-week double-blind extension trials. We assessed the safety and tolerability of EMPA using pooled data from these trials.

**Materials and methods:** In every trial, patients received EMPA 10 mg, EMPA 25 mg, or PBO until the last patient who entered the extensions had been treated for 76 weeks. Data were pooled from 2477 patients (N=825 on PBO, N=830 on EMPA 10 mg, N=822 on EMPA 25 mg) of whom 68.6% were treated in the extensions. Adverse events (AEs) were assessed descriptively in patients who took ≥1 dose of study drug. AEs included confirmed hypoglycaemic AEs (plasma glucose ≤70mg/dl and/or requiring assistance), AEs consistent with urinary tract infection (UTI), genital infection and volume depletion, identified using prospectively defined searches of investigator-reported AEs based on 77, 89 and 8 MedDRA preferred terms, respectively, and hepatic events identified from 4 Standardised MedDRA Queries.

**Results:** Total exposure was 1029, 1202 and 1162 patient-years in the PBO, EMPA 10 mg and EMPA 25 mg groups, respectively. The percentages of patients with any AE(s), with serious AE(s), and with AE(s) leading to treatment discontinuation were similar in the PBO, EMPA 10 mg and EMPA 25 mg groups (Table). Confirmed hypoglycaemic AEs were reported in slightly higher percentages of patients on EMPA 10 mg or EMPA 25 mg than PBO, but very few required assistance. Events consistent with UTI were reported by similar percentages of patients on PBO, EMPA 10 mg and EMPA 25 mg, and by more female than male patients. Events consistent with genital infection

were reported by a higher percentage of patients on EMPA than PBO, and by more female than male patients. AEs consistent with volume depletion were reported by 2 patients (0.2%) on PBO, 10 (1.2%) on EMPA 10 mg and 6 (0.7%) on EMPA 25 mg. Bone fractures were reported by 21 patients (2.5%) on PBO, 16 (1.9%) on EMPA 10 mg and 10 (1.2%) on EMPA 25 mg. Hepatic events were reported by 28 patients (3.4%) on PBO, 15 (1.8%) on EMPA 10 mg and 25 (3.0%) on EMPA 25 mg.

**Conclusion:** Based on assessment of AEs, EMPA 10 mg and EMPA 25 mg as monotherapy or add-on therapy for  $\geq 76$  weeks were well tolerated in patients with T2DM.

### Reduced risk of hypoglycaemic events with dapagliflozin vs glipizide as add-on therapy in type 2 diabetes mellitus: 4-year data from a phase 3 study

K. Rohwedder<sup>1</sup>, E. Johnsson<sup>2</sup>, S. Parikh<sup>3</sup>;

<sup>1</sup>AstraZeneca, Wedel, Germany, <sup>2</sup>AstraZeneca, Mölndal, Sweden,

<sup>3</sup>AstraZeneca, Wilmington, USA.

**Background and aims:** Dapagliflozin (DAPA), a selective inhibitor of the sodium-glucose co-transporter 2, reduces plasma glucose by increasing renal glucose excretion. Its insulin-independent mechanism results in a low risk of hypoglycaemia in contrast to sulphonylureas. In a phase 3, randomised, double-blind trial of DAPA versus glipizide in combination with metformin (MET) in adults with type 2 diabetes mellitus inadequately controlled by MET alone (N=814), DAPA was associated with reduced hypoglycaemic events versus glipizide over 52 weeks. We now report the 4-year hypoglycaemia- and key safety-related data.

**Materials and methods:** The phase 3, randomised, double-blind trial of DAPA ( $\leq 10$  mg/d) versus glipizide ( $\leq 20$  mg/d) in combination with MET (median 2000 mg/d) was extended from 52 weeks to 4 years. DAPA and glipizide were down-titrated if medically indicated.

**Results:** At the start of the study, 406 patients were randomised to the DAPA arm and 408 patients to the glipizide arm. The 4-year study was completed by 161 patients in the DAPA arm and by 141 patients in the glipizide arm. Including data after rescue, the rate of hypoglycaemia was ~10-fold less with DAPA (Table). Most events were minor (capillary or plasma glucose  $< 3.5$  mmol/L [ $< 63$  mg/dL]). The majority of hypoglycaemic events occurred during the first year of treatment: in year 1, 3.4% versus 39.7%, year 2, 1.6% versus 23.6%, year 3, 1.5% versus 37.2%, and in year 4, 2.2% versus 28.4% in the DAPA and glipizide arms, respectively. Study medication was down-titrated in the DAPA arm only during year 1, and in only 2.7% of patients. In the glipizide arm, 15.8% of patients had a down-titration in year 1, 1.9% in year 2, and 4.8% in years 3 and 4. Key adverse events are also shown in the Table. The effect of therapy on HbA1c attenuated over time in both arms, but DAPA showed more persistent benefits versus glipizide up to year 4 (Table).

**Conclusion:** Fewer patients experienced hypoglycaemic events over 4 years with DAPA than with glipizide as add-on therapy to MET. DAPA treatment in combination with MET was efficacious and well tolerated over a 4-year period.

|   | Glipizide + MET N=408 | DAPA + MET N=406                   |

### Risk factors associated with treatment discontinuation and down-titration in type 2 diabetes patients treated with sulfonylureas

K. Iglay<sup>1</sup>, Y. Qiu<sup>1</sup>, C.-P. Fan<sup>2</sup>, Z. Li<sup>2</sup>, J. Tang<sup>2</sup>, P. Laires<sup>1</sup>;<sup>1</sup>Merck & Co., Inc., Whitehouse Station, <sup>2</sup>Asclepius JT, New York, USA.

**Background and aims:** Sulfonylurea (SU) therapy can be discontinued or down-titrated for reasons such as hypoglycemia or weight gain. A retrospective cohort study using the MarketScan database was conducted to identify risk factors associated with therapy changes (ie, discontinuation or down-titration).

**Materials and methods:** Patients (pts) were included when the following criteria were satisfied: first SU prescription (Rx) (index date) between 2009 and 2011,  $\geq 18$  years of age on the index date, and  $\geq 1$  year continuous enrollment pre- and post-index. Pts with type 1, gestational or secondary diabetes, insulin use before the index date, or  $\geq 2$  SUs on the index date were excluded. Therapy changes were determined during the 1 year post-index period. Discontinuation occurred when the gap between the end date of current SU fill and the start date of subsequent fill was  $\geq 90$  days apart. Down-titration occurred when an SU fill had a lower equivalent dose than that on the index date. The Kaplan-Meier method was used to estimate 3- and 6-month therapy change rates. Cox regression was used to identify risk factors associated with therapy changes in hazard ratios (HRs).

**Results:** 104,082 pts were included, of which 55,233 (53.1%) experienced therapy changes in the 1-year post-index period. 3- and 6-month therapy change rates were 23.2% and 38.9%, respectively. Major risk factors associated with therapy changes were post-index hypoglycemic events (discontinuation HR= 1.78 [1.68, 1.90],  $p < .01$ ; down-titration HR=2.79 [2.40, 3.23],  $p < .01$ ) and concomitant use of insulin (discontinuation HR= 1.48 [1.40, 1.57],  $p < .01$ ; down-titration HR=1.82 [1.56, 2.11],  $p < .01$ ). Other risk factors include younger age, use of 2nd generation SUs, prior cardiovascular conditions and liver disease.

**Conclusion:** More than half of type 2 diabetes pts who newly initiated SU therapy experienced discontinuation or down-titration within 1 year following treatment initiation. Insulin use and hypoglycemic events elevated the risk of therapy changes.

809

### Severe hypoglycaemia during treatment with sulphonylurea in patients with type 2 diabetes in the capital region of Copenhagen, Denmark

S. Pilemann-Lyberg<sup>1,2</sup>, B. Thorsteinsson<sup>3,4</sup>, O. Snorgaard<sup>5</sup>, M. Zander<sup>6</sup>, H. Vestergaard<sup>7,8</sup>, M.E. Røder<sup>9</sup>;<sup>1</sup>Department of Endocrinology, Gentofte Hospital, <sup>2</sup>Diabetes complications research, Steno Diabetes Center, Gentofte, <sup>3</sup>Department of Cardiology, Endocrinology and Nephrology, Nordsjællands Hospital, Hillerød,<sup>4</sup>University of Copenhagen, <sup>5</sup>Department of Endocrinology, Hvidovre Hospital, <sup>6</sup>Department of Endocrinology, Bispebjerg Hospital, <sup>7</sup>Department of Endocrinology, Herlev Hospital, <sup>8</sup>NNF-CBMR, Copenhagen,<sup>9</sup>Department of Medicin F, Gentofte Hospital, Denmark.

**Background and aims:** Sulphonylureas (SU) are still recommended as a well established second line treatment in current guidelines for type 2-diabetes (T2DM). 16.865 patients in the Capital Region of Copenhagen were given SU as part of their treatment of T2DM in 2010-2011. Hypoglycaemia is a well-known side-effect, however to what extent SUs are associated with hospitalizations due to severe hypoglycaemic episodes, defined as episodes with a need for external assistance, less is known. The aim of the present study was to investigate the prevalence and characterize patients with type 2-diabetes treated with SU and hospitalized due to hypoglycaemia.

**Materials and methods:** All patients with ICD-10 diagnosis codes of hypoglycaemia and/or T2DM, in the hospital admittance register for a period of two years (2010-2011), were included. All hospitals in the Capital Region of Copenhagen were included. From the hospital records, patients who met the inclusion criteria were included in the analysis. Inclusion criteria were T2DM, hospitalization due to hypoglycemia and treatment with SU as monotherapy or in combination with other glucose-lowering drugs, excluding insulin treatment.

**Results:** From the hospital admittance register we found 3.156 patients admitted to hospital with T2DM and/or hypoglycaemia. Of these, 163 patients

fulfilled the inclusion criteria. The mean age was 76 (53-97) years and 54% were males. Nearly half of the patients were treated with SU monotherapy, 45% were treated with SU and metformin and 6% with triple therapy. Among the patients, 74% were on glimepiride, 15% glibenclamide, 6% gliplizide and 2% gliclazide treatment. Sixty percent of the patients had diabetic complications, including 19% with diabetic nephropathy. The major reason for the severe hypoglycaemic episodes was unchanged dose of SU despite of a significant decline in food intake (57%). In 10% of the patients (over)use of other medications, such as benzodiazepine and opioid drugs were recorded. In 6% of the patients intoxication by alcohol was noted as reason. A concomitant infection existed in 5%. In 22% of the patients more than one reason was listed, most common were unchanged dose of SU despite of a significant decline in food intake and concomitant infection. In 22%, the reason for hypoglycaemia was unknown.

**Conclusion:** In conclusion, the incidence of hospital admission-requiring severe hypoglycaemia in patients treated with SU seems relatively low (below 1% of SU-treated patients). It was mainly older patients with diminished food intake, (over) use of alcohol or other medications, and with concomitant diabetic complications.

### HNF1A and HNF4A mutations are associated with prolonged half-life of glibenclamide but not gliplizide in human MODY subjects

J. Urbanova<sup>1,2</sup>, M. Anděl<sup>1,2</sup>;<sup>1</sup>Center for Research in Diabetes, Metabolism and Nutrition, 2nd Department of Internal Medicine, Prague, <sup>2</sup>Third Faculty of Medicine, Charles University in Prague, Czech Republic.

**Background and aims:** Patients with Maturity Onset Diabetes of the Young (MODY), which is caused by mutations in the transcriptional factors HNF-1 $\alpha$  or HNF-4 $\alpha$ , display a hypersensitivity to the hypoglycaemic effects of sulfonylurea derivatives. The transcriptional network, including HNF-1 $\alpha$  and HNF-4 $\alpha$ , synergistically up-regulates the transcriptional activity of human xenobiotic-inducible genes, such as CYP2C9, which ensures the biotransformation of sulfonylurea derivatives in the liver. We hypothesized that MODY-associated HNF1A/HNF4A mutations induce the reduction of sulfonylurea derivatives clearance, thereby prolonging their action and promoting hypersensitivity in affected patients.

**Materials and methods:** Single doses of 3mg gliplizide and 5mg glibenclamide were administered sequentially to seven MODY subjects (six HNF1A-MODY and one HNF4A-MODY) and six age- and BMI-matched individuals with the wild-type sequence of HNF1A/HNF4A exons. Pharmacokinetics (plasma concentration levels, C<sub>max</sub>, t<sub>max</sub>, t<sub>1/2</sub>, AUC) and pharmacodynamics parameters (glycaemia, C-peptide and insulin plasma levels) were followed for 24 hours after the drug administration. CYP2C9 genotype was tested in each subject.

**Results:** Following gliplizide treatment, there were no significant decreases in any of the pharmacokinetic parameters as measured when comparing MODY and control subjects. In contrast, the responses to glibenclamide treatment displayed a prolonged t<sub>1/2</sub> from 5.0 $\pm$ 1.4h in control subjects to 9.5 $\pm$ 6.7h in HNF1A/HNF4A MODY subjects ( $p = 0.04$ ). When focusing on pharmacodynamics, we observed a differential response in control subjects to the doses of gliplizide and glibenclamide applied. However, this differential response was not achieved in MODY subjects, suggesting a partially different mechanism of action of gliplizide and glibenclamide.

**Conclusion:** It was only prolonged half-life of glibenclamide, but not gliplizide, which we observed in HNF1A/HNF4A MODY subjects compared to control subjects. Importantly, the response of individual MODY subject to gliplizide or glibenclamide treatment was highly correlated with each other (but not in control subjects), thereby providing a novel platform for the application of personalized medicine. Further research on the mutation-specific responses of HNF1A or HNF4A MODY subjects is needed.

**Impact of hypoglycaemic events and HbA1c level on SU discontinuation and down-titration**Y. Qiu<sup>1</sup>, P. Laires<sup>1</sup>, C.-P. Fan<sup>2</sup>, Z. Li<sup>2</sup>, J. Tang<sup>2</sup>, K. Iglay<sup>1</sup>;<sup>1</sup>Merck & Co., Inc., Whitehouse Station, <sup>2</sup>Asclepius JT, New York, USA.

**Background and aims:** A retrospective cohort study using GE Centricity electronic medical records (EMR) was conducted to assess the association of hypoglycemic events and HbA1c level with discontinuation and down-titration of sulfonylureas (SUs) among patients with type 2 diabetes mellitus (DM).

**Materials and methods:** Patients with  $\geq 12$  months EMR activity before and after initial SU prescription (index date) in 2010–2012 were included. Patients were excluded if they had type 1, gestational or secondary DM, received insulin before the index date, used  $\geq 2$  SUs on the index date, or had incomplete prescription data in 1 year post-index. Discontinuation occurred when consecutive SU prescriptions (Rx) were  $\geq 90$  days apart. Down-titration occurred when a subsequent SU Rx had a lower equivalent dose than the index dose. Post-index hypoglycemic events (identified using ICD-9 codes) occurred after the index date and before therapy changes or the end of the 1 year post-index. Multivariate Cox regression was used to assess the association of post-treatment hypoglycemic events and HbA1c with discontinuation/down-titration.

**Results:** 28,371 patients were included in the study, of which 13,459 (47.4%) were discontinuers, 717 (2.5%) down-titrators, and 14,195 (50.0%) continuers. 0.6% of the continuers had hypoglycemic events in the 1 year post-index period, compared to 3.1% of down-titrators and 0.8% of discontinuers ( $p < 0.01$ ). Patients with hypoglycemic events were at higher risk for discontinuation (HR = 1.82, [1.47, 2.23];  $p < 0.01$ ) and down-titration (HR = 4.25, [1.92, 8.03];  $p < 0.01$ ). Patients with higher post-index HbA1c levels or use of 2<sup>nd</sup> generation SUs (vs. 3<sup>rd</sup> generation) were at higher risk of discontinuation (HR = 1.05 [1.04, 1.06], and HR = 1.19 [1.14, 1.24] respectively, both  $p < 0.01$ ). **Conclusion:** Hypoglycemic events were a significant risk factor for SU discontinuation or down-titration. Higher HbA1c levels were significantly associated with SU discontinuation.

## 812

**Efficacy and safety of trelagliptin, a novel once-weekly oral DPP-4 inhibitor: a phase 3, double-blind, non-inferiority study in Japanese type 2 diabetes mellitus patients**N. Inagaki<sup>1</sup>, H. Onouchi<sup>2</sup>, H. Sano<sup>2</sup>, S. Kuroda<sup>2</sup>, K. Kaku<sup>3</sup>;<sup>1</sup>Department of Diabetes, Endocrinology and Nutrition, Kyoto University Graduate School of Medicine, <sup>2</sup>Pharmaceutical Development Division,

Takeda Pharmaceutical Company Limited, Osaka,

<sup>3</sup>Kawasaki Medical School, Okayama, Japan.

**Background and aims:** There are some options of oral hypoglycaemic agents for type 2 diabetes mellitus (T2DM). In patients with T2DM, improving adherence to medication is important in order to maintain favourable glycaemic control during long-term treatment and, thus prevent the onset or aggravation of complications. Trelagliptin is a novel dipeptidyl peptidase-4 (DPP-4) inhibitor, which is currently under development as a once-weekly oral hypoglycaemic agent. A phase 1 single-dose study (3.125 mg to 800 mg) and a multiple-dose study (100 mg or 200 mg) in healthy adult subjects were completed, and a dose-dependent increase in pharmacokinetic parameter values was observed. Sustained Inhibition of DPP-4 activity up to 168 hours after administration was also observed. Furthermore, a phase 2 dose-ranging study (12.5 mg to 200 mg; once-weekly for 12 weeks) in T2DM patients showed a statistically significant HbA1c reduction at all doses compared with placebo. Based on these results, a phase 3 study in T2DM patients was conducted to evaluate the efficacy and safety of once-weekly trelagliptin treatment compared with a daily DPP-4 inhibitor (alogliptin).

**Materials and methods:** This was a phase 3, multicentre, randomised, double-blind, parallel-group, non-inferiority study to evaluate the efficacy and safety of trelagliptin 100 mg once-weekly for 24 weeks with alogliptin 25 mg daily as a comparator in Japanese T2DM patients with inadequate glycaemic control despite diet and/or exercise therapy. A placebo group was also set as a reference group. Patients were randomly assigned (allocation ratio 2:2:1) to receive either trelagliptin, alogliptin or placebo. The primary endpoint was the change from baseline in HbA1c at the end of the treatment period.

**Results:** A total of 243 patients were enrolled to receive trelagliptin (n=101), alogliptin (n=92), or placebo (n=50). Baseline characteristics were as fol-

lows: mean age (SD) of 58.9 (10.39) years, mean BMI of 24.96 (4.161) kg/m<sup>2</sup> and mean HbA1c of 7.78 (0.837) %. There was no major difference among the treatment groups. At the end of the treatment period, the least square mean difference (trelagliptin - alogliptin) of change from baseline in HbA1c was 0.11% (95% CI: -0.054 to 0.281). Non-inferiority of trelagliptin group to alogliptin Group was attained. Additionally, HbA1c was decreased significantly in the trelagliptin and alogliptin groups compared to the placebo group at the end of the treatment period ( $p < 0.0001$ ). Inhibition rate of DPP-4 activity was also measured, and trelagliptin group showed sustained inhibition of DPP-4 activity throughout the treatment period. The frequency of adverse events in the trelagliptin group was similar to those in alogliptin and placebo groups. No hypoglycaemia was reported in trelagliptin group. Once-weekly treatment with trelagliptin was well tolerated and no major concern was seen.

**Conclusion:** In this study, once-weekly trelagliptin treatment was as effective as a daily DPP-4 inhibitor, alogliptin, and was well-tolerated over 24 weeks. It may provide a new treatment option for T2DM patients.

*Clinical Trial Registration Number: NCT01632007**Supported by: Takeda Pharmaceutical Company Limited*

## 813

**Cost-effectiveness of metformin plus vildagliptin versus metformin plus sulphonylurea for the treatment of type 2 diabetes patients in Portugal**D. Viriato<sup>1</sup>, F. Calado<sup>2</sup>, J.-B. Gruenberger<sup>2</sup>, S.H. Ong<sup>2</sup>, D. Carvalho<sup>3</sup>,J. Silva-Nunes<sup>4</sup>, S. Johal<sup>5</sup>, R. Viana<sup>1</sup>;<sup>1</sup>Novartis Farma SA, Porto Salvo, Portugal, <sup>2</sup>Novartis Pharma AG, Basel,Switzerland, <sup>3</sup>Faculty of Medicine, São João Hospital, Porto, <sup>4</sup>Curry CabralHospital, Lisbon, Portugal, <sup>5</sup>HERON Commercialization, London, UK.

**Background and aims:** The objective of the study is to evaluate the cost-effectiveness of vildagliptin plus metformin compared with generic sulphonylurea plus metformin in patients with type 2 diabetes mellitus, not controlled with metformin, from a Portuguese healthcare system perspective.

**Materials and methods:** A cost-effectiveness model was constructed using risk equations from the United Kingdom Prospective Diabetes Study Outcomes Model with a 10,000-patient cohort and a lifetime horizon. The model predicted microvascular and macrovascular complications and mortality in yearly cycles. Patients, who entered the model as metformin monotherapy failures, were modelled as switching to alternative treatments (metformin plus basal-bolus insulin and subsequently metformin plus intensive insulin) using a threshold of glycated haemoglobin A1c  $> 7.5\%$  for inadequate glycaemic control. Baseline patient characteristics and clinical variables were derived from a Portuguese epidemiological study. Costs estimates were based on direct medical costs only. One-way and probabilistic sensitivity analyses were conducted to test the robustness of the model assumptions.

**Results:** Over a lifetime horizon, there were fewer non-fatal diabetes-related adverse events (AEs) in patients treated with metformin plus vildagliptin compared with patients treated with metformin plus sulphonylurea (6752 versus 6815). Addition of vildagliptin compared with sulphonylurea led to increased drug acquisition costs counterbalanced with reduced costs of AEs, managing morbidities, and monitoring patients. Treatment with metformin plus vildagliptin yielded a mean per-patient gain of 0.1279 quality-adjusted life years (QALYs) and a mean per-patient increase in total cost of €1161, giving an incremental cost-effectiveness ratio (ICER) of €9072 per QALY. Univariate analyses showed that ICER values were robust and ranged from €4195 to €16,052 per QALY when different parameters were varied. The Probabilistic Sensitivity Analysis suggested that, for a willingness-to-pay threshold of €30,000 per QALY, treatment with metformin plus vildagliptin had a 79% probability of being cost-effective compared with metformin plus sulphonylurea.

**Conclusion:** Treatment with metformin plus vildagliptin compared with metformin plus sulphonylurea is expected to result in a lower incidence of diabetes-related AEs and to be a cost-effective treatment strategy.

## 814

### Predictors of glycaemic response to add-on therapy with a DPP-IV inhibitor: a retrospective cohort study using the primary care THIN database

J. Mamza<sup>1</sup>, R. Mehta<sup>2</sup>, R. Donnelly<sup>1</sup>, I. Idris<sup>1</sup>;

<sup>1</sup>School of Medicine,

<sup>2</sup>Trent Research Design Services, University of Nottingham, UK.

**Background and aims:** Apart from baseline HbA1c, little is known about clinical or biochemical factors that affect the magnitude of the glycaemic response to a DPP-IV inhibitor when used in routine practice as part of combination therapy in patients with type 2 diabetes. Similarly, there is limited information about the effectiveness of a DPP-IV inhibitor in different drug combinations. These subjects were investigated using a large UK Primary Care database.

**Materials and methods:** A cohort of 25,183 patients with type 2 diabetes, newly treated with a DPP-IV inhibitor between June 2007 and May 2013, was sourced from UK General Practices via the Health Initiative Network (THIN) database. The index date was defined as the date of initiation of DPP-IV inhibitor therapy. Baseline clinical parameters of patients with suboptimal glucose control (HbA1c >6.5% or 48mmol/mol) 6 months or more after starting a DPP-IV inhibitor in combination with other glucose-lowering therapy (n=17,697) were compared against 12-months follow-up data using multivariate logistic regression. Response to DPP-IV inhibitor therapy was defined as HbA1c <6.5% and/or >1% (13mmol/mol) reduction at 12 months. A comparative analysis of on-treatment effects of various combination regimens were examined using a propensity score matching technique. Associations were examined using t test and Chi squared test.

**Results:** Among patients whose glucose-lowering therapy was intensified by co-administration of a DPP-IV inhibitor, independent predictors of response were baseline HbA1c [1.57, 95%CI (1.53-1.61)], and use of metformin [1.31, 95%CI (1.20-1.44)] and aspirin [1.14, 95%CI (1.06-1.23)]. The independent predictors of non-response included obesity [0.82, 95%CI (0.72-0.93)], previous hypoglycaemia events [0.84, 95%CI (0.77-0.93)], total cholesterol level [0.94, 95%CI (0.90-0.97)], concurrent use of lipid lowering drugs [0.88, 95%CI (0.81-0.97)], and combination therapy involving metformin, sulphonylurea and thiazolidinediones (TZDs) [0.80, 95%CI (0.70-0.91)]. Overall, intensification of therapy with the addition of a DPP-IV inhibitor resulted in significant reductions in HbA1c (0.5%, 6.5mmol/mol), body weight (1Kg) and total cholesterol 0.1mmol/L (p<0.001). Using propensity score analysis, the addition of a DPP-IV inhibitor to metformin monotherapy yielded a 5% greater glycaemic effect [1.05, 95%CI (1.02-1.07)] compared with other regimens, while adding a DPP-IV inhibitor to Metformin+ Sulphonylurea+TZD had a negative effect on glucose control [0.95, 95%CI (0.93-0.98)].

**Conclusion:** This large Primary Care database shows that in routine clinical practice the glycaemic response to a DPP-IV inhibitor is greatest in patients concurrently receiving metformin and aspirin and those with higher baseline HbA1c. Lower responses were observed in those on triple therapy (Met+SU+TZD) and with previous hypoglycaemic events. Serum lipids and statin therapy may also influence the response to a DPP-IV inhibitor.

## 815

### Efficacy and safety of initial therapy with linagliptin and pioglitazone fixed-dose combinations versus monotherapy with pioglitazone or linagliptin

S. Weber-Born<sup>1</sup>, M. Nauck<sup>2</sup>, S. Patel<sup>3</sup>, M. Kobe<sup>4</sup>, R. Toorawa<sup>3</sup>, H.-J. Woerle<sup>1</sup>;

<sup>1</sup>Boehringer Ingelheim Pharma GmbH & Co. KG, Ingelheim,

<sup>2</sup>Diabetes Centre Bad Lauterberg, Harz, Germany,

<sup>3</sup>Boehringer Ingelheim Ltd, Bracknell, UK,

<sup>4</sup>Boehringer Ingelheim Pharmaceuticals Inc., Ridgefield, USA.

**Background and aims:** Targeting the core defects in type 2 diabetes (T2D) by combining oral antidiabetes drugs (OAD) with different mechanisms of action may produce additive improvements in glycaemic control. This study evaluated the efficacy and safety of fixed-dose combinations (FDC) of the DPP-4 inhibitor linagliptin (LINA) plus the thiazolidinedione pioglitazone (PIO) vs LINA or PIO monotherapy.

**Materials and methods:** This multicentre, double-blind, parallel group, phase 3 study randomised 936 T2D patients with insufficient glycaemic control to 1 of 7 treatment arms: LINA+PIO FDC (LINA5 mg plus PIO15, 30, or 45 mg) or monotherapy with LINA5 mg or PIO15, 30, or 45 mg. An initial 30-wk treatment (Part A) was followed by a 54-wk extension (Part B; 557

patients) in which LINA+PIO FDC (LINA5 mg plus PIO30 or 45 mg) were further assessed vs LINA5 mg or PIO30 or 45 mg monotherapy. The primary endpoint was HbA1c change from baseline after 30 wks (FAS LOCF).

**Results:** At baseline, 54.8% were male, 85.1% were white, mean ± sd age was 57 ± 11 yrs, and weight was 93.1 ± 19.5 kg. In the full analysis set (n=893), 68.1% had T2D for ≤5 years, 33.9% received ≥1 prior OAD, and mean ± sd HbA1c was 8.1 ± 0.9%. The FDC arms had larger decreases from baseline after 30 wks in HbA1c than the respective monotherapies (Part A; Figure). At 84 wks (Part B), mean ± sd change from baseline in HbA1c ranged from -0.61 ± 0.61% (LINA; n=12) to -1.30 ± 0.78% (LINA+PIO45 FDC; n=15). In patients with baseline HbA1c ≥7.0%, each FDC arm was more likely than LINA monotherapy to achieve HbA1c <7.0% at wk 30 (p<0.001); in the comparison vs PIO monotherapy, only LINA+PIO45 FDC was more likely than PIO45 to achieve HbA1c <7.0% (p=0.0254). Adjusted mean ± se changes from baseline after 30 wks in FPG ranged from -0.08 ± 0.19 mmol/l (LINA) to -1.95 ± 0.19 mmol/l (LINA+PIO45 FDC). Adjusted mean ± se body weight changes were lower with LINA monotherapy (-0.62 ± 0.76 kg) and FDC (range: +0.63 ± 0.70 kg to +1.50 ± 0.74 kg) than with PIO monotherapy (range: +1.53 ± 0.78 kg to +3.24 ± 0.73 kg). In the safety analysis (up to 84 wks from Parts A and B combined), frequencies of overall AEs and serious AEs ranged from 65.7% (PIO30) to 74.6% (PIO45) and 3.6% (PIO45) to 11.3% (LINA+PIO30 FDC), respectively. Drug-related AEs ranged from 11.1% (LINA+PIO15/30 FDC) to 16.5% (LINA+PIO45 FDC). Predefined AEs of oedema ranged from 4.4% (LINA) to 12.8% (LINA+PIO45 FDC). One on-treatment fatality was reported (PIO45). Frequency of investigator-reported hypoglycaemia was ≤1.5% per arm. One patient had severe hypoglycaemia (LINA+PIO15/30 FDC).

**Conclusion:** FDC therapy with LINA+PIO was well tolerated with no new safety concerns compared with the known safety profiles of the individual monotherapies and had possible additive effects on glycaemic control; in addition, LINA attenuated the weight gain effects of PIO.

**Vildagliptin as add-on to insulin improves glycaemic control without increased risk of hypoglycaemia in Asian (predominantly Chinese) patients with type 2 diabetes mellitus**

G. Ning<sup>1</sup>, W. Wang<sup>1</sup>, L. Li<sup>2</sup>, J. Ma<sup>3</sup>, X. Lv<sup>4</sup>, M. Yang<sup>5</sup>, W. Wang<sup>5</sup>, M. Woloschak<sup>6</sup>, V. Lukashevich<sup>6</sup>, W. Kothny<sup>7</sup>;

<sup>1</sup>Ruijin Hospital, Shanghai Jiao-Tong University School of Medicine, <sup>2</sup>Shengjing Hospital of China Medical University, Shenyang, <sup>3</sup>Nanjing First Hospital, <sup>4</sup>General Hospital of Beijing Military Region, <sup>5</sup>Beijing Novartis Pharma Co., Ltd., Shanghai, China, <sup>6</sup>Novartis Pharmaceuticals Corporation, East Hanover, USA, <sup>7</sup>Novartis Pharma AG, Basel, Switzerland.

**Background and aims:** There are limited data from randomized controlled trials evaluating the efficacy and safety of oral antidiabetic drugs in combination with insulin in Asian patients with T2DM, who may be at higher risk of hypoglycaemia due to lower weight and increased insulin sensitivity. Here we present the efficacy and safety of vildagliptin in combination with insulin with or without metformin from a dedicated Asian study in a predominantly Chinese population with T2DM.

**Materials and methods:** In this 24-week, multicentre, double-blind, placebo-controlled trial, patients with T2DM inadequately controlled (HbA1c 7.5–11.0%) on stable therapy with long-acting, intermediate-acting or premixed insulin, with or without concomitant metformin were randomized to receive vildagliptin 50 mg bid (n=146) or placebo (n=147). The primary efficacy endpoint was change in HbA1c from baseline to week 24. Key secondary endpoints included change in FPG and the proportion of patients achieving HbA1c <7.0%. Safety and tolerability were also assessed.

**Results:** Of the 293 randomized patients, 276 completed the study. The demographic and baseline characteristics of patients were comparable between the groups. At baseline the mean age of patients was 58.1 years, mean T2DM duration was 11.3 years, mean FPG was 9.5 mmol/L, mean BMI was 26.1 kg/m<sup>2</sup> and mean HbA1c was 8.7%. At baseline, 71% of patients were on stable metformin therapy. The mean doses of insulin and metformin were 32.5 U/day and 1587.7 mg/day, respectively. After 24 weeks vildagliptin showed a clinically relevant and statistically significant reduction in HbA1c vs. placebo (-1.1% vs. -0.4%, respectively; p<0.001). The decrease in FPG from baseline was numerically higher in the vildagliptin group than in the placebo group (-0.72 mmol/L vs. -0.28 mmol/L; p=0.250). The proportion of patients achieving HbA1c <7.0% was significantly higher in the vildagliptin group than in the placebo group (23.6% vs. 11.1%, p<0.005). The overall incidences of adverse events were 43.8% vs. 46.3% and serious adverse events were 3.4% vs. 6.8% in the vildagliptin and placebo groups, respectively. Hypoglycaemia was less frequent with vildagliptin (n=4, 2.7%) than with placebo (n=8, 5.4%); one patient in the placebo group reported a severe hypoglycaemic event. No deaths were reported during the study.

**Conclusion:** In Asian (predominantly Chinese) patients with T2DM inadequately controlled on insulin (with or without metformin), the addition of vildagliptin 50 mg bid significantly improved glycaemic control without an increased risk of hypoglycaemia. Vildagliptin is an attractive treatment for these patients.

## 817

**The cost-effectiveness of canagliflozin (CANA) versus sitagliptin (SITA) as third-line therapy in the treatment of type 2 diabetes mellitus (T2DM) in the UK**

G. Thompson<sup>1</sup>, M. Schroeder<sup>1</sup>, C. Neslusan<sup>2</sup>, M. Willis<sup>3</sup>, P. Johansen<sup>3</sup>, A. Teschemaker<sup>2</sup>;

<sup>1</sup>Janssen UK, High Wycombe, UK, <sup>2</sup>Janssen Global Services, LLC, Raritan, USA, <sup>3</sup>The Swedish Institute for Health Economics, Lund, Sweden.

**Background and aims:** CANA is a novel treatment for T2DM that inhibits the sodium glucose co-transporter 2, a mechanism that is complementary to other anti-hyperglycemic drug classes, including insulin. In a previously reported analysis of a randomized, double-blind, active-controlled, Phase 3 study in 756 subjects inadequately controlled on dual therapy with metformin (MET) and sulfonylureas (SU), CANA 300mg demonstrated statistical superiority compared to SITA 100mg in lowering HbA1c at 52 weeks (-1.03% [-11.3 mmol/mol] and -0.66% [-7.2 mmol/mol], respectively; least squares mean difference -0.37% [95% CI, -0.50 to -0.25] or -4.0 mmol/mol [-5.5 to -2.7]). CANA 300mg also significantly reduced systolic blood pressure (SBP) and body weight (BW) versus SITA 100mg (SBP: -5.1 mmHg; 0.9 mmHg), (BW: -2.5%; 0.3%). The objective of this study was to evaluate the long-term cost-effectiveness of using CANA 300mg versus SITA 100mg as an add-on therapy in patients inadequately controlled on a background of MET plus SU in the UK.

**Materials and methods:** Outcomes and costs associated with CANA 300mg versus SITA 100mg in triple therapy with background MET plus SU were simulated over 40 years using ECHO (Economic and Health Outcomes)-T2DM, a validated micro-simulation model. Treatment effects (HbA1c, BW, SBP, LDL and HDL cholesterol) and incidence of adverse events (AEs) were sourced from the trial. Simulated treatment was intensified when HbA1c exceeded 7.5% by adding basal insulin, and subsequently prandial insulin. Costs and quality of life impacts associated with the development of micro- and macro-vascular events and AEs were adapted to the UK setting. In the base case, initial patient characteristics were sourced from the trial. In a second simulation, initial patient characteristics were based on a sample of patients with T2DM in the THIN (The Health Improvement Network) database, a large anonymised primary care electronic medical record data resource representative of UK population.

**Results:** In the base case simulation, use of CANA 300mg versus SITA 100mg as an add-on in patients inadequately controlled on MET plus SU increased Quality-Adjusted Life-Years (QALYs) (0.04). Total lifetime treatment costs for CANA 300mg were marginally higher (£671), yielding an incremental cost-effectiveness ratio (ICER) of £17,813. The scenario that used baseline patient characteristics from the UK THIN database also yielded an increase in QALYs (0.02), with a corresponding ICER of £17,968.

**Conclusion:** The magnitudes of the ICERs estimated in these simulations are below the current threshold used in the UK to assess whether an intervention is cost-effective. As such, treating patients inadequately controlled on MET plus SU with CANA 300mg is likely to be a more efficient use of limited health care resources compared to using SITA 100mg.

**Effect of empagliflozin compared with glimepiride as add-on to metformin for 2 years on the amount and distribution of body fat in patients with type 2 diabetes**

G. Kim<sup>1</sup>, M. Ridderstråle<sup>2</sup>, K.R. Andersen<sup>3</sup>, C. Zeller<sup>4</sup>, H.J. Woerle<sup>1</sup>, U.C. Broedl<sup>1</sup>;

<sup>1</sup>Boehringer Ingelheim Pharma GmbH & Co. KG, Ingelheim, Germany, <sup>2</sup>Steno Diabetes Center, Gentofte, Denmark, <sup>3</sup>Boehringer Ingelheim Norway KS, Asker, Norway, <sup>4</sup>Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach, Germany.

**Background and aims:** In a randomized, double-blind, Phase III trial in patients with type 2 diabetes (T2DM), the SGLT2 inhibitor empagliflozin (EMPA) 25 mg qd as add-on to metformin for 104 weeks led to significant

and sustained reductions in body weight compared with an increase in body weight with glimepiride (GLIM). Patients had the option to participate in a dedicated body composition sub-study in which we aimed to determine the effects of EMPA vs GLIM on the amount and distribution of body fat.

**Materials and methods:** Body composition was evaluated in 91 randomised patients in the sub-study. Using whole body dual energy X-ray absorptiometry (DXA), changes from baseline to week 52 and week 104 in trunk fat, limb fat, total fat mass and fat-free mass were assessed in 62 patients (36 receiving EMPA and 26 receiving GLIM). Using magnetic resonance imaging (MRI), changes from baseline to week 52 and week 104 in abdominal visceral adipose tissue (VAT) and abdominal subcutaneous adipose tissue (SAT) were assessed in 51 patients (29 receiving EMPA and 22 receiving GLIM). Changes from baseline were evaluated using mixed model repeated measures (MMRM) analyses.

**Results:** In the 91 patients evaluated in the sub-study, baseline mean [SD] age was 55.7 [10.4] years, weight was 85.1 [14.7] kg, BMI was 31.9 [4.9] kg/m<sup>2</sup> and 60% had BMI ≥30 kg/m<sup>2</sup>. EMPA significantly reduced trunk fat, limb fat and total fat mass vs GLIM at week 52 and week 104 (table). EMPA also significantly reduced fat-free mass vs GLIM at week 52 but not at week 104 (table). Adjusted mean (SE) changes from baseline in abdominal VAT at week 52 were -15.5 (5.2) cm<sup>2</sup> with EMPA compared with +10.0 (6.1) cm<sup>2</sup> with GLIM ( $p<0.01$ ) and at week 104 were 16.0 (8.4) cm<sup>2</sup> with EMPA compared with +17.7 (10.0) cm<sup>2</sup> with GLIM ( $p<0.05$ ). Adjusted mean (SE) changes from baseline in abdominal SAT at week 52 were 29.9 (7.3) cm<sup>2</sup> with EMPA compared with +25.8 (8.6) cm<sup>2</sup> with GLIM ( $p<0.001$ ) and at week 104 were 32.5 (9.2) cm<sup>2</sup> with EMPA compared with +34.4 (10.7) cm<sup>2</sup> with GLIM ( $p<0.001$ ).

**Conclusion:** When used as add-on to metformin, treatment with EMPA led to reductions in trunk fat, limb fat, abdominal VAT and SAT at week 52 and further reductions at week 104 compared with GLIM. Reductions in fat-free mass with EMPA vs GLIM were observed at week 52 but not at week 104.

### Empagliflozin decreases inflammation and AGE/RAGE markers in the aortic vessel wall of a streptozotocin type 1 diabetic model

S. Steven<sup>1</sup>, M. Oelze<sup>1</sup>, S. Kröller-Schön<sup>1</sup>, P. Welschof<sup>1</sup>, Y. Mikhed<sup>1</sup>, S. Abgdauletova<sup>1</sup>, E. Schulz<sup>1</sup>, E. Mayoux<sup>2</sup>, T. Münzel<sup>1</sup>, A. Daiber<sup>1</sup>;

<sup>1</sup>Department of Cardiology, 2nd Medical Clinic of the University Medical Center, Mainz, <sup>2</sup>Boehringer Ingelheim Pharma GmbH & Co. KG, CardioMetabolic Diseases Research, Ingelheim, Germany.

**Background and aims:** Hyperglycemia and associated glucotoxicity is a major cause of vascular complication in patients with Type 1 and Type 2 diabetes. Pharmacological interventions, aiming to decrease blood glucose via stimulation of glucose entry in the tissues appeared unsuccessful to decrease significantly the cardiovascular complications and associated mortality. SGLT2 inhibitors may interrupt the vicious cycle of maintaining glucotoxicity within the tissue in particular in the vessel walls by excreting glucose out of the body rather than pushing it back into the tissue. Therefore we investigated whether empagliflozin, a potent and selective SGLT2 inhibitor has the potential to decrease the inflammation and AGE/RAGE signalling in aortic vessel wall of streptozotocin (STZ) type 1 animal model.

**Materials and methods:** Type 1 diabetes in Wistar rats was induced by an intravenous injection of STZ (60mg/kg). One week after injection, empagliflozin was administered via drinking water at two doses (10mg/kg Lo dose,

and 30mg/kg Hi dose) for 8 weeks. Two control groups were run in parallel, non-diabetic animals and diabetic animals treated with solvent in drinking water. At the end of treatment, animals were sacrificed and blood sample and aortic vessel wall collected for analysis. Glucose and methylglyoxal (by HPLC) were determined in blood. In vessel wall, several markers of inflammatory pathway, AGE-positive protein, RAGE expression, were determined by quantitative rtPCR or western blot analysis.

**Results:** Plasmatic glucose and HbA1c were significantly decreasing in a dose dependant manner with empagliflozin treatments. The expression of the NADPH oxidase isoforms Nox1 and Nox2 as well as the general stress response enzyme heme oxygenase-1 (HO-1) was increased in diabetes and significantly reduced by SGLT2i therapy. Aortic RAGE expression and levels of AGE-positive proteins was increased in the STZ group and normalized by SGLT2i therapy. In line with this, serum levels of the AGE precursor methylglyoxal were significantly increased in the STZ group and improved by SGLT2i therapy. The inflammatory genes monocyte chemoattractant protein-1 (MCP-1, CCL-2), the monocyte/macrophage-specific protein CD68 and the cytokine interleukin-6 (IL-6) were up-regulated at the mRNA level in the aorta and significantly reduced by both SGLT2i doses. Likewise the immune-signaling proteins interferon- $\gamma$  (IFN- $\gamma$ ), tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) and the general markers of inflammation, cyclooxygenase-2 (COX-2) or intercellular adhesion molecule-1 (ICAM-1) were all up-regulated in STZ-treated rats and reduced by SGLT2i therapy.

**Conclusion:** These results show that the specific SGLT2 inhibitor, empagliflozin, by decreasing blood glucose via its excretion in urine is able to decrease several markers of oxidative stress, inflammation and AGE/RAGE signaling in aortic vessel wall of Type 1 diabetic animals. Therefore these results support the improvement of endothelial function that we have observed with empagliflozin in this model and are very promising in term of long term effects of empagliflozin on cardiovascular complications. Ongoing cardiovascular trials in Type 2 diabetic population will address this question.

### Predicted temporal changes in energy intake and energy expenditure in subjects with type 2 diabetes treated with canagliflozin

D. Polidori<sup>1</sup>, A. Sanghvi<sup>2</sup>, R. Seeley<sup>3</sup>, K. Hall<sup>2</sup>;

<sup>1</sup>Janssen Research & Development, LLC, San Diego,

<sup>2</sup>National Institute of Diabetes and Digestive and Kidney Diseases,

National Institutes of Health, Bethesda, <sup>3</sup>University of Cincinnati, USA.

**Background and aims:** Canagliflozin (CANA), an SGLT2 inhibitor approved for the treatment of type 2 diabetes, reduces plasma glucose concentrations by increasing urinary glucose excretion (UGE), with sustained increases in UGE of ~80–120 g/day (~320–480 kcal/day) observed with CANA treatment. CANA treatment also induces weight loss, with body weight (BW) decreasing for approximately 26 weeks before reaching a new, lower steady-state BW that is maintained with sustained CANA treatment. Data from animal studies and small short-term studies in humans suggest that energy intake (EI) is increased in response to SGLT2 inhibition. The aim of this analysis was to calculate the temporal changes in energy expenditure (EE) and EI that occur with CANA treatment.

**Materials and methods:** Data from a 52-week Phase 3 study comparing the efficacy of placebo (PBO), CANA 100 mg, and CANA 300 mg were used in the analysis (N = 371, mean (SD) baseline BW = 87 (21) kg, HbA1c = 7.8 (0.8)%, 55% female). Following the 26-week core study period, PBO-treated subjects were switched to sitagliptin (SITA) 100 mg (which is BW neutral) for the remaining 26 weeks. BW was measured approximately every 6 weeks and treatment-induced UGE increases of 0, 80, and 90 g/day were assumed for PBO/SITA, CANA 100 mg, and CANA 300 mg, respectively, based on data from previous studies. A previously validated mathematical model was used to calculate the changes in EE and EI in each treatment group based on the measured BW and UGE data.

**Results:** CANA treatment dose-dependently reduced BW (Figure A), with mean (SE) reductions in BW of 0.9 (0.4)%, 3.3 (0.4)%, and 4.5 (0.3)% observed at Week 52 for PBO/SITA, CANA 100 mg, and CANA 300 mg, respectively ( $p<0.001$  for both CANA doses vs. PBO/SITA). EI increased over time in CANA-treated subjects until approximately Week 26 when the sustained increase in daily EI nearly matched the daily caloric loss due to UGE (Figure B), thereby obtaining a new state of energy balance and a stable BW. Only small changes in EE were predicted, as the decrease in metabolic rate associated with weight-loss was nearly balanced by increased dietary thermogenesis arising from increased EI (Figure B).

**Conclusion:** CANA treatment reduces BW due to UGE-associated caloric loss. The sustained UGE increase leads to a period of weight loss followed by a plateau in which a lower equilibrium BW is maintained. The plateau in BW is predicted to be due to sustained increases in EI that match the caloric loss to UGE, with only minimal changes in EE predicted.

**The SGLT2 inhibitor empagliflozin ameliorates early features of diabetic nephropathy in BTBR ob/ob type 2 diabetic mice with and without hypertension**

F. Gembardt<sup>1</sup>, C. Bartaun<sup>1</sup>, N. Jarzebska<sup>1</sup>, E. Mayoux<sup>2</sup>, V.T. Todorov<sup>1</sup>, B. Hohenstein<sup>1</sup>, C. Hugo<sup>1</sup>;

<sup>1</sup>Department of Internal Medicine III - Nephrology, University Hospital Carl Gustav Carus, Dresden, Germany, <sup>2</sup>Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach a. d. Riss, Germany.

**Background and aims:** Diabetic nephropathy is the leading cause of end-stage renal disease in man in the western world. Recent development of sodium-glucose co-transporter 2 (SGLT2) inhibitors offers a new anti-diabetic therapy via enhanced glucose excretion. Whether this strategy exerts beneficial effects on developing type 2 diabetic nephropathy is unclear. We investigated the effects of the SGLT2 inhibitor empagliflozin in BTBR ob/ob mice, which spontaneously develop type 2 diabetic nephropathy.

**Materials and methods:** In a first experiment, BTBR ob/ob mice either received a diet containing 300ppm empagliflozin or equicaloric placebo chow for 12 weeks. In a second experimental setting, BTBR ob/ob mice received angiotensin (Ang) II and were separated in the same 2 diet groups for 6 weeks. Urine, blood, and tissues were harvested and blood pressure was monitored by tail cuff measurements.

**Results:** In both experiments, empagliflozin treatment enhanced glucosuria, (6,987±987μmol/mg Crea vs 2,182±972μmol/mg Crea;  $P<0.001$ ; Ang II: 9,716±658μg/mg Crea vs 5,303±947μg/mg Crea;  $P<0.05$ ) thereby lowering blood glucose (204±16 vs 402±27mg/dl  $P<0.001$ ; Ang II: 170±20 vs 410±39mg/dl  $P<0.01$ ). While Ang II infusion induced profound hypertension (146±4 vs 84±1mmHg,  $P<0.0001$ ), empagliflozin treatment had no significant effect on blood pressure in normotensive or hypertensive mice (81±1 vs 84±1mmHg; 139±6 vs 146±4mmHg). In both experiments, empagliflozin reduced albuminuria in diabetic mice (2,291±524 vs 834±135μg/mg Crea,  $P<0.001$ ; Ang II: 4,869±1776 vs 1,470±226μg/mg Crea,  $P<0.05$ ). Empagliflozin treatment did not affect matrix expansion as evaluated by immunohistochemistry, while it decreased the diabetes-related glomerular hypertrophy in normotensive BTBR ob/ob mice (3,392±100.9 vs 3,646±59.8 μm<sup>2</sup>,  $P<0.05$ ), but not in hypertensive mice (3,786±230.0 vs 3,877±88.6 μm<sup>2</sup>). After 6 weeks, diabetic BTBR ob/ob mice on the placebo diet showed a significant increased MCP-1 (~1.4-fold;  $P<0.05$  vs WT), RANTES (~2.6-fold;  $P<0.05$  vs WT), and IL-6 (~2.4-fold;  $P<0.05$  vs WT) mRNA expression. While none of these inflammatory markers were significantly affected after 6 weeks of empagliflozin treatment, 12 weeks of empagliflozin treatment reduced renal mRNA expression of MCP-1 by ~75% ( $P<0.05$  vs placebo), of RANTES by ~55% ( $P<0.05$  vs placebo), and of IL-6 by 52% ( $P<0.05$  vs placebo).

**Conclusion:** Taken together, our present results confirm that SGLT2 inhibition by empagliflozin is a good therapeutic option to lower blood glucose levels and improve albuminuria in a type 2 diabetes model without or with hypertension. Moreover, empagliflozin treatment differentially ameliorates markers of renal injury such as glomerular hypertrophy in murine diabetic nephropathy without hypertension. In conclusion these results support the concept of SGLT2 inhibition for the prevention of diabetic nephropathy.

**Dapagliflozin lowers blood pressure in hypertensive and nonhypertensive patients with type 2 diabetes**

D. Sjöström<sup>1</sup>, P. Johansson<sup>1</sup>, A. Ptaszynska<sup>2</sup>, J. List<sup>2</sup>, E. Johnsson<sup>1</sup>;

<sup>1</sup>AstraZeneca, Mölndal, Sweden, <sup>2</sup>Bristol-Myers Squibb, Princeton, USA.

**Background and aims:** Consistent with mild diuresis and weight loss, dapagliflozin (DAPA), a highly selective sodium-glucose co-transporter 2 inhibitor, also reduces BP in patients (pts) with type 2 diabetes mellitus (T2DM). High BP is associated with an increased risk of cardiovascular events and reducing BP has been shown to reduce this risk regardless of pretreatment BP. Therefore, it is of interest to investigate the ability of DAPA to safely reduce BP across different BP categories in the T2DM population. These analyses evaluated the effect of DAPA on BP in hypertensive (baseline [BL] systolic BP [SBP] > 140) and nonhypertensive (BL SBP ≤ 140) pts across the phase 2b/3 clinical development programme.

**Materials and methods:** Safety data were pooled from 13 placebo (PBO)-controlled studies in which pts with T2DM were randomised to DAPA 10 mg/d (N=2360) or PBO (N=2295) for up to 24 weeks.

**Results:** At BL, 91.5% and 91.1% of the hypertensive pts were being treated with antihypertensive medications in the DAPA and PBO groups, respectively, compared with 68.2% and 72.6% of the pts in the nonhypertensive group. In studies with 24 weeks of follow-up, treatment with DAPA resulted in mean PBO subtracted changes (95% CI) in SBP of -3.6 (-4.9 to -2.3) mm Hg in hypertensive, and -2.6 (-3.4 to -1.8) mm Hg in nonhypertensive pts (figure). The corresponding data for diastolic BP (DBP) were -1.2 (-2.0 to -0.4) mm Hg and -1.2 (-1.7 to -0.7) mm Hg, respectively. The difference from PBO in proportion of pts with any measured orthostatic reaction (defined as a decrease from supine to standing of > 20 mm Hg in SBP or > 10 mm Hg in DBP) over 24 weeks was similar in hypertensive (DAPA, 17.4%; PBO, 15.5%), and nonhypertensive (DAPA, 11.4%; PBO, 9.6%) pts. At the 24-week visit there was no increase in the proportion of pts with measured orthostatic reactions in DAPA-treated vs PBO-treated pts in either hypertensive (6.1% vs 6.6%) or nonhypertensive (4.0% vs 4.2%) pts. Adverse events registered under the preferred term "orthostatic hypotension" were rare and none were classified as serious. The highest rate (0.4%) was registered in the nonhypertensive PBO group. There was no clinically significant mean change in heart rate with DAPA in either hypertensive or nonhypertensive pts (-0.5 and 0.1 beats/min, respectively). The proportion of pts on antihypertensive drugs was stable over the observation period (change ≤ 1%).

**Conclusion:** DAPA 10 mg induces a modest BP reduction across BP categories and may thereby contribute to a reduced cardiovascular risk in hypertensive as well as nonhypertensive T2DM pts. The potential of DAPA to reduce cardiovascular events is currently under investigation in a large-scale outcomes study, DECLARE.

**Sodium glucose cotransporter 2 inhibition with empagliflozin reduces microalbuminuria in patients with type 2 diabetes**

D. Cherney<sup>1</sup>, M. von Eynatten<sup>2</sup>, S.S. Lund<sup>3</sup>, S. Kaspers<sup>3</sup>, S. Crowe<sup>3</sup>, H.J. Woerle<sup>3</sup>, T. Hach<sup>3</sup>;

<sup>1</sup>Toronto General Hospital, University of Toronto, Canada, <sup>2</sup>Boehringer Ingelheim Pharmaceuticals, Inc., Ridgefield, USA, <sup>3</sup>Boehringer Ingelheim Pharma GmbH & Co. KG, Ingelheim, Germany.

**Background and aims:** Empagliflozin (EMPA) is a sodium glucose cotransporter 2 (SGLT2) inhibitor that lowers HbA1c, blood pressure (BP) and weight in patients with type 2 diabetes (T2D) and has similar potential in type 1 diabetes (T1D). It has also been shown that EMPA reduces renal hyperfiltration associated with T1D, suggesting a renoprotective reduction in intraglomerular pressure. Based on preclinical data, we hypothesised that the addition of EMPA to standard care, including stable doses of renin-angiotensin system inhibitors (RASi), would reduce microalbuminuria versus placebo, consistent with attenuated renal injury.

**Materials and methods:** This post-hoc analysis assessed the effect of EMPA on urine albumin to creatinine ratio (UACR). Data were pooled from 458 patients with T2D and pre-existing microalbuminuria (UACR 30–300 mg/g; mean [SD] estimated glomerular filtration rate [eGFR; modification of diet in renal disease] 87.9 [23.3] mL/min/1.73m<sup>2</sup>; mean [SD] age 56.7 [10.1] years) who had participated in 1 of 4 Phase III randomised placebo-controlled tri-

als. Changes in UACR were assessed in 438 patients who received EMPA 10 mg (n=141), EMPA 25 mg (n=150) or placebo (n=147) for 24 weeks.

**Results:** After controlling for baseline log-transformed UACR, HbA1c, systolic BP, eGFR, region, trial and treatment, EMPA 10 mg and EMPA 25 mg significantly reduced UACR by 30% and 25%, respectively, compared with placebo at week 24 (Table; p<0.01).

**Conclusion:** EMPA 10 mg and EMPA 25 mg reduced microalbuminuria by a clinically meaningful amount when used as add-on to standard therapy including stable RASi in patients with T2D. Prospective studies are needed to examine the potential renal protective effects of EMPA in patients with T1D and in patients with T2D.

**Albuminuria, the sentinel marker of renal failure, is consistently decreased with empagliflozin in several preclinical models of diabetic nephropathy**

M. Mark<sup>1</sup>, V. Vallon<sup>2</sup>, C. Hugo<sup>3</sup>, R.J. Roman<sup>4</sup>, E. Mayoux<sup>1</sup>;

<sup>1</sup>Cardiometabolic, Boehringer-Ingelheim, Biberach, Germany, <sup>2</sup>University of California, San Diego, USA, <sup>3</sup>University Hospital CGC, Dresden, Germany, <sup>4</sup>University of Mississippi Medical Center, Jackson, USA.

**Background and aims:** Diabetic nephropathy (DN) is the leading cause of end-stage renal disease worldwide. The earliest clinical sign of diabetic nephropathy is microalbuminuria. Moreover albuminuria is considered a predictive surrogate marker for cardiovascular and renal risk. Long term renal and/or cardiovascular protection with the emergent new class of anti-diabetic drugs, SGLT2 inhibitors, are not yet established. However we were interested to determine whether empagliflozin, a potent, selective sodium glucose cotransporter 2 inhibitor, could impact the sentinel maker of renal disease albuminuria in different preclinical models of diabetic nephropathy.

**Materials and methods:** Type 1 diabetic Akita mice, hypertensive Type 2 diabetic Dahl-STZ rats, normotensive and hypertensive (with angiotensin implant) BTBR ob/ob mice were treated for several weeks (9–15 weeks) with empagliflozin (10 to 30mg/kg). Dahl-rats, made hypertensive with 4% high salt diet and diabetic with an injection of 50mg/kg streptozotocin were also treated with an ACE inhibitor (lisinopril 10mg/kg) or empagliflozin (20mg/kg) in drinking water or with the combination of both drugs. Blood and urine were collected to determine plasmatic glucose concentration and proteinuria respectively. Blood pressure (BP) was determined using the tail-cuff system.

**Results:** As expected, in all these different preclinical models empagliflozin was effective in lowering significantly blood glucose (-58% up to -100%: normalization). A 76% blood pressure reduction was observed in Akita mice with empagliflozin while no effect on blood pressure was observed in normotensive and hypertensive BTBR ob/ob mice. In hypertensive Dahl-STZ rat, either lisinopril or empagliflozin was able to reduce blood pressure while the combination induced a significant drop in blood pressure. Interestingly, proteinuria was significantly and consistently reduced by empagliflozin in diabetic mice (~ 60 %). In Dahl-STZ rat, lisinopril alone did not reduce proteinuria while empagliflozin decreased it by -28%. When used in combination with lisinopril the effect of empagliflozin on proteinuria was even further pronounced (~50%).

**Conclusion:** These results show that the specific SGLT2 inhibitor, empagliflozin, is able - on top of lowering blood glucose levels - to consistently decrease proteinuria, in several preclinical models of nephropathy independent of their origin as Type 1 or type 2 diabetes and also independent of their BP status. Whereas these are promising results hinting towards a renal benefit

on the long term use of empagliflozin, it is premature to speculate about the clinical outcomes with empagliflozin. Studies are currently underway to address this question.

### Dapagliflozin lowered ambulatory BP in patients with type 2 diabetes mellitus and hypertension inadequately controlled by a renin-angiotensin system blocker ± another agent

N. Iqbal<sup>1</sup>, M.A. Weber<sup>2</sup>, T.A. Mansfield<sup>1</sup>, J.F. List<sup>1</sup>, A. Ptaszynska<sup>3</sup>;

<sup>1</sup>Global Clinical Research, Bristol-Myers Squibb, Princeton,

<sup>2</sup>Department of Medicine, SUNY Downstate College of Medicine, New York,

<sup>3</sup>Bristol-Myers Squibb, Princeton, USA.

**Background and aims:** Hypertension is common in patients with type 2 diabetes mellitus (T2DM) and treatment usually starts with an ACE inhibitor (ACEi) or an angiotensin receptor blocker (ARB), with other antihypertensive (AHT) therapies added if required. Dapagliflozin reduces renal glucose reabsorption accompanied by weight reduction and a diuretic effect, both contributing to BP reduction. Here we assess the effects of dapagliflozin in two studies of patients with inadequately controlled T2DM and hypertension.

**Materials and methods:** Two randomized, double-blind studies assessed the effects of 12 weeks of dapagliflozin 10 mg or placebo on BP in patients with inadequately controlled T2DM (HbA1C 7.0–10.5%) and hypertension (seated systolic BP [SBP] / diastolic BP: 140–164 / 85–104 mmHg) despite receiving glucose-lowering drugs and an ACEi or ARB (Study 1) plus a 2nd AHT agent (Study 2). Preliminary results have been presented previously; here we describe ambulatory BP data.

**Results:** In Study 1, 613 patients on an ACEi or ARB were randomized to dapagliflozin or placebo. At Week 12, mean 24-hour ambulatory SBP was 2.9 (SEM: 1.01) mmHg lower with dapagliflozin versus placebo ( $p=0.0043$ , Figure) and night-time SBP was reduced versus placebo ( $-2.34$  [1.16] mmHg). In Study 2, 449 patients on an ACEi or ARB plus another AHT drug (thiazide/thiazide-like diuretics in ~44% of patients, calcium channel blockers ~27%, beta blockers ~27%) were randomized to dapagliflozin or placebo. At Week 12, mean 24-hour ambulatory SBP was lower with dapagliflozin versus placebo ( $-4.5$  [1.37] mmHg,  $p=0.0012$ , Figure) and a reduction in night time SBP was also evident versus placebo ( $-3.9$  [1.51] mmHg). Dapagliflozin was well tolerated and heart rate showed no significant change from baseline.

**Conclusion:** Dapagliflozin significantly reduced mean 24-hour ambulatory SBP versus placebo in patients with T2DM and hypertension in combination with an ACEi or ARB ± 1 AHT over 12 weeks.

## 826

**Impact of weight loss on weight-related quality of life (WRQL) and health satisfaction (HS): evidence from a head-to-head study of canagliflozin (CANA) vs sitagliptin (SITA)**S. Traina<sup>1</sup>, A. Slee<sup>2</sup>, C. Neslusan<sup>1</sup>;<sup>1</sup>Janssen Global Services, LLC, Raritan, <sup>2</sup>Axio, Seattle, USA.

**Background and aims:** The positive health impacts of performing diabetes self-care (e.g., healthy food choices, increased physical activity, and medication taking) are not always apparent to a person with type 2 diabetes mellitus (T2DM); therefore, adherence can be difficult. People with T2DM are more likely to adhere to treatments that offer noticeable benefits, such as convenience, avoidance of hypoglycemic episodes, and weight loss vs. those that do not. Previous studies have demonstrated associations between WRQL and disease outcomes and between HS and performance of self-care behaviors. In this study, we explore the impact of the amount of weight loss demonstrated with CANA treatment on WRQL as measured by the Impact of Weight on Quality of Life (IWQOL-Lite) and physical HS (which includes satisfaction with weight, energy, appetite, sleep, physical activity, and general health) as measured by the Current Health Satisfaction Questionnaire (CHES-Q). In a previously reported study of CANA vs. SITA in dual therapy with metformin and background diet and exercise, CANA was associated with a mean weight loss of -2.1 kg to -2.5 kg vs. SITA after 52 weeks.

**Materials and methods:** In that study, the IWQOL-Lite and CHES-Q were administered at baseline and over time. Post hoc analyses were used to explore the strength of the relationship between weight change and improvement in IWQOL-Lite total and physical HS scores. Empirical distributions of scores were examined to investigate floor and ceiling effects. The final analytical sample was limited to subjects with baseline scores that were not at the ceiling (e.g., allowing for improvement in score). Differences in least squares mean (LSM) change in weight by changes in IWQOL-Lite and CHES-Q after 52 weeks were compared using ANCOVA models adjusting for selected baseline covariates (i.e., weight, age, and gender). Logistic regression, adjusted for the same covariates, was used to generate odds ratios (ORs) for score changes associated with weight change.

**Results:** Empirical distributions of change scores indicated that 29.1% of IWQOL-Lite and 5.4% of CHES-Q scores were at the ceiling at baseline; these scores did not decline over time and were thus excluded from the analytical sample. Subjects with improved IWQOL-Lite total and CHES-Q physical scores lost more weight than those with no score improvement (IWQOL-Lite: -3.54 kg; 95% CI -4.07, -3.01 and -2.33 kg; 95% CI -2.78, -1.87, respectively; LSM difference -1.21 kg; 95% CI -1.92, -0.51; CHES-Q: -3.50 kg; 95% CI -3.89, -3.12 and -1.86 kg; 95% CI -2.25, -1.47, respectively; LSM difference -1.65 kg; 95% CI -2.17, -1.12). Weight loss of 2 kg was associated with a 68% greater chance of IWQOL-Lite total score improvement (OR 1.68; 95% CI 1.16, 2.42) and a 72% greater chance of CHES-Q physical domain score improvement (OR 1.72; 95% CI 1.28, 2.31).

**Conclusion:** Results suggest that the magnitude of weight loss shown in clinical trials to be associated with CANA vs. SITA is noticeable by and important to people living with T2DM. Treatments providing adequate glycemic control that also offer a weight loss benefit are likely to improve WRQL and HS, and in turn, may support persistent and consistent performance of healthy behaviors.

## 827

**The 2 week fasting glucose as a predictor of response to once weekly dulaglutide 1.5 mg**T. Forst<sup>1</sup>, S. Gough<sup>2</sup>, G. Grunberger<sup>3</sup>, V. Pechtner<sup>4</sup>, R. Shaginian<sup>5</sup>, H. Wang<sup>6</sup>, L. Fernandez<sup>6</sup>;<sup>1</sup>Profil Mainz, Germany, <sup>2</sup>University of Oxford and Oxford University Hospitals NHS Trust, UK, <sup>3</sup>Grunberger Diabetes Institute, Bloomfield Hills, USA, <sup>4</sup>Lilly Diabetes, Eli Lilly and Company, Neully-Sur-Seine, France, <sup>5</sup>Lilly Diabetes, Eli Lilly and Company, Houten, Netherlands, <sup>6</sup>Lilly Diabetes, Indianapolis, USA.

**Background and aims:** The identification of patients most likely to respond to a specific treatment is important when attempting to individualize patient care. Predictors of treatment success for weekly GLP-1 receptor agonists are, to date, largely unknown. This analysis was therefore conducted to assess whether laboratory fasting blood glucose (FBG) in patients with type 2 diabetes mellitus (T2DM) measured early in treatment with the once weekly GLP-1 receptor agonist dulaglutide (DU) 1.5 mg predicts treatment response.

**Materials and methods:** Post hoc analyses were conducted separately for 2 double-blind, randomized Phase 3 studies (AWARD-5, in combination with metformin, and AWARD-1, in combination with metformin and pioglitazone) in patients with T2DM assigned to once weekly DU 1.5 mg. Baseline tertile values from AWARD 5 were used to categorize FBG at baseline and weeks 2 and 8 as follows: Low (L, <7.9 mmol/l); Intermediate (I, ≥7.9 to <10.3 mmol/l); and High (H, ≥10.3 mmol/l). Treatment response in AWARD-5 was assessed at week 12 and 26 by the following composite efficacy endpoint (CEE): HbA<sub>1c</sub> <7.0% (53 mmol/mol) or HbA<sub>1c</sub> reduction from baseline >0.8% [if baseline HbA<sub>1c</sub> <8.0% (64 mmol/mol)]; >1.1% [if baseline A1c ≥8.0% (64 mmol/mol) and <9.0% (75 mmol/mol)]; or >1.6% [if baseline HbA<sub>1c</sub> ≥9.0% (75 mmol/mol)]. The association between FBG categories and the CEE was analyzed using chi-square tests. The association between week 2 FBG and HbA<sub>1c</sub> treatment response at weeks 13 and 26 was validated in AWARD-1 using the same FBG categorization and CEE definition.

**Results:** In AWARD-5, mean baseline HbA<sub>1c</sub> for DU 1.5 mg (N=304) was 8.1% (65 mmol/mol). At baseline, mean FBG was 9.8 mmol/l and 33% (n=99), 32% (n=97), and 36% (n=108) of patients had FBG in the L, I, and H categories, respectively. After 2 weeks of treatment, mean FBG was 7.2 mmol/l and 68% (n=208), 21% (n=64), and 11% (n=32) of patients had FBG in L, I, and H categories, respectively. At week 26, mean HbA<sub>1c</sub> was 6.9% (52 mmol/mol). There was a strong association between FBG at week 2 and achieving the CEE at week 26 ( $p<0.001$ ). A significantly higher percentage of patients in FBG category L (83% [172/208]) at week 2 met the CEE at week 26 compared to patients in FBG categories I (61% [39/64]),  $p<0.001$ , and H (34% [11/32]),  $p<0.001$ , at this time. CEE results at week 12 were consistent with those at week 26. Similar findings were seen using AWARD-1 data.

**Conclusion:** In patients treated with once weekly DU 1.5 mg in AWARD-5 and AWARD-1, FBG values at week 2 were strongly associated with treatment response at week 26 as measured by a CEE. The probability of achieving a treatment response at week 26 was greatest for patients in the lower FBG categories at week 2. FBG values at week 2 may be an early and useful measurement for predicting response to once weekly DU 1.5 mg treatment in patients with T2DM.

**Real-world comparative effectiveness of exenatide once weekly and liraglutide in patients with type 2 diabetes mellitus**W. Saunders<sup>1</sup>, H. Hiep Nguyen<sup>2</sup>, I. Kalsekar<sup>2</sup>;<sup>1</sup>Saunders Research, Charlotte, <sup>2</sup>AstraZeneca, Fort Washington, USA.

**Background and aims:** Exenatide once weekly (EQW) and liraglutide once daily (LIRA), glucagon-like peptide-1 receptor agonists (GLP-1RAs), have demonstrated improvements in glycaemic outcomes in patients with type 2 diabetes mellitus (T2DM) in randomized clinical trials. However, little is known about their real-world comparative effectiveness. This retrospective cohort study used the Quintiles Electronic Medical Record (EMR) database

to evaluate the 6-month change in HbA<sub>1c</sub> for patients initiating EQW or LIRA.

**Materials and methods:** Patients with T2DM prescribed EQW or LIRA between 01 February 2012 and 31 May 2013 were identified. Baseline HbA<sub>1c</sub> measures were from 75 days prior to 15 days after initiating EQW or LIRA, with follow-up measures documented at 6 months ( $\pm$  45 days). Adjusted linear regression models compared the difference in mean HbA<sub>1c</sub> change. *A priori* defined sensitivity analyses were performed in the subgroup of patients with baseline HbA<sub>1c</sub>  $\geq$ 7.0% and no prescription for insulin during the 12-month pre-index period.

**Results:** For EQW and LIRA respectively, mean (SD) age of the main study cohort was 58.0 (11.0) and 58.1 (11.0) years, mean (SD) baseline HbA<sub>1c</sub> was 8.3% (1.7) and 8.4% (1.6), and 48.1% and 54.1% of patients were women. In adjusted models, change in HbA<sub>1c</sub> did not differ between EQW and LIRA during 6 months of follow-up (Table). Results were consistent in the subgroup analyses.

**Conclusion:** In a real-world setting, HbA<sub>1c</sub> similarly improved in patients initiating EQW or LIRA.

| Change in HbA <sub>1c</sub> from Baseline at 6 Months |                      |                   |         |                   |         |

### Effectiveness of lixisenatide before breakfast or the main meal using CGM with AGP analysis

E. Strock<sup>1</sup>, R. Mazze<sup>1</sup>, M. Powers<sup>1</sup>, A. Monk<sup>1</sup>, S. Richter<sup>2</sup>, R. Bergenstal<sup>1</sup>, E. Souhami<sup>3</sup>, N. Demil<sup>3</sup>, B. Åhrén<sup>4</sup>;

<sup>1</sup>International Diabetes Center, Minneapolis, <sup>2</sup>Park Nicollet Institute, Minneapolis, USA, <sup>3</sup>Sanofi, Paris, France, <sup>4</sup>Lund University, Sweden.

**Background and aims:** Lixisenatide is a once-daily glucagon-like peptide-1 receptor agonist that has been shown by 7-point self-monitoring blood glucose to lower postprandial and fasting glycaemia. The aim of this study was to understand, in a subset of type 2 diabetes mellitus (T2DM) patients in a multicentre randomized trial, the change in diurnal glucose patterns using continuous glucose monitoring (CGM) prior to and during lixisenatide treatment based on the time of administration: before breakfast (BK) or the main meal (MM) as defined by the patient.

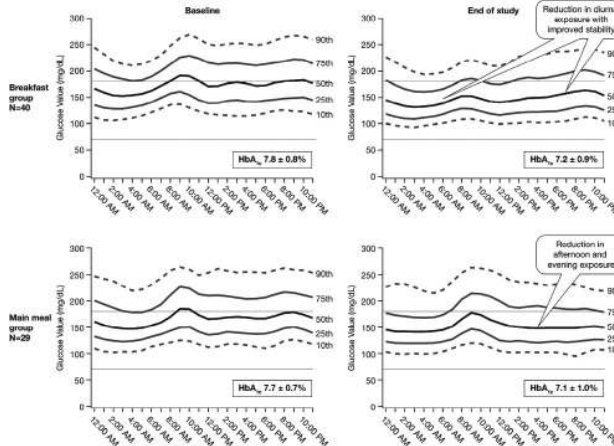

**Materials and methods:** Blinded CGM was used 14 days before and during lixisenatide treatment (BK or MM). CGM data were analyzed using Ambulatory Glucose Profile (AGP) analysis to detect changes in diurnal glucose patterns.

**Results:** Sixty-nine patients completed (T2DM 7.8 $\pm$ 4.9y; age 57.8 $\pm$ 10.2y; 53.6% female). AGP analysis showed significant reduction in 24h glucose exposure (AUC) in both groups (BK: 4918.1 $\pm$ 652.3 to 3681.2 $\pm$ 699.6 mg/dL\*24h,  $p$ <0.0001; MM: 4127.9 $\pm$  876.6 to 3880.9 $\pm$ 1165.0 mg/dL\*24h,  $p$ =0.0224). Reduction in hourly waking AUC was significant in both groups

(BK: 181.1 $\pm$ 28.1 to 157.2 $\pm$ 29.5 mg/dL\*h,  $p$ <0.0001, MM: 177.9 $\pm$ 37.7 to 165.6 $\pm$ 48.2 mg/dL\*h,  $p$ =0.0184). However, hourly sleeping AUC reduction was significant in the BK group (161.8 $\pm$ 28.0 to 144.6 $\pm$ 28.8 mg/dL\*h,  $p$ <0.001) and not in the MM group (159.8 $\pm$ 36.4 to 153.4 $\pm$ 51.5,  $p$ =0.0942). Variability (IQR) improved in both groups, although was not significant. Subjects in both groups had less than 1% of time spent in hypoglycaemic range (<60mg/dL). HbA<sub>1c</sub> reduction was similar in both groups. Figure 1 shows composite AGPs for each group.

**Conclusion:** In summary, lixisenatide before MM appears to benefit afternoon and evening glucose exposure, while lixisenatide before BK appears to have a sustained improvement in the overall diurnal glucose patterns.

**Figure 1.** Composite AGPs for the BK and MM groups at baseline and study end. The AGP diurnal glucose profiles indicate that patients in the BK had improvements in sleeping, walking, post-meal glucose exposure and stability, whereas those in the MM group shows reductions in HbA<sub>1c</sub>, primarily due to lowering of afternoon and evening exposure.

### Harmony 2 year 3 Results: albiglutide monotherapy in drug naïve patients with type 2 diabetes mellitus

M.C. Carr<sup>1</sup>, M. Rendell<sup>2</sup>, R.A. Scott<sup>3</sup>, J. Ye<sup>4</sup>, M.W. Stewart<sup>1</sup>, M. Nauck<sup>5</sup>;

<sup>1</sup>GlaxoSmithKline, King of Prussia, <sup>2</sup>Greentown University Diabetes Center, Omaha, USA, <sup>3</sup>GlaxoSmithKline, Uxbridge, UK, <sup>4</sup>GlaxoSmithKline, Research Triangle Park, USA, <sup>5</sup>Diabeteszentrum Bad Lauterberg, Germany.

**Background and aims:** This 3 year (y), double-blind, placebo (Pbo)-controlled study examined efficacy/safety of albiglutide at 30mg (A30) and 50mg (A50) vs Pbo in patients with A1C (53–85.8 mmol/mol [7–10%]) on diet and exercise.

**Materials and methods:** Both Albi arms began A30 QW (A50 started at Wk 12) and continued on randomized medication after hyperglycemic rescue. Primary endpoint (PE) was A1C change from baseline at Wk 52.

**Results:** Baseline characteristics were similar between arms; mean A1C 65 mmol/mol (8.1%); age 53 y; diabetes duration 4 y. The PE reported previously showed Wk 52 A1C difference (Albi – Pbo) -9.2 mmol/mol (95% CI: -12.1, -6.3) [-0.84% (95% CI: -1.11, -0.58)] for A30 and -11.4 mmol/mol (95% CI: -14.3, -8.4) [-1.04% (95% CI: -1.31, -0.77)] for A50; both  $P$ <0.001. In pts completing 3y without rescue, A1C reduction was durable to Wk 156 in both albi arms (-10.5 mmol/mol, SD 10.6 [-0.96%, SD 0.968], A30 (n=30), -11.7 mmol/mol, SD 9.7 [-1.07%, SD 0.887], A50 (n=32), -6.7 mmol/mol, SD 7.0 [-0.61%, SD 0.644], Pbo (n=14), with generally greater reductions in the A50 arm. FPG (mmol/L [mg/dL]) decreased in a dose dependent manner in the albi arms, (-1.3, SD 1.77, A30; -1.8, SD 2.01, A50; -0.23, SD 0.81, Pbo [-23.6, SD 31.87, A30; -32.9, SD 36.14, A50; -4.3, SD 14.63, Pbo]) and was maintained to Wk 156. Modest weight loss (kg) occurred in all arms (-2.91 Pbo, -1.32 A30, -2.24 A50). The probability of requiring rescue by Wk 156 was 74% Pbo, 54% A30, and 42% A50. Metformin was the most common rescue medication. In pts completing 3y with rescue, A1C reduction was -7.5 mmol/mol, SD 14.1 [-0.69%, SD 1.293], A30 (n=66), -9.3 mmol/mol, SD 9.3 [-0.85%, SD 0.85], A50 (n=51), -9.0 mmol/mol, SD 14.4 [-0.82%, SD 1.319], Pbo (n=47), confounded by a higher use of rescue medication in the Pbo arm. On-therapy adverse event (AE) % was higher in the A30 and A50 arms than Pbo 89.1/89.9/83.1 but SAE % was similar 14.9/17.2/15.8. GI AEs for Pbo/A30/A50 were: nausea 10/14/11; diarrhea 15/13/16; vomiting 1/4/4. Injection site reactions were higher for A30 and A50 vs Pbo 22/28/11. Pre-rescue

documented ( $\leq 3.88$  mmol/L [70 mg/dL]) symptomatic hypoglycemia events were low: A30 2%, A50 1%, Pbo 3%; no severe events reported.

**Conclusion:** Albi monotherapy resulted in robust, durable A1C reduction through Wk 156 and was generally well tolerated.

## 831

### Harmony 3 year 3 Results: albiglutide vs sitagliptin and glimepiride in patients with type 2 diabetes mellitus on metformin

J.E. Matthews<sup>1</sup>, B. Ahren<sup>2</sup>, J. Ye<sup>1</sup>, M.C. Carr<sup>3</sup>, M.W. Stewart<sup>3</sup>;

<sup>1</sup>GlaxoSmithKline, Research Triangle Park, USA, <sup>2</sup>Department of Clinical

Sciences, Division of Medicine, Lund University, Sweden,

<sup>3</sup>GlaxoSmithKline, King of Prussia, USA.

**Background and aims:** This 3-year (y), randomized (rzd), double-blind, placebo (Pbo) controlled, study examined albiglutide (Albi) 30mg vs placebo (Pbo), sitagliptin (Sita), or glimepiride (SU) in patients (pts) with T2DM (A1C 53–85.8 mmol/mol [7–10%]) on Metformin (Met).

**Materials and methods:** Pts meeting predefined hyperglycemia criteria qualified for blinded dose titration (SU 2–4mg, Albi 30–50mg). Pts received hyperglycemic rescue if prespecified rescue criteria were met & continued receiving rzd medication. Pts (%) who completed the 3y study (including rescue): Pbo 53, Sita 61, SU 60 & Albi 61.

**Results:** Primary endpoint at Wk 104 (baseline A1c  $65 \pm 8.7$  mmol/mol [ $8.1 \pm .8\%$ ]), Albi treatment difference was superior to Pbo ( $-9.9$  mmol/mol [ $-.91\%$ ];  $P < .0001$ ), Sita ( $-3.8$  mmol/mol [ $-.35\%$ ];  $P = .0001$ ) & SU ( $-3.0$  mmol/mol [ $-.27\%$ ];  $P = .003$ ). At Wk 156, probability of rescue (%) was lower in Albi: Pbo 65.6 ( $P < .0001$ ), Sita 47.8 ( $P = .0124$ ), SU 44.3 ( $P = .1605$ ), Albi 37.3.

In pts completing 3y of treatment with & without rescue, durability of Albi was demonstrated with both A1c & FPG reduction from baseline. There was minimal change in weight at 3y (kg): Pbo  $-.41$ , Sita  $-.61$ , albi  $-1.0$  & weight gain with SU  $+1.60$ . GI AEs (% pts) to Wk 156 with Pbo/Sita/SU/Albi were: nausea 13/7/8/12 & vomiting 1/5/4/7. Prerescue documented ( $\leq 3.88$  mmol/L [70 mg/dL]) symptomatic hypoglycemic events (%) were Pbo 4.0, Sita 1.7, SU 19.9, Albi 3.6; with 1 severe event (SU).

**Conclusion:** We conclude that Albi treatment, as add on to Met, was generally well tolerated with maintained glycemic control over a 3y study period.

### Effectiveness of switching from a DPP-4 inhibitor to the human GLP-1 analogue liraglutide in patients with type 2 diabetes: data from the EVIDENCE study

S. Madani<sup>1</sup>, G. Charpentier<sup>2</sup>, L. Martinez<sup>3</sup>, E. Eschwège<sup>4</sup>, A. Penfornis<sup>5</sup>, P. Gourdy<sup>6</sup>, J.-F. Gautier<sup>7</sup>;

<sup>1</sup>Novo Nordisk, Paris la Defense, <sup>2</sup>Centre Hospitalier Sud Francilien,

Corbeil, <sup>3</sup>Université Pierre & Marie Curie, Paris, <sup>4</sup>INSERM, Villejuif,

<sup>5</sup>University of Franche-Comté, Besançon, <sup>6</sup>Toulouse University Hospital,

<sup>7</sup>Lariboisière Hospital, Paris, France.

**Background and aims:** We used data from a post-marketing study in France to assess the effectiveness of switching from a DPP-4 inhibitor (DPP-4i) to liraglutide in patients with type 2 diabetes.

**Materials and methods:** EVIDENCE is a multicentre, observational, post-marketing outpatient study requested by the French National Health Authority to evaluate the efficacy and safety of the human GLP-1 analogue liraglutide. Its primary objective is to determine the percentage of patients still taking liraglutide and at HbA1c target ( $< 7\%$ ) after 2 years. Statistical analyses: for quantitative variables a normality Kolmogorov-Smirnov test was used; comparisons of two dependent groups were performed using the Wilcoxon signed rank test; for paired qualitative variables the McNemar test was used.

**Results:** Data were collected from 3152 subjects of whom 1261 (40%) were receiving a DPP-4i prior to liraglutide initiation. A total of 1002 (32%) subjects switched from a DPP-4i to liraglutide at the start of the study. Baseline characteristics of subjects who switched and were still on liraglutide treatment at the end of the study are presented in Table 1. These subjects ( $n = 624$ ) achieved significant reductions in mean HbA1c ( $-0.85\%$ ,  $p < 0.0001$ ), fasting plasma glucose ( $-0.28$  g/l,  $p < 0.0001$ ) and body weight ( $-3.60$  kg,  $p < 0.0001$ ). An increased percentage of subjects reached the HbA1c target of  $< 7\%$  after switching to liraglutide (31.7% at the end of the study vs. 9.7% at baseline;  $p < 0.0001$ ). Withdrawals (21.4% in overall study cohort) were mostly due to gastrointestinal disorders experienced at the start of the study.

**Conclusion:** Switching from a DPP-4i to liraglutide led to significant improvements in glycaemic control and body weight in this observational study. In a randomised controlled trial, switching from the DPP-4 inhibitor sitagliptin to liraglutide provided significant HbA1c ( $-0.5\%$ ;  $p < 0.0001$ ) and body weight reductions ( $-2.5$  kg;  $p < 0.0001$ ). The greater reductions in HbA1c and body weight in this observational study versus the controlled setting of a clinical trial may reflect different baseline characteristics and concomitant diabetes medications. However, these data support the potential benefits of switching from a DPP-4i to a GLP-1 analogue, as previously observed in a randomised clinical trial.

Table: Baseline characteristics of subjects who switched from a DPP-4i to liraglutide and still on liraglutide treatment at the end of the study

| Baseline characteristics                  |               |
|---|---------------|
| N   | 624           |
| Age, years                                | $58 \pm 10$   |
| Diabetes duration, years                  | $9.2 \pm 5.8$ |
| HbA1c, %                                  | $8.4 \pm 1.4$ |
| Fasting plasma glucose, g/l               | $1.8 \pm 0.6$ |
| Body weight, kg                           | $96 \pm 18$   |
| BMI, kg/m <sup>2</sup>                    | $34 \pm 6$    |
| Proportion of patients with HbA1c $< 7\%$ | 9.7%          |

**Safety and tolerability of liraglutide 3.0 mg in overweight and obese adults: the SCALE obesity and prediabetes randomised trial**

C. le Roux<sup>1</sup>, D.C.W. Lau<sup>2</sup>, A. Astrup<sup>3</sup>, K. Fujioka<sup>4</sup>, F. Greenway<sup>5</sup>, A. Halpern<sup>6</sup>, M. Krempf<sup>7</sup>, R. Violante Ortiz<sup>8</sup>, J.P.H. Wilding<sup>9</sup>, C.B. Jensen<sup>10</sup>, C.B. Svendsen<sup>10</sup>, X. Pi-Sunyer<sup>11</sup>;

<sup>1</sup>University College Dublin, Ireland, <sup>2</sup>University of Calgary, Canada, <sup>3</sup>University of Copenhagen, Denmark, <sup>4</sup>Scripps Clinic, La Jolla, <sup>5</sup>Louisiana State University, Baton Rouge, USA, <sup>6</sup>University of São Paulo Medical School, Brazil, <sup>7</sup>Université de Nantes, France, <sup>8</sup>Instituto Mexicano del Seguro Social, Ciudad Madero, Mexico, <sup>9</sup>University of Liverpool, UK, <sup>10</sup>Novo Nordisk A/S, Søborg, Denmark, <sup>11</sup>Columbia University, New York, USA.

**Background and aims:** The primary objective of this trial was to investigate the efficacy of the GLP-1 receptor agonist (RA) liraglutide 3.0 mg, as adjunct to diet and exercise, for weight management. Key safety and tolerability data are presented.

**Materials and methods:** Individuals (BMI  $\geq 27$  kg/m<sup>2</sup> with  $\geq 1$  comorbidity or  $\geq 30$  kg/m<sup>2</sup>) were advised on a 500 kcal/day deficit diet and exercise programme and randomised 2:1 to once daily sc liraglutide 3.0 mg (n=2487) or placebo (n=1244). Certain event types (deaths, select CV disorders, pancreatitis, neoplasms, thyroid disorders requiring thyroidectomy) underwent blind independent assessment.

**Results:** Baseline characteristics: age 45.1 years, 78.5% female, body weight 106.2 kg, BMI 38.3 kg/m<sup>2</sup>. Liraglutide 3.0 mg induced greater weight loss (primary endpoint; 8.0%) vs placebo (2.6%) after 56 weeks (estimated treatment difference [ETD] -5.4%;  $p < 0.0001$ ). Consistent with the known effects of GLP-1RAs, the most common AEs with liraglutide 3.0 mg were mild/moderate nausea and diarrhoea, mostly transient and with onset in weeks 1–4. AEs leading to withdrawal occurred in 9.9% of individuals on liraglutide 3.0 mg, mostly in weeks 1–12 and due to GI AEs, vs 3.8% with placebo. Similar proportions reported serious AEs in both treatment groups (6.3% vs 5.0%). None occurred in  $\geq 1\%$  of individuals. 3 deaths occurred: liraglutide 3.0 mg (n=1) vs placebo (n=2) (1 CV-related death in each group). Liraglutide treatment was not associated with increased risk of depression or suicidality. Gallbladder-related AEs were more common with liraglutide 3.0 mg vs placebo (2.5% vs 1.0%), due to more events of ‘cholelithiasis’ and ‘cholecystitis’. The frequency of pancreatitis was higher with liraglutide (0.3%) vs placebo (0.1%). 1 individual per group co-reported gallbladder-related AEs and pancreatitis. An increase in mean serum lipase activity was seen with liraglutide, but few individuals (2.5% vs 1.1% with placebo) had levels  $\geq 3$  times the UNR. Most elevations were transient and not predictive of pancreatitis. Liraglutide reduced mean SBP and DBP vs placebo at week 56 (ETD -2.8 and -0.9 mmHg,  $p < 0.001$ ), but increased mean pulse (ETD 2.4 bpm,  $p < 0.0001$ ) and a persistent increase of  $> 20$  bpm at  $\geq 2$  consecutive visits occurred in 5.1% vs 1.4% of individuals, respectively. CV events were similar with liraglutide (8.7%) vs placebo (9.9%). There were no cases of medullary thyroid carcinoma or C-cell hyperplasia and liraglutide did not increase calcitonin. Injection site reaction rates were 22.4 and 14.9 events/100 patient years of exposure (PYE) with liraglutide and placebo, respectively, with similar allergic reaction rates between treatments (2.6 and 3.2 events/100 PYE).

**Conclusion:** The safety profile of liraglutide 3.0 mg was consistent overall with the known effects of a GLP-1RA. The clinical significance of the imbalance in gallbladder and pancreatitis events is currently unknown.

## 834

**Efficacy and safety of liraglutide for perioperative blood sugar control in diabetic subjects within enhanced recovery after surgery protocols**

K. Mori, Y. Sato, Y. Tahara, Y. Iwasaki, S. Kaneko;  
Division of Diabetes, Endocrinology and Lifestyle-Related Disease,  
Takatsuki Red Cross Hospital, Japan.

**Background and aims:** Enhanced recovery after surgery (ERAS) protocols are multimodal perioperative care pathways designed to achieve early recovery after surgical procedures by maintaining preoperative organ function and reducing the profound stress response following surgery. The key principles of the ERAS protocol include perioperative nutritional management such as avoidance of perioperative fasting and carbohydrate loading up to 2 hours preoperatively. This perioperative nutritional management may result in blood sugar fluctuations in insulin-dependent diabetic patients. It has been

controversial to employ glucagon-like peptide-1 receptor (GLP-1R) agonist therapy for perioperative glycemic control. To investigate the efficacy and safety of liraglutide, a GLP-1R agonist, for perioperative glycemic control of surgical patients within ERAS protocol, we performed a randomized prospective study.

**Materials and methods:** Informed consents were obtained from 25 subjects with T2DM undergoing elective operations within ERAS protocol. Twelve subjects (male; 7, Age; 67.3 $\pm$ 8.7 years old) were initiated with liraglutide, and 13 subjects (male; 6, Age; 67.1 $\pm$ 9.3 years old) were administered insulin therapy before elective operations, e.g. orthopedic operations (23 cases) and urological surgery (2). In cases of hyperglycemia during perioperative period, regular insulin was added. As GLP-1 decreases gastrointestinal motility, surgical cases with gastrointestinal tracts were excluded. Fluctuation in glycemic level, hypoglycemic events, BMI change, doses of insulin administered if needed and perioperative complications were analyzed.

**Results:** Liraglutide was continued through the entire period of hospital stay including the operation day (day 0). The mean glucose levels of liraglutide or insulin therapy on day 0 and day 1 were 137.6 $\pm$ 26.41, 138.2 $\pm$ 33.1 and 146.5 $\pm$ 24.4, 187.1 $\pm$ 35.6 mg/dl, respectively. The body weight of patients receiving liraglutide or insulin therapy before the operation decreased -4.7 $\pm$ 1.0 kg or -1.8 $\pm$ 0.9 kg, respectively. Additional regular insulin was not needed except in the case of 1 patients. There was an additional benefit of body weight loss enabling efficient rehabilitation. Hypoglycemic events, wound healing retardations, or other complications were not observed in patients receiving liraglutide.

**Conclusion:** Liraglutide provides an effective and optional way for perioperative blood sugar control within ERAS protocols in patients with T2DM, especially those with limited exercise ability and those at risk of hypoglycemia.

## 835

**Novel combination of insulin degludec and liraglutide (IDegLira) is efficacious across the range of disease progression in type 2 diabetes**

H.W. Rodbard<sup>1</sup>, J.B. Buse<sup>2</sup>, V.C. Woo<sup>3</sup>, T. Vilsbøll<sup>4</sup>, I. Langbakke<sup>5</sup>, L. Korsholm<sup>5</sup>, S. Gough<sup>6</sup>;

<sup>1</sup>Endocrine and Metabolic Consultants, Rockville, <sup>2</sup>University of North Carolina School of Medicine, Chapel Hill, USA, <sup>3</sup>University of Manitoba, Winnipeg, Canada, <sup>4</sup>University of Copenhagen, Hellerup, Denmark, <sup>5</sup>Novo Nordisk A/S, Søborg, Denmark, <sup>6</sup>University of Oxford, UK.

**Background and aims:** This study explored whether a novel combination of insulin degludec (IDeg) and liraglutide (Lira), IDegLira, was consistently effective across three parameters of type 2 diabetes (T2D) progression: HbA<sub>1c</sub>, diabetes duration and dose of insulin.

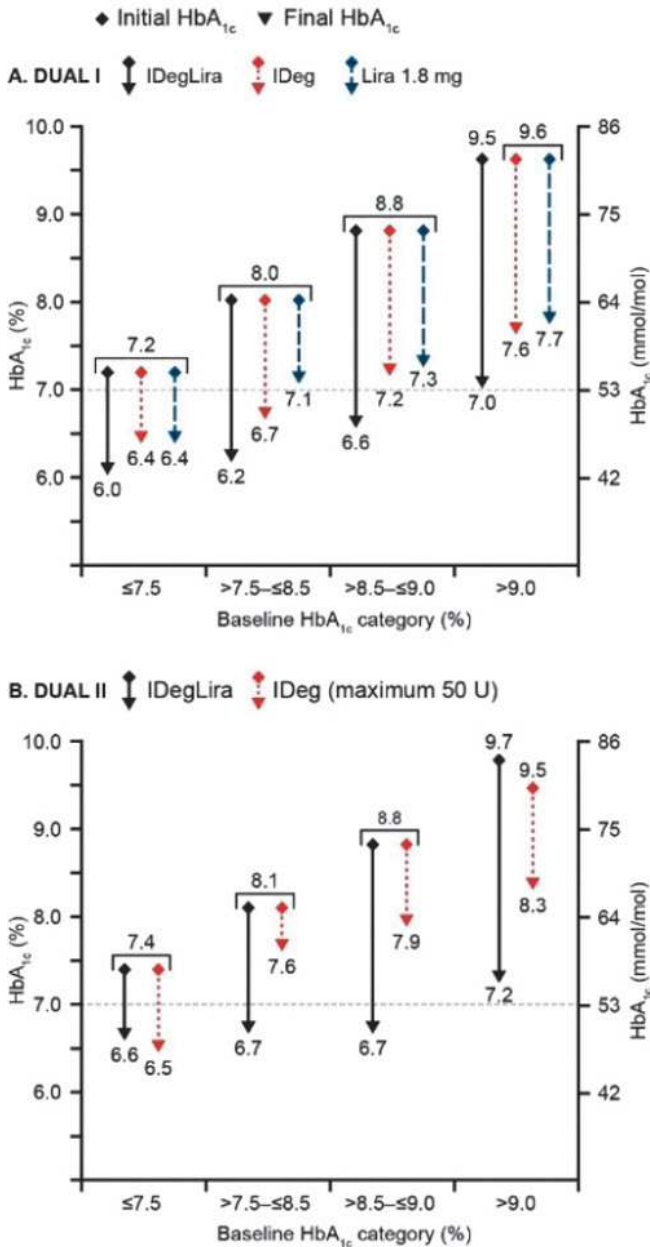

**Materials and methods:** Mean HbA<sub>1c</sub> reductions of 1.8 and 1.9% were observed with IDegLira in two Phase 3 trials: DUAL I (IDegLira versus IDeg and Lira 1.8 mg in patients uncontrolled on metformin  $\pm$  thiazolidinedione [TZD] for 52 weeks) and DUAL II (IDegLira versus IDeg [max 50 U] in patients uncontrolled on basal insulin + oral glucose lowering drugs for 26 weeks), respectively. This *post-hoc* analysis investigated how the extent of progression of T2D at baseline, defined as baseline HbA<sub>1c</sub> category, insulin dose and diabetes duration, impacted the efficacy of IDegLira.

**Results:** In DUAL I, HbA<sub>1c</sub> reductions (1.1–2.5%) were significantly greater ( $p < 0.01$ ) with IDegLira versus IDeg or Lira in all four baseline HbA<sub>1c</sub> categories assessed ( $\leq 7.5\%$ ;  $> 7.5\%$  to  $\leq 8.5\%$ ;  $8.5$  to  $\leq 9.0\%$  and  $> 9.0\%$ ). HbA<sub>1c</sub> reductions were similar to those observed in DUAL II (0.9–2.5%) (Figure). In DUAL I, higher baseline HbA<sub>1c</sub> categories were associated with greater HbA<sub>1c</sub> reductions with IDegLira ( $p < 0.0001$ ). HbA<sub>1c</sub> reduction was independent of diabetes duration. In DUAL II, pre-trial basal insulin dose ( $\leq 30$  U or  $> 30$  U) did not affect HbA<sub>1c</sub> reduction with IDegLira (1.9 vs 1.9%, estimated treatment difference (ETD) 0.02, 95% CI -0.26 to 0.30,  $p = 0.91$ ). Those patients entering DUAL II on metformin (48%) achieved a greater HbA<sub>1c</sub>

reduction (2.1 vs 1.7%, ETD -0.44, 95% CI -0.71 to -0.16,  $p < 0.01$ ) than the remaining 52% who entered on metformin + sulphonylureas (SU) or glinides and then discontinued SU or glinide at randomisation.

**Conclusion:** HbA<sub>1c</sub> reductions with IDegLira were substantial for patients with all levels of baseline HbA<sub>1c</sub> and were independent of diabetes duration and prior insulin dose. Similar levels of glycaemic control can be obtained with IDegLira irrespective of stage of progression of T2D

**HbA<sub>1c</sub> reductions across baseline HbA<sub>1c</sub> categories in A. DUAL I; B. DUAL II**

**836**

**IDegLira, a combination of insulin degludec and liraglutide, enables patients with type 2 diabetes to reach target glycaemic control faster than its individual components alone**

T. Vilsbøll<sup>1</sup>, J. Vora<sup>2</sup>, H. Jarlov<sup>3</sup>, K. Kvist<sup>3</sup>, L. Blonde<sup>4</sup>,  
<sup>1</sup>Internal Medicine F, Gentofte Hospital, Copenhagen, Denmark,  
<sup>2</sup>Department of Diabetes & Endocrinology, Royal Liverpool University Hospitals, UK, <sup>3</sup>Novo Nordisk A/S, Søborg, Denmark,  
<sup>4</sup>Ochsner Medical Center, New Orleans, USA.

**Background and aims:** IDegLira is a novel combination of insulin degludec (IDeg) and liraglutide (Lira). The aim of this *post hoc* analysis was to investigate the time to glycaemic control and to observe changes in body weight in response to IDegLira vs Lira or IDeg alone, in patients with type 2 diabetes (T2D).

**Materials and methods:** In two completed phase 3 trials: DUAL I (IDegLira vs IDeg and Lira in patients uncontrolled on oral antidiabetic drugs [OADs]; 52 weeks) and DUAL II (IDegLira vs IDeg in patients uncontrolled on basal insulin + OADs; 26 weeks), a greater HbA<sub>1c</sub> reduction was observed with IDegLira compared with IDeg or Lira alone (DUAL I: IDegLira: -1.84%, IDeg: -1.40%, Lira: -1.21%; DUAL II: IDegLira: -1.90%, IDeg: -0.89%). In this analysis of both trials, we compared the proportion of patients achieving HbA<sub>1c</sub> (<7%) and fasting plasma glucose (FPG) (≤7.2 mmol/L) targets and mean change in body weight during the first 12 weeks of treatment. HbA<sub>1c</sub> was assessed after 8 and 12 weeks; FPG and weight were assessed at Weeks 4, 8 & 12. All data were analysed using LOCF to account for missing data.

**Results:** At baseline, HbA<sub>1c</sub> was well matched across treatment arms in both trials. In DUAL I, the proportion of patients achieving HbA<sub>1c</sub> <7% at Week 8 was significantly greater with IDegLira (57%) than with IDeg (38%) or Lira (47%). These differences in proportions were more pronounced at Week 12. In DUAL II, the proportion of patients at HbA<sub>1c</sub> target was significantly higher with IDegLira than with IDeg at Weeks 8 & 12. At baseline, the proportion of patients with FPG ≤7.2 mmol/L was similar in both trials. In DUAL I, the proportion of patients at target at Week 4 was significantly higher with IDegLira (76%) than with IDeg (62%) and Lira (62%); these differences persisted at Weeks 8 & 12. In DUAL II, patients were also more likely to achieve FPG target at Weeks 4, 8 & 12. In DUAL I at Weeks 4, 8 & 12, treatment with IDegLira resulted in a significantly greater reduction in mean body weight compared with IDeg, which was associated with a small overall weight gain, but the weight loss with IDegLira was less than that achieved with Lira. In DUAL II, weight loss was greater with IDegLira vs IDeg at Weeks 4, 8 & 12.

**Conclusion:** Patients treated with IDegLira were more likely to achieve HbA<sub>1c</sub> and FPG targets earlier than with IDeg or Lira alone. IDegLira provided a favourable early change in weight when compared with IDeg alone, but less than with Lira alone. Treatment with IDegLira results in rapid and substantial improvement in glycaemic control with a beneficial weight profile as early as 4 weeks after initiation in both insulin-naïve and insulin-treated patients. Early improvement in achieving target glycaemia levels may have a positive impact on patients' perception of their progress and on adherence to treatment.

|   | DUAL I (n=1660)   |               |               |                                       | DUAL II (n=398)                          |                                      |               |                                       |   |

### Harmony 4: 3 year efficacy of albiglutide (albi) vs insulin glargine (glar) in patients with type 2 diabetes mellitus

P.N. Weissman<sup>1</sup>, M.W. Stewart<sup>2</sup>, D.T. Cirkel<sup>3</sup>, J. Ye<sup>4</sup>, P.D. Ambery<sup>5</sup>,  
<sup>1</sup>Endocrinology Associates, Miami, <sup>2</sup>GlaxoSmithKline, King of Prussia, USA, <sup>3</sup>GlaxoSmithKline, Stevenage, UK, <sup>4</sup>GlaxoSmithKline, Research Triangle Park, USA, <sup>5</sup>MedImmune, Cambridge, UK.

**Background and aims:** This 3 year (y) randomized, open label, Ph 3 study assessed efficacy and safety of Albi 30 mg once weekly vs Glar in T2DM pts uncontrolled (A1c 53.0–85.8 mmol/mol [7–10%]) on metformin (met) ± sulfonylurea (SU).

**Materials and methods:** Pts were treated to a target A1c ≤53.0 mmol/mol (7.0%) and FPG ≤5.6 mmol/L (100 mg/dL). If needed, pts could uptitrate Albi to 50 mg QW and Glar per prespecified criteria. Patients could continue if hyperglycemic rescue was required. Primary endpoint (PE) was change from baseline in A1c at wk 52 in Albi vs Glar.

**Results:** Baseline demographics were similar between groups; mean age 56 y, A1c 67.2 mmol/mol (8.3%), 82% on met + SU. Treated N=504/241 (Albi/Glar). A1c decreased in both groups and was maintained for 3 y. The PE showed non-inferiority between Albi and Glar at wk 52 with a treatment difference of 1.20 mmol/mol (95% CI: 0.44, 2.95) (0.11% [95% CI: -0.04%, 0.27%]). At wk 156, a similar proportion of patients in each group required rescue: Albi 56.2%, Glar 48.0%, p=0.1515. In pts completing 3 y with and without rescue, A1c reduction was durable in both groups. Change in FPG favored Glar, whereas change in weight favored Albi. AEs through wk 156 for Albi/Glar were (% pts): nausea 13.3%/7.5%; diarrhea 10.9%/7.9%; vomiting 5.4%/5.4%. Prerescue documented (≤3.9 mmol/L [70 mg/dL]) symptomatic and severe hypoglycemia events were less with Albi vs Glar (18.5%/0.6% vs 30.3%/0.8%). Injection site reactions occurred in 17.5% of Albi and 10.0% of Glar pts.

**Conclusion:** Albi showed similar A1c improvement at wk 156 to Glar with modest weight loss and acceptable tolerability.

### Harmony 5 - year 3 Results: albiglutide vs placebo and vs pioglitazone in triple therapy (background metformin and glimepiride) in people with type 2 diabetes

P. Shamanna<sup>1</sup>, P. Home<sup>2</sup>, M.W. Stewart<sup>3</sup>, J.M. Mallory<sup>3</sup>, D.M. Miller<sup>3</sup>,  
 C.R. Perry<sup>3</sup>, M.C. Carr<sup>3</sup>;

<sup>1</sup>Bangalore Diabetes Centre, India, <sup>2</sup>Newcastle University, Newcastle upon Tyne, UK, <sup>3</sup>GlaxoSmithKline, King of Prussia, USA.

**Background and aims:** A 3-year, randomized, double-blind, multicenter study evaluated once weekly (QW) GLP-1 receptor agonist albiglutide (Albi) vs placebo (Pbo) and vs pioglitazone (Pio) in people with A1C 53–85.8 mmol/mol [7.0–10.0%] on background dual therapy of metformin and glimepiride.

**Materials and methods:** Uptitration of Albi 30 to 50 mg QW and Pio 30 to 45 mg QD was allowed if needed. If hyperglycemic rescue was required, people remained in the study.

**Results:** Baseline characteristics were similar between groups. At Week 52 (primary endpoint), Albi significantly decreased A1C vs Pbo but did not meet criteria for noninferiority vs Pio. Among people remaining in the study for 3-years (including those who received rescue medication), glycemic control was enhanced on Albi and Pio and maintained on Pbo (figure). Weight loss (kg) was observed on Albi and Pbo (-0.6 and -0.6), but weight increased on Pio (5.9 kg). Adverse events were higher on Albi than Pbo and Pio for injection site reactions (14.4%, 5.2%, 5.1% of participants, respectively), diarrhea (13.7%, 10.4%, 8.3%), and nausea (11.1%, 6.1%, 7.2%), but not vomiting (2.6%, 3.5%, 5.1%). The incidence of SAEs (14.4%, 18.3%, 17.3%) and AEs leading to withdrawal (8.1%, 10.4%, 10.5%) was lower on Albi than Pbo and Pio.

**Conclusion:** Albi in triple therapy gives effective glucose lowering to 3-years, was well tolerated, and was associated with less weight gain than Pio.

### Change from baseline in A1C (mean [SE] mmol/mol) (intent-to-treat population, including postrescue)

### A network meta-analysis to compare once weekly dulaglutide versus other GLP-1 receptor agonists in patients with type 2 diabetes

A. Padiyar<sup>1</sup>, J.C. Thompson<sup>1</sup>, J.N. Eaton<sup>1</sup>, N.S. Hawkins<sup>1</sup>, K. Norrbacka<sup>2</sup>,  
 M. Reaney<sup>2</sup>, R. Shaginian<sup>3</sup>, K.S. Boye<sup>4</sup>, N. Varol<sup>5</sup>;  
<sup>1</sup>ICON Health Economics, Oxford, <sup>2</sup>Eli Lilly and Company, Windlesham, UK, <sup>3</sup>Eli Lilly and Company, Houten, Netherlands, <sup>4</sup>Eli Lilly and Company, Indianapolis, USA.

**Background and aims:** A network meta-analysis (NMA) was performed to compare the efficacy of once weekly dulaglutide 1.5mg to other GLP-1 receptor agonists (GLP1 RAs) licensed for use in the USA/Europe for the treatment of hyperglycaemia in type 2 diabetes (T2D).

**Materials and methods:** A systematic review was conducted in CENTRAL, EMBASE, MEDLINE and recent conference proceedings from ADA, EASD, IDF-WDC, IDF-WPR and AASD (1990-Jan 2014) to identify randomised controlled trials of adults with T2D treated with liraglutide (1.2mg QD, 1.8mg QD), exenatide (5µg BID, 10µg BID, 2mg QW), lixisenatide (20µg QD) and/or albiglutide (30mg QW, 50mg QW). The AWARD 1, 2, 5 and 6 trials provided data for once weekly dulaglutide 1.5mg. The primary endpoint of the NMA was relative reduction in HbA<sub>1c</sub>. To adjust for potential heterogeneity, networks were stratified by background therapy: metformin monotherapy (add-on to MET) and metformin in combination with sulfonylurea (SU) and/or thiazolidinediones (TZD) (add-on to MET ± SU ± TZD). Networks were further stratified by study duration of 16–36 weeks and 37–56 weeks to generate four networks. Baseline HbA<sub>1c</sub> was adjusted for using meta-regression. The NMA was performed within a Bayesian framework; both fixed and random effects models were assessed.

**Results:** Baseline HbA<sub>1c</sub> adjusted results are presented as mean differences in HbA<sub>1c</sub> (%) change from baseline and 95% credible intervals (CrI) for once weekly dulaglutide 1.5mg versus other GLP1 RAs in Table 1. Random effects

models are presented where convergence was achieved; otherwise, fixed effects models are presented. The 37–56 weeks add-on to MET network was disconnected; therefore a NMA could not be conducted. In the 16–36 week network meta-analyses, once weekly dulaglutide 1.5mg showed improved control of HbA<sub>1c</sub> (%) compared to exenatide 5µg BID and lixisenatide 20µg QD as add-on to both MET and MET ± SU ± TZD, and exenatide 10µg BID as add-on to MET ± SU ± TZD only with statistically significant reductions from baseline. In the 17–56 week add-on to MET ± SU ± TZD NMA, once weekly dulaglutide 1.5mg showed a significant reduction in HbA<sub>1c</sub> (%) compared to albiglutide 30mg QW and exenatide 10µg BID. A higher baseline HbA<sub>1c</sub> (%) was associated with greater reductions in HbA<sub>1c</sub> (%) but the effect was non-significant.

**Conclusion:** In the AWARD clinical trial program, once weekly dulaglutide 1.5mg demonstrated significant improvements in HbA<sub>1c</sub> (%) reduction from baseline. In these NMAs, we have shown statistically significant improvements in HbA<sub>1c</sub> (%) control with once weekly dulaglutide 1.5mg in seven comparisons. The results in the remaining comparisons were not statistically significant. Once weekly dulaglutide 1.5mg was not statistically significantly inferior to other GLP1 RAs in any of the comparisons.

**Table 1:** Mean difference (95% CrI) in HbA<sub>1c</sub> (%) change for once weekly dulaglutide 1.5mg vs. comparator

<sup>5</sup>Université Pierre & Marie Curie, Paris, <sup>6</sup>INSERM, Villejuif,

<sup>7</sup>Lariboisière Hospital, Paris, France.

**Background and aims:** We report 2-year data on effectiveness and tolerability of the GLP-1 analogue liraglutide in the EVIDENCE observational, postmarketing study.

**Materials and methods:** EVIDENCE is a 2-year multicentre, observational, postmarketing outpatient study requested by the French National Health Authority in order to evaluate the efficacy and safety of liraglutide in clinical practice. Diabetologists and general practitioners in France recruited patients starting treatment with liraglutide. Patients and physicians completed questionnaires at study entry, 3 months and 6 months, then at 6-month intervals for a further 18 months. The primary objective was to determine the percentage of patients still taking liraglutide and at HbA<sub>1c</sub> target (<7%) after 2 years. We present here data on effectiveness as measured by change in the proportion of patients with HbA<sub>1c</sub> <7%, HbA<sub>1c</sub>, fasting plasma glucose and weight. Tolerability and persistence under treatment are also presented. The characteristics of included participants were described by the mean and standard deviation (mean±SD) for continuous measures, and frequency for categorical measures. The changes from baseline to the end of the study were compared by the McNemar test for proportion, and by the Wilcoxon test for continuous measures.

**Results:** Baseline data were collected from 3152 patients (53% male, age 59±11 years, BMI 34±7 kg/m<sup>2</sup>, diabetes duration 10±6 years, HbA<sub>1c</sub> 8.5±1.5%); 2029 patients (64.4%) were still taking liraglutide at the end of the study, beyond the initial objective of 1707. Most patients (n=2804, 90%) exceeded the ADA/EASD target with an HbA<sub>1c</sub> ≥7% at baseline. The proportion of patients with HbA<sub>1c</sub> <7% was significantly higher after 2 years' liraglutide treatment (n=759, 39.4%) vs. baseline (n=213, 11.0%; p<0.0001).

Following 2 years of liraglutide treatment, significant reductions in HbA<sub>1c</sub> (-1.01±1.54%, p<0.0001), fasting plasma glucose (-0.32±0.63 g/l, p<0.0001) and body weight (-4.09±6.97 kg, p<0.0001) were observed from baseline. These data are from patients who had both baseline and 2-year data available and were still on liraglutide treatment at the end of the study (n=1928). GI disorders (nausea, vomiting, diarrhoea) were the most frequent adverse events, reported by 261 patients (8.7%) treated with liraglutide; they were also the most common reason for withdrawal.

**Conclusion:** These results show that the results obtained at 1 year were maintained at the end of the study. The effectiveness of liraglutide in real world clinical practice is similar to efficacy observed in randomised clinical trials (RCTs) (up to -1.5% HbA<sub>1c</sub> reductions and -3.24 kg weight loss). However, the absence of a control arm makes it difficult to evaluate if observed improvements are attributable to liraglutide alone. The slightly lower mean HbA<sub>1c</sub> in this study may be due to differing treatment strategies: in RCTs, liraglutide was generally added on to existing therapy, whereas in EVIDENCE a third of patients switched from a DPP-4 inhibitor to liraglutide. The incidence of GI events was lower than that reported in RCTs (up to 26.5%). In summary, 2-year results from the EVIDENCE study suggest that clinical trial data for liraglutide translate into therapeutic benefits in clinical practice.

**Background and aims:** This post hoc assessment evaluated the efficacy and safety of the once-daily prandial glucagon-like peptide-1 (GLP-1) receptor agonist (RA) lixisenatide in patients with type 2 diabetes mellitus and renal impairment.

**Materials and methods:** Patients from the modified intent-to-treat populations of nine GetGoal trials were categorized by baseline estimated GFR (eGFR) according to ADA 2013 categories of renal function at randomization (normal renal function, eGFR ≥90 ml/min; mild renal impairment [Stage II], eGFR 60–89 ml/min; moderate renal impairment [Stage III], eGFR 30–59 ml/min). Meta-analyses were performed using effect estimates (placebo-adjusted mean difference or placebo-adjusted rate difference for lixisenatide-treated patients between baseline renal categories) and their standard errors, entered as generic inverse variances.

**Results:** Patient distribution across renal function categories was as follows: normal renal function, lixisenatide n=2081, placebo n=1158; mild renal impairment, lixisenatide n=592, placebo n=404; moderate renal impairment, lixisenatide n=110, placebo n=62. HbA<sub>1c</sub>, 2h postprandial plasma glucose and fasting plasma glucose were reduced in lixisenatide-treated patients with normal and Stage I, II and III renal function. Meta-analyses showed no significant difference between normal renal function and mild or moderate renal impairment groups for clinical endpoints (Table). The most common adverse events in all groups were gastrointestinal (GI); mainly nausea and vomiting. There was 10% higher risk of nausea and vomiting between patients with normal renal function and those with mild renal impairment (placebo-adjusted rate difference p=0.003), but no significant difference between patients with mild and moderate renal impairment (p=0.92).

**Conclusion:** This study shows that a difference in baseline renal status did not have an effect on efficacy outcomes in lixisenatide- vs placebo-treated patients, and a uniform placebo-adjusted effect of lixisenatide was observed across renal categories.

### Predicting treatment success with exenatide twice daily (EBID) at 6 mo: Are baseline postprandial glucose excursions important?

J. Shaw<sup>1</sup>, B. Gallwitz<sup>2</sup>, G. Scherthaner<sup>3</sup>, J. Han<sup>4</sup>, J. Malloy<sup>5</sup>;  
<sup>1</sup>Baker IDI Heart and Diabetes Institute, Melbourne, Australia,  
<sup>2</sup>Eberhard-Karls-University, Tubingen, Germany, <sup>3</sup>Rudolfstiftung Hospital, Vienna, Austria, <sup>4</sup>AstraZeneca, <sup>5</sup>Bristol-Myers Squibb, San Diego, USA.

**Background and aims:** Information on predicting glycaemic treatment success in patients (pts) before initiation of specific therapies, particularly GLP-1 receptor agonists, is limited. As EBID effectively suppresses postprandial blood glucose (BG) through mechanisms including decreased gastric emptying, we assessed whether a greater postprandial BG defect was predictive of treatment success for EBID and, conversely, whether a pt with a greater fasting BG defect was less likely to achieve treatment success with EBID.

**Materials and methods:** A pooled dataset (24–30 wks) from 8 EBID studies that collected self-monitored BG data was used. Treatment success at 6 mo was defined as HbA<sub>1c</sub> <7% or HbA<sub>1c</sub> decrease ≥1%. Logistic regression models were applied to analyze these binary outcomes, with baseline HbA<sub>1c</sub>, post-breakfast (postprandial) BG excursion and pre-breakfast (fasting) BG as independent variables. Odds ratios (ORs) were calculated for baseline HbA<sub>1c</sub>, post-breakfast BG excursion, and pre-breakfast BG.

**Results:** 1414 EBID pts were included; mean baseline HbA<sub>1c</sub> was 8.0%. Most pts (93%) received background therapy with ≥1 other agent. At endpoint, mean reduction in HbA<sub>1c</sub> was 1.0%; 58% of pts achieved HbA<sub>1c</sub> <7% and 52% achieved HbA<sub>1c</sub> decrease ≥1% with EBID. Baseline HbA<sub>1c</sub> was the most significant baseline predictor of treatment success (P<0.0001). The likelihood of attaining treatment success for every 1% increase in baseline HbA<sub>1c</sub> given the same baseline pre-breakfast and post-breakfast BG depended on the definition of success (Table); pts close to 7% HbA<sub>1c</sub> at baseline were more likely to attain HbA<sub>1c</sub> <7% at endpoint, while pts further from 7% HbA<sub>1c</sub> at baseline were more likely to achieve HbA<sub>1c</sub> decrease ≥1% at endpoint. For pts with higher post-breakfast (post-prandial) BG treated with EBID, each 1.11 mmol/L increase was significantly associated with a 7.4% increased likelihood of achieving an HbA<sub>1c</sub> reduction ≥1% given comparable HbA<sub>1c</sub> and pre-breakfast BG. Baseline post-breakfast BG excursion did not predict achievement of HbA<sub>1c</sub> <7%. Conversely, pts with an increased pre-breakfast (fasting) BG were significantly less likely to achieve either goal with EBID; ORs for HbA<sub>1c</sub> <7% or HbA<sub>1c</sub> reduction ≥1% decreased by 9 and 12%, respectively, for each 1.11 mmol/L increase given comparable baseline HbA<sub>1c</sub> and post-breakfast glucose.

**Conclusion:** A greater postprandial BG defect was predictive of a greater likelihood of achieving an HbA<sub>1c</sub> reduction ≥1% but not HbA<sub>1c</sub> <7% with EBID and, conversely, a greater fasting BG defect was associated with less likelihood of achieving HbA<sub>1c</sub> <7% or an HbA<sub>1c</sub> reduction ≥1% among those treated with EBID. However, neither postprandial nor fasting BG defects

at baseline predicted treatment success with EBID as effectively as baseline HbA<sub>1c</sub>.

| Odd ratios (95% CI) for treatment success at 6 months |                                     |                                   |

### Lixisenatide added to basal insulin reduces glycaemic variability in patients with type 2 diabetes mellitus

D. O'Neal<sup>1</sup>, G. Umpierrez<sup>2</sup>, A. DiGenio<sup>3</sup>, R. Goldenberg<sup>4</sup>, E. Hernandez-Triana<sup>5</sup>, J. Lin<sup>6</sup>, C.-Y. Park<sup>7</sup>, E. Renard<sup>8</sup>, B. Kovatchev<sup>9</sup>;  
<sup>1</sup>University of Melbourne Dept of Medicine, St Vincent's Hospital, Australia,  
<sup>2</sup>Emory University School of Medicine, Atlanta, <sup>3</sup>ISIS Pharmaceuticals, Carlsbad, USA, <sup>4</sup>LMC Diabetes & Endocrinology, Thronhill, Canada,  
<sup>5</sup>Endocare Research Institute, Universidad del Rosario, Bogota, Colombia,  
<sup>6</sup>Novosys Health, Flemington, USA, <sup>7</sup>Sungkyunkwan University School of Medicine, Seoul, Republic of Korea, <sup>8</sup>Montpellier University Hospital, France, <sup>9</sup>University of Virginia Health System, Charlottesville, USA.

**Background and aims:** This analysis evaluated the impact on glycaemic variability (GV) of lixisenatide (LIXI) vs placebo (PBO) as add-on to basal insulin ± oral antidiabetes drugs (OADs) in patients with type 2 diabetes mellitus (T2DM).

**Materials and methods:** Patient-level data from GetGoal-L, GetGoal-Duo1, and GetGoal-L-Asia were pooled: standard deviation (SD); mean amplitude of glycaemic excursions (MAGE); mean absolute glucose (MAG); area under the curve-fasting glucose (AUC-F); and high and low blood glucose indices (HBGI/LBGI) were calculated. Changes in GV metrics over 24 weeks of treatment were compared. Relationships between baseline GV, patient characteristics, and clinical outcomes were assessed.

**Results:** Data from 1,198 patients were analysed (665 LIXI and 533 PBO); 47.9% of patients were men, mean age was 57.2 years, mean BMI 30.4 kg/m<sup>2</sup>, mean T2DM duration 11.7 years, and mean HbA<sub>1c</sub> 8.1%. GV significantly decreased at Week 24 with LIXI vs PBO, respectively: SD -8.28 vs -3.89 mg/dL (p = 0.003); MAG -6.80 vs -1.48 mg/dL (p < 0.001); MAGE -16.02 vs -7.02 mg/dL (p = 0.003); HBGI -3.65 vs -0.88 (p < 0.001); and AUC-F -298.51 vs -15.49 mg/dL\*h (p < 0.001). LBGI was unchanged 0.04 vs -0.03 (p = 0.277). Higher baseline GV correlated with older age, longer T2DM duration, lower BMI, higher baseline HbA<sub>1c</sub>, greater postprandial plasma glucose (PPG) reduction, and higher symptomatic hypoglycaemia rates (Table).

**Conclusion:** When added to basal insulin ± OADs, LIXI significantly reduced GV and PPG excursions vs PBO, without increased risk of hypoglycaemia (as shown by LBGI). This may have relevance in patients with advanced T2DM where GV is increased.

|                | Age               | T2DM Duration     | Baseline BMI       | Baseline HbA <sub>1c</sub> | PPG Change From Baseline | No. of Symptomatic Hypoglycaemic Events per Year |

**Sustained glycaemic control with exenatide once weekly versus insulin glargine: associations with baseline factors and early treatment response**M.E. Trautmann<sup>1</sup>, J. Malloy<sup>2</sup>, J. Han<sup>3</sup>;<sup>1</sup>Diabetes Research, Hamburg, Germany, <sup>2</sup>Bristol-Myers Squibb,<sup>3</sup>AstraZeneca, San Diego, USA.

**Background and aims:** To assist decision making in type 2 diabetes mellitus therapy, this post hoc analysis explored the association between baseline characteristics or early ( $\leq 12$  week) treatment responses with sustained glycaemic control, comparing the glucagon-like peptide-1 receptor agonist exenatide once weekly (QW) with titrated insulin glargine (glargine).

**Materials and methods:** Three-year data were analysed from the open-label DURATION-3 study, in which patients received exenatide QW (N=233) or glargine (N=223) in addition to metformin alone or with a sulphonylurea. Loss of, or inability to achieve, HbA1c control was defined as HbA1c  $> 7\%$  at 2 consecutive visits or HbA1c  $> 9\%$  at 1 visit after 26 weeks of treatment. Baseline characteristics considered were: age, gender, body mass index, weight, background glucose-lowering medication, disease duration, creatinine clearance, HbA1c, fasting serum glucose (FSG), Homeostasis Model Assessment (HOMA) -S (insulin sensitivity) and HOMA-B ( $\beta$ -cell function). Early treatment responses considered were HbA1c, FSG and weight. Cox proportional hazard models were used to analyse the intention to treat (ITT) population and logistic regression was used to analyse the 3-year Completer population (exenatide QW, N=140; glargine, N=147).

**Results:** Of the ITT patients, 50% on exenatide QW versus 43% on glargine achieved the sustained glycaemic goal; of 3-year Completers, 43 versus 33% achieved the glycaemic goal. The median duration of HbA1c control was 25.0 versus 16.7 months for exenatide QW versus glargine (ITT; Kaplan-Meier;  $P=0.03$ ). The hazard ratio (glargine/exenatide; Cox model) of inability to achieve the glycaemic goal was 1.4 ( $P=0.006$ ). In 3-year Completers (both treatments), stepwise logistic regression showed that only baseline HbA1c and HOMA-B were significantly associated with sustained glycaemic control. Regardless of therapy, every 1% higher baseline HbA1c ( $> 7\%$ ) increased the risk of losing glycaemic control by 90% ( $P=0.0002$ ); every 10% higher baseline HOMA-B decreased the risk of losing glycaemic control by 11% ( $P=0.0288$ ). The rate of weight change in weeks 1-8 was the most relevant early treatment response predictor of HbA1c control ( $P=0.0640$ ). The medium slope of weight change was  $-0.0308$  kg/day for exenatide QW ( $-0.86$  kg in 4 weeks) versus  $0.0018$  kg/day for glargine ( $0.05$  kg in 4 weeks). The odds (glargine/exenatide QW) of losing glycaemic control if the same weight change was seen in both groups was 1.2 (weight loss) and 1.1 (weight gain), indicating that glargine-treated patients were more likely to lose glycaemic control over time regardless of weight gain or loss. For a 1 kg decrease in weight over weeks 1-4 with exenatide QW, the odds of losing glycaemic control decreased by 30%; for a 1 kg increase in weight over weeks 1-4 with glargine, the odds increased by 29%.

**Conclusion:** Despite continued glargine titration, more patients achieved sustained glycaemic control with exenatide QW. Baseline HbA1c and HOMA-B significantly impacted the odds of sustained control. The analysis of early treatment responses from this study suggest that the rate of weight change following treatment initiation (weeks 1-8) may potentially predict the chance of patients achieving longer term sustained glycaemic control.

**Daily blood glucose variability with exenatide once weekly versus basal insulin in 3 randomised controlled trials**J. Vora<sup>1</sup>, J. Malloy<sup>2</sup>, M. Zhou<sup>3</sup>, E. Hardy<sup>4</sup>, N. Iqbal<sup>5</sup>, M. Trautmann<sup>6</sup>;<sup>1</sup>Royal Liverpool University Hospital, UK, <sup>2</sup>Bristol-Myers Squibb, San Diego,<sup>3</sup>Bristol-Myers Squibb, Hopewell, <sup>4</sup>Astra Zeneca, Wilmington, <sup>5</sup>Bristol-Myers Squibb, Princeton, USA, <sup>6</sup>Diabetes Research, Hamburg, Germany.

**Background and aims:** Glucose lowering therapy aims to improve overall glycaemic control in patients with type 2 diabetes mellitus. However, data on blood glucose variability with different treatments are scarce. Because basal insulin mainly affects fasting plasma glucose and exenatide once weekly (QW) controls both fasting plasma glucose and postprandial plasma glucose, we hypothesized that daily blood glucose variability would be improved more by exenatide QW than by titrated basal insulin in randomised controlled trials.

**Materials and methods:** After 26 weeks, 7-point self-monitored blood glucose profiles were assessed in 3 randomised controlled trials of exenatide QW: 2 versus insulin glargine (once daily at night) in global and Japanese populations; 1 versus insulin detemir (once daily at night [90%] or twice daily [10%]). All patients had failed  $\geq 1$  oral drug; Japanese patients discontinued sulphonylureas at randomisation. Outcomes assessed were mean amplitude of glucose excursion (MAGE; average daily mealtime glucose excursion), blood glucose range (average difference between maximum and minimum daily blood glucose) and blood glucose variability (average SD of daily blood glucose).

**Results:** In all 3 studies, HbA1c reductions were greater with exenatide QW than basal insulin ( $-1.5$  vs  $-1.3\%$   $P<0.02$ ;  $-1.1$  vs  $-0.7\%$ ,  $P<0.001$ ;  $-1.3$  vs  $-0.9\%$ ,  $P<0.001$ , respectively). Baseline characteristics and laboratory results were well balanced across treatments within studies. Exenatide QW significantly reduced different measures of blood glucose variability (including MAGE, range and variability) more than insulin glargine in both available studies (Table), demonstrating greater consistency in blood glucose over the day. A greater decrease in glucose variability was also observed for exenatide QW versus insulin detemir, although comparison between treatments was not statistically significant in this analysis. Basal insulin reduced pre-breakfast (fasting) blood glucose from baseline more than exenatide QW ( $-2.54$  to  $-3.41$  vs  $-1.88$  to  $-2.77$  mmol/L;  $P<0.05$ ) but the relative effect of exenatide QW increased through the day, with a greater reduction in blood glucose post-dinner versus basal insulin ( $-2.89$  to  $-4.23$  vs  $-1.84$  to  $-2.54$  mmol/L;  $P<0.05$ ). The loss of control with basal insulin in the latter half of the day is consistent with its once daily kinetics.

**Conclusion:** Exenatide QW improved daily blood glucose variability more than insulin glargine, and lowered fasting blood glucose less - but post-dinner blood glucose more - than both basal insulins (glargine and detemir).

<sup>1</sup>School of Life and Health Sciences, Aston University, Birmingham, UK, <sup>2</sup>American University of Beirut Medical Center, Lebanon, <sup>3</sup>Ochsner Medical Center, New Orleans, USA, <sup>4</sup>Hasharon Hospital-Rabin Medical Center, Petach-Tikva, Israel, <sup>5</sup>Universitat Autònoma de Barcelona, Badalona, Spain, <sup>6</sup>CPClin – Clinical Research Center, São Paulo, Brazil, <sup>7</sup>Global Medical Affairs, Diabetes Division, Sanofi, Bridgewater, USA, <sup>8</sup>Université Paris-Diderot, France, <sup>9</sup>Kobe University Graduate School of Medicine, Japan, <sup>10</sup>Instituto de Diabetes Obesidad y Nutrición S.C., Cuernavaca, Mexico, <sup>11</sup>Diabeteszentrum Bad Lauterberg, Germany.

**Background and aims:** Lixisenatide, a once-daily prandial glucagon-like peptide-1 receptor agonist, reduces postprandial (PP) glycaemic excursions and HbA<sub>1c</sub>. We report an exploratory analysis of the GetGoal-M and S trials in patients with type 2 diabetes mellitus (T2DM) with different changes in PP glucagon levels in response to lixisenatide treatment.

**Materials and methods:** Patients (n=423) were stratified by their change in 2 hour PP glucagon level between baseline evaluation and Week 24 of treatment with lixisenatide as add-on to oral antidiabetics (OADs) into groups of Greater Change (GC; n=213) or Smaller Change (SC; n=210) in plasma glucagon levels (median change -23.57 ng/L). ANOVA and Chi-squared tests were used for the comparison of continuous and categorical variables, respectively. Baseline and endpoint continuous measurements in each group were compared using paired *t*-tests.

**Results:** Mean change from baseline in 2 hour PP glucagon levels for the GC vs SC groups was -47.19 vs -0.59 ng/L (*p*<0.0001), respectively. Patients in the GC group had a shorter mean duration of diabetes (7.3 vs 9.0 years; *p*=0.0036) and lesser OAD use (4.5 vs 5.7 years; *p*=0.0092) than those in the SC group. Patients in the GC group had a greater mean reduction in HbA<sub>1c</sub> (-1.10 vs -0.67%; *p*<0.0001), fasting plasma glucose (FPG; -25.20 vs -9.30 mg/dL [*p*<0.0001]), PP plasma glucose (PPG; -129.40 vs -78.22 mg/dL [*p*<0.0001]), and a greater drop in weight (-2.27 vs -1.17 kg; *p*=0.0002) and body mass index (-0.84 vs -0.44 kg/m<sup>2</sup>; *p*=0.0002) than those in the SC group. More patients in the GC group also achieved composite endpoints, including HbA<sub>1c</sub> <7% with no symptomatic hypoglycaemia and no weight gain (40.38 vs 19.52%; *p*<0.0001), than in the SC group.

**Conclusion:** Greater reductions in PP glucagon associated with lixisenatide as add-on to OADs in patients with T2DM are also associated with greater reductions in HbA<sub>1c</sub>, FPG, PPG, and greater weight loss, highlighting the importance of glucagon suppression on therapeutic response.

### Glycaemic efficacy of canagliflozin by baseline HbA<sub>1c</sub> and known duration of type 2 diabetes mellitus

S. Cerdas<sup>1</sup>, L.A. Leiter<sup>2</sup>, L. Blonde<sup>3</sup>, J. Wilding<sup>4</sup>, C. Tong<sup>5</sup>, J. Yee<sup>5</sup>, G. Meininger<sup>5</sup>;

<sup>1</sup>Hospital Cima, Centro de Investigación Clínica San Agustín, San José, Costa Rica, <sup>2</sup>Keenan Research Centre in the Li Ka Shing Knowledge Institute of St. Michael's Hospital, University of Toronto, Canada, <sup>3</sup>Department of Endocrinology, Diabetes, and Metabolic Diseases, Ochsner Medical Center, New Orleans, USA, <sup>4</sup>Department of Obesity and Endocrinology, University of Liverpool, UK, <sup>5</sup>Janssen Research & Development, LLC, Raritan, USA.

**Background and aims:** Canagliflozin (CANA) is a sodium glucose co-transporter 2 (SGLT2) inhibitor that has demonstrated glycaemic efficacy across a range of type 2 diabetes mellitus (T2DM) patient populations. This analysis evaluated the effects of CANA compared with placebo (PBO) on changes in HbA<sub>1c</sub> based on baseline HbA<sub>1c</sub> and duration of T2DM using pooled data from 4 clinical studies in patients with T2DM.

**Materials and methods:** Data were pooled from the 4 randomised, double-blind, 26-week, PBO-controlled, Phase 3 studies that enrolled a general population of patients with T2DM (N = 2,313; mean age, 56.0 y; HbA<sub>1c</sub>, 8.0%; BMI, 32.1 kg/m<sup>2</sup>; SBP, 128.4 mmHg). Changes in HbA<sub>1c</sub> with CANA 100 and 300 mg and PBO were evaluated at 26 weeks in subgroups by baseline HbA<sub>1c</sub> (<8.0%, 8.0%–<9.0%, and ≥9.0%) and T2DM duration (<5 y, 5–<10 y, and ≥10 y).

**Results:** CANA 100 and 300 mg, respectively, were associated with progressively greater PBO-subtracted reductions in HbA<sub>1c</sub> as baseline HbA<sub>1c</sub> increased (<8.0%: -0.45% and -0.65%; 8.0%–<9.0%: -0.91% and -1.07%; ≥9.0%: -1.25% and -1.48%, Table). CANA 100 and 300 mg were associated with PBO-subtracted reductions in HbA<sub>1c</sub> in patients with T2DM <5 y duration (-0.70% and -0.96%, respectively) as well as those with 5–<10 y T2DM duration (-0.74% and -0.91%, respectively) and ≥10 y T2DM duration (-0.74% and -0.85%, respectively). Overall AE rates with CANA 100 and 300 mg and PBO were 60.1%, 59.2%, and 59.4%, respectively. CANA 100 and 300 mg were associated with a higher incidence of genital mycotic infections and osmotic diuresis-related AEs (eg, pollakiuria [increased urine frequency], thirst) compared with PBO; these AEs led to few discontinuations.

**Conclusion:** CANA provided glycaemic improvements in patients with T2DM regardless of baseline HbA<sub>1c</sub> or known duration of T2DM. Greater reductions in HbA<sub>1c</sub> with CANA were seen in patients with higher baseline HbA<sub>1c</sub>, similar to what has been observed with other antihyperglycaemic agents. Reductions in HbA<sub>1c</sub> were similar across all T2DM duration subgroups.

Table. Change in HbA<sub>1c</sub> by Baseline HbA<sub>1c</sub> and T2DM Duration (LOCF)

|   | HbA <sub>1c</sub> <8.0% |                       |                       | HbA <sub>1c</sub> , 8.0%–<9.0% |                       |                       | HbA <sub>1c</sub> ≥9.0% |                       |                       |

**Durability of glycaemic response with dapagliflozin as add-on therapy in type 2 diabetes inadequately controlled with metformin; 4-year data versus glipizide**S. Del Prado<sup>1</sup>, M. Nauck<sup>2</sup>, K. Rohwedder<sup>3</sup>, E. Johnsson<sup>4</sup>, S. Parikh<sup>5</sup>;<sup>1</sup>University of Pisa, Italy, <sup>2</sup>Diabetes Center, Bad Lauterberg,<sup>3</sup>AstraZeneca, Wedel, Germany, <sup>4</sup>AstraZeneca, Mölndal, Sweden,<sup>5</sup>AstraZeneca, Wilmington, USA.

**Background and aims:** Dapagliflozin (DAPA), a selective inhibitor of the sodium-glucose co-transporter 2, reduces plasma glucose by increasing renal glucose excretion. Its insulin-independent mechanism results in a low risk of hypoglycaemia in contrast to sulphonylureas. In a phase 3 trial of DAPA ( $\leq 10$  mg/d) versus glipizide ( $\leq 20$  mg/d) in patients (N=814) with type 2 diabetes mellitus inadequately controlled by metformin (MET) alone (median 2000 mg/d), the change in HbA<sub>1c</sub> with DAPA was statistically noninferior to glipizide over 52 weeks. Further to these previously presented data on the primary end point we report the durability of glycaemic control over 4 years.

**Materials and methods:** The durability of glycaemic control was evaluated by calculating the coefficient of failure (CoF; the slope of the regression line vs time) for HbA<sub>1c</sub> and fasting plasma glucose (FPG) from 18 weeks (end of titration period) to 208 weeks. DAPA and glipizide were down-titrated if medically indicated. The CoF was determined for 3 groups: patients who had at least 3 postbaseline values from after week 18 to week 208 (full analysis set), all patients who completed 208 weeks of treatment (all completers), and patients who completed 208 weeks of treatment but who were not down-titrated (completers not down-titrated). Patients who required rescue medication were excluded from the analyses.

**Results:** The CoF for DAPA was significantly lower compared with glipizide, irrespective of which glycaemic variable (HbA<sub>1c</sub> or FPG) or analysis set was employed (Table). For the full analysis set, the CoF for HbA<sub>1c</sub> showed a rise of 0.2%/year (95% CI, 0.1 to 0.3) with DAPA and a rise of 0.6%/year (95% CI, 0.5 to 0.7) with glipizide. Corresponding values for FPG were 0.4 mmol/L/year (95% CI, 0.2 to 0.5) for DAPA and 0.8 mmol/L/year (95% CI, 0.5 to 1.1) for glipizide. More patients treated with DAPA completed the 208-week study than patients treated with glipizide (161 vs 141, respectively). Fewer DAPA-treated patients had their dose down-titrated (3 vs 42, respectively; Table). For all completers and for completers who were not down-titrated, the CoFs for HbA<sub>1c</sub> and FPG were significantly lower with DAPA compared with glipizide (Table). Thus, the higher rates of discontinuation or down-titration with glipizide did not account for the lower CoF with DAPA. Treatment with DAPA in combination with MET was well tolerated over the 208-week period.

**Conclusion:** Glycaemic durability over a 4-year period was significantly better with DAPA compared with glipizide as demonstrated by the CoF. DAPA in combination with MET was well tolerated.

| Analysis set [n: DAPA vs glipizide]          | Difference: DAPA versus glipizide   |                                 |

**Empagliflozin twice daily versus once daily as add-on to metformin in patients with type 2 diabetes**S. Ross<sup>1</sup>, C. Thamer<sup>2</sup>, J. Cescutti<sup>3</sup>, T. Meinicke<sup>4</sup>, H.J. Woerle<sup>4</sup>, U.C. Broedl<sup>4</sup>;<sup>1</sup>University of Calgary, LMC Endocrinology Centres, Canada,<sup>2</sup>Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach, Germany,<sup>3</sup>Boehringer Ingelheim France S.A.S., Reims, France,<sup>4</sup>Boehringer Ingelheim Pharma GmbH & Co. KG, Ingelheim, Germany.

**Background and aims:** A randomized, double-blind, placebo-controlled, parallel-group study compared the efficacy and safety of empagliflozin (EMPA) twice daily (bid) versus once daily (qd) regimens as add-on to metformin (MET) in patients with type 2 diabetes (T2DM).

**Materials and methods:** Patients (n=983) were randomised to EMPA 12.5 mg bid (n=219), EMPA 25 mg qd (n=218), EMPA 5 mg bid (n=219), EMPA 10 mg qd (n=220) or placebo (PBO; n=107) added on to stable dose MET bid ( $\geq 1500$  mg/day) for 16 weeks. The primary endpoint was change from baseline in HbA<sub>1c</sub> at week 16. The secondary endpoint was change from baseline in fasting plasma glucose (FPG) at week 16. Exploratory endpoints included changes from baseline in body weight, systolic and diastolic blood pressure (SBP and DBP) at week 16. The primary analysis was a test of non-inferiority of EMPA 12.5 mg bid versus EMPA 25 mg qd and of EMPA 5 mg bid versus EMPA 10 mg qd. The superiority of EMPA doses versus placebo was also tested. Efficacy was evaluated in 965 patients (mean [SD] age 58.2 [10.3] years; weight 89.0 [18.5] kg; BMI 31.8 [5.2] kg/m<sup>2</sup>; HbA<sub>1c</sub> 7.77 [0.80] %).

**Results:** Reductions from baseline in HbA<sub>1c</sub> were non-inferior for EMPA 12.5 mg bid versus 25 mg qd and for EMPA 5 mg bid versus 10 mg qd. Reductions from baseline in HbA<sub>1c</sub> were statistically significant with all EMPA doses compared with PBO. FPG changes with EMPA were consistent with HbA<sub>1c</sub> changes. EMPA qd and bid doses reduced body weight, SBP and DBP to a similar extent. Adverse events (AEs) were reported by 45.7%, 41.7%, 43.8%, 50.0% and 47.7% of patients on EMPA 12.5 mg bid, EMPA 25 mg qd, EMPA 5 mg bid, EMPA 10 mg qd and PBO, respectively. Confirmed hypoglycaemic AEs (<70 mg/dl and/or requiring assistance) were reported by 1 patient each on EMPA 25 mg qd, EMPA 5 mg bid, EMPA 10 mg qd and PBO, and were generally mild in intensity; none required assistance. AEs consistent with urinary tract infection (UTI) were reported in 5.9%, 5.5%, 7.8%, 9.5% and 3.7% of patients on EMPA 12.5 mg bid, EMPA 25 mg qd, EMPA 5 mg bid, EMPA 10 mg qd and PBO, respectively. AEs consistent with genital infection were reported in 4.1%, 4.1%, 3.7%, 3.2% and 2.8% of patients in these groups, and increased urination in 2.7%, 2.8%, 2.7%, 2.3% and 1.9% of patients in these groups, respectively. AEs consistent with volume depletion were reported in 0.5% of patients on EMPA 12.5 mg bid, 0.9% on EMPA 10 mg qd and no patients in other groups.

**Conclusion:** As add-on to MET in patients with T2DM, HbA<sub>1c</sub> reductions with EMPA bid dose regimens were statistically non-inferior to those with EMPA qd dose regimens. All EMPA dose regimens led to significant reductions in HbA<sub>1c</sub> versus PBO and were well tolerated.

### Systematic review and network meta-analysis to compare dapagliflozin with other diabetes medications in combination with metformin for adults with type 2 diabetes

G. Wygant<sup>1</sup>, A.H. Barnett<sup>2</sup>, M.E. Orme<sup>3</sup>, P. Fenici<sup>4</sup>, R. Townsend<sup>5</sup>, M. Roudaut<sup>6</sup>;

<sup>1</sup>Bristol-Myers Squibb, Princeton, USA, <sup>2</sup>Diabetes Centre, Birmingham, <sup>3</sup>ICERA Consulting Ltd, Swindon, UK, <sup>4</sup>Bristol-Myers Squibb (at the time of research), Paris, France, <sup>5</sup>AstraZeneca (at the time of research), Brussels, Belgium, <sup>6</sup>Bristol-Myers Squibb, Paris, France.

**Background and aims:** Effective management of type 2 diabetes mellitus (T2DM) and its complications is required in order to address the growing burden of the disease on healthcare resources. However, there are many factors to consider when assessing the suitability of available treatments. A network meta-analysis (NMA) update was undertaken to evaluate the sodium glucose co-transporter-2 (SGLT-2) inhibitor, dapagliflozin, versus other diabetes medications as add-on to metformin. This update allowed inclusion of a new drug class (glucagon-like peptide-1 [GLP-1] analogues), a new time-point (24-weeks) and covariate analysis.

**Materials and methods:** The systematic review identified recent randomised controlled trials (2011–July 2013) involving T2DM patients inadequately controlled on metformin monotherapy. Comparators licensed in the EU included dipeptidyl peptidase-4 inhibitors (DPP-4i), thiazolidinediones (TZDs), glucagon-like peptide-1 (GLP-1s) analogues, sulfonylureas (SUs) and dapagliflozin. Bayesian NMA was conducted for outcomes at 24- and 52-weeks, and both fixed and random-effect models were explored. Covariate analyses were performed to assess confounding baseline parameters where feasible.

**Results:** Of 2247 articles retrieved, 16 were included in the review. Combined with 19 from the pre-2011 analysis, a total of 19 and 8 studies were included in the 24-week and 52-week basecase NMA, respectively. There were sufficient data to analyse mean change in HbA1c, systolic blood pressure (SBP), change in weight, as well as the proportion of patients experiencing hypoglycaemia at both 24 and 52-weeks. There were no significant differences in change in HbA1c or SBP between dapagliflozin and the other classes of diabetes drugs as add-on to metformin at 24 or 52-weeks. Significant weight loss results were seen by 24-weeks for dapagliflozin compared to DPP-4i and TZD and at 52-weeks for dapagliflozin compared to SU, DPP-4i and TZD: -4.66 kg (-6.43, -2.90); -2.59 kg (-4.53, -0.66) and -4.76 kg (-7.28, -2.24) at 52 weeks, respectively. Dapagliflozin resulted in a significantly lower risk of hypoglycaemia compared to SU (OR: 0.05 [0.01, 0.19]) over 52-weeks. Covariate analysis indicated that a higher HbA1c at baseline was predictive of a larger treatment effect.

**Conclusion:** This NMA update supports previous findings that effects on HbA1c are largely similar between drug classes. However, dapagliflozin compared with DPP-4i, TZDs and SUs offered superior weight control when added to metformin and was associated with a significantly reduced risk of hypoglycaemia in comparison to SUs. The wider evidence base compared to previous analysis increases the confidence in the results.

**Table 1** Summary of results from basecase NMA: Dapagliflozin head-to-head with other drug classes

| Outcome                  | Difference in HbA1c              | Difference in weight kg | Difference in SBP         | OR of hypoglycaemia |

### Fixed dose combinations of empagliflozin and linagliptin for 52 weeks in drug-naïve subjects with type 2 diabetes

A. Lewin<sup>1</sup>, R. DeFronzo<sup>2</sup>, S. Patel<sup>3</sup>, D. Liu<sup>4</sup>, R. Kaste<sup>4</sup>, H.J. Woerle<sup>5</sup>, U.C. Broedl<sup>5</sup>;

<sup>1</sup>National Research Institute, Los Angeles, <sup>2</sup>University of Texas Health Sciences, San Antonio, USA, <sup>3</sup>Boehringer Ingelheim Ltd., Bracknell, Berkshire, UK, <sup>4</sup>Boehringer Ingelheim Pharmaceuticals Inc., Ridgefield, USA, <sup>5</sup>Boehringer Ingelheim Pharma GmbH & Co. KG, Ingelheim, Germany.

**Background and aims:** A randomized, double-blind, parallel group Phase III study evaluated the efficacy and safety of fixed dose combinations (FDCs) of empagliflozin/linagliptin (EMPA/LINA) in drug-naïve subjects with type 2 diabetes (T2DM).

**Materials and methods:** Subjects were randomized to EMPA 25 mg/LINA 5 mg (n=137), EMPA 10 mg/LINA 5 mg (n=136), EMPA 25 mg (n=135), EMPA 10 mg (n=134), or LINA 5 mg (n=135) for 52 weeks. Primary analysis was at week 24. Exploratory endpoints at week 52 were changes from baseline in HbA1c, body weight, systolic and diastolic blood pressure (SBP and DBP), and percentage of subjects with baseline HbA1c ≥7% who reached HbA1c <7%. Efficacy was evaluated in 667 subjects (mean [SD] age 54.6 [10.2] years; weight 87.9 [20.1] kg; BMI 31.6 [5.6] kg/m<sup>2</sup>; HbA1c 8.02 [0.96] %).

**Results:** Compared with LINA 5 mg, both FDCs led to significant reductions in HbA1c and higher percentages of subjects with HbA1c <7% at week 52. EMPA 10 mg/LINA 5 mg led to significant reductions in HbA1c and a higher percentage of subjects with HbA1c <7% vs EMPA 10 mg. There were no significant differences in changes from baseline in HbA1c or percentages of subjects with HbA1c <7% with EMPA 25 mg/LINA 5 mg vs EMPA 25 mg. Compared with LINA 5 mg, body weight was significantly reduced with EMPA 25 mg/LINA 5 mg (difference: -2.2 kg [95% CI 3.4, 1.0]; p<0.001) and EMPA 10 mg/LINA 5 mg (difference: 1.5 kg [95% CI -2.8, -0.3]; p<0.05). The FDCs did not reduce weight vs their respective EMPA monotherapies. There were no changes from baseline in SBP or DBP with LINA 5 mg but EMPA and FDCs reduced SBP from baseline by 2.1 to 2.5 mmHg and DBP by 0.2 to 1.6 mmHg. Adverse events (AEs) were reported in 75.7%, 72.8%, 68.9%, 81.5% and 71.9% of subjects on EMPA 25 mg/LINA 5 mg, EMPA 10 mg/LINA 5 mg, EMPA 25 mg, EMPA 10 mg and LINA 5 mg, respectively, over 52 weeks. Confirmed hypoglycemic AEs (glucose ≤70 mg/dL and/or requiring assistance) were reported in 1 patient each on EMPA 25 mg and LINA 5 mg and 4 subjects on EMPA 10 mg; none required assistance. AEs consistent with urinary tract infection were reported in 12.5%, 15.4%, 10.4%, 16.3% and 10.4% of subjects on EMPA 25 mg/LINA 5 mg, EMPA 10 mg/LINA 5 mg, EMPA 25 mg, EMPA 10 mg and LINA 5 mg, respectively, and AEs consistent with genital infection were reported in 5.9%, 2.9%, 4.4%, 5.2% and 3.0% of subjects in these groups, respectively.

**Conclusion:** In drug-naïve subjects with T2DM, FDCs of EMPA 25 mg/LINA 5 mg and EMPA 10 mg/LINA 5 mg for 52 weeks significantly reduced HbA1c vs LINA 5 mg. HbA1c reductions were significantly greater with EMPA 10 mg/LINA 5 mg vs EMPA 10 mg, but not with EMPA 25 mg/LINA 5 mg vs EMPA 25 mg. FDCs were well tolerated, with overall safety profiles similar to those known for the individual components.

### Improvement in glycaemic control and reduction in body weight over 52 weeks with dapagliflozin as add-on therapy to metformin plus sulphonylurea

S. Matthaei<sup>1</sup>, K. Bowering<sup>2</sup>, K. Rohwedder<sup>3</sup>, A. Grohl<sup>4</sup>, E. Johnsson<sup>5</sup>;

<sup>1</sup>Diabetes-Zentrum Quakenbrück, Germany,

<sup>2</sup>University of Alberta, Edmonton, Canada, <sup>3</sup>AstraZeneca, Wedel,

<sup>4</sup>Aptiv Solutions, Köln, Germany, <sup>5</sup>AstraZeneca, Mölndal, Sweden.

**Background and aims:** Dapagliflozin (DAPA), a highly selective sodium-glucose co-transporter 2 inhibitor, improves glycaemic control and promotes body weight loss in patients with type 2 diabetes mellitus (T2DM) as monotherapy or in combination with other antihyperglycaemic drugs. This phase 3 study evaluated DAPA as an add-on therapy to metformin (MET) plus sulphonylurea (SU).

**Materials and methods:** Patients (men and women aged  $\geq 18$  years) with T2DM (HbA1c  $\geq 7.0\%$ – $\leq 10.5\%$  at randomisation) who were receiving a stable ( $\geq 8$  weeks prior to enrolment) dose combination of MET ( $\geq 1500$  mg/d) and SU (maximum tolerated dose of at least half maximum dose) were eligible to participate. Patients were randomised to receive DAPA 10 mg or placebo (PBO) once daily for 52 weeks (24-week double-blind period and 28-week extension).

**Results:** At week 52, HbA1c and fasting plasma glucose (FPG) improved with DAPA versus PBO (HbA1c -0.8% vs -0.1%; FPG -1.5 mmol/L [-27.6 mg/dL] vs 0.6 mmol/L [11.5 mg/dL]; Table). Over 52 weeks more patients achieved the American Diabetes Association recommended glycaemic goal of HbA1c < 7.0% with DAPA (27.3%) versus PBO (11.3%). Both body weight and systolic blood pressure were reduced with DAPA versus PBO. Total, low-density lipoprotein, and high-density lipoprotein cholesterol increased and triglycerides decreased from baseline to week 52 with DAPA versus PBO. No patient discontinued as a result of a lack of glycaemic control and fewer patients on DAPA (10.1%) than on PBO (42.7%) were rescued for failing to reach glycaemic targets (week 4–16, FPG >13.2 mmol/L (240 mg/dL); week 16–24, FPG >11.1 mmol/L (200 mg/dL); week 24–52, HbA1c > 8.0%). In DAPA versus PBO groups the frequency of adverse events (AEs) was 69.7% versus 73.4%, respectively; serious AEs were 6.4% versus 7.3%, and hypoglycaemic events were 15.6% versus 8.3% (1 event of hypoglycaemia led to discontinuation in the DAPA treatment arm). Genital infections were reported by 10.1% versus 0.9% of patients with DAPA versus PBO (women 14.3% vs 2.0%; men 4.3% vs 0%). Urinary tract infections were reported by 10.1% versus 11.0% of patients with DAPA versus PBO (women 12.7% vs 22.4%; men 6.5% vs 1.7%).

**Conclusion:** DAPA 10 mg resulted in sustained glycaemic benefits and weight loss over the duration of this 52-week study in patients with T2DM and inadequate glycaemic control on a background combination of MET and SU.

| Longitudinal analysis, excluding data after rescue           | PBO (n=108)                              | DAPA (n=108)                                    |

### Efficacy and safety of canagliflozin in patients with type 2 diabetes mellitus who were, or were not, on antihyperglycaemic agents at screening

G. González-Gálvez<sup>1</sup>, E. Jodar<sup>2</sup>, K. Kim<sup>3</sup>, M. Alba<sup>4</sup>, C. Tong<sup>4</sup>, G. Meiningner<sup>4</sup>;

<sup>1</sup>Instituto Jalisciense de Investigación en Diabetes y Obesidad, Guadalajara, Mexico,

<sup>3</sup>Department of Internal Medicine, Dongguk University Ilsan Hospital,

<sup>4</sup>Dongguk University School of Medicine, Goyang, Republic of Korea,

<sup>5</sup>Janssen Research & Development, LLC, Raritan, USA.

**Background and aims:** Canagliflozin (CANA), a sodium glucose co-transporter 2 (SGLT2) inhibitor, demonstrated glycaemic improvement and was generally well tolerated in a Phase 3 study of patients with type 2 diabetes mellitus (T2DM) inadequately controlled on diet and exercise. In that study, the efficacy and safety of CANA monotherapy compared with placebo (PBO) were evaluated in patients who were, or were not, on antihyperglycaemic agents (AHAs) at screening.

**Materials and methods:** In this randomised, double-blind, PBO-controlled study, patients with T2DM inadequately controlled with diet and exercise (N = 584; age, 55.4 y; HbA1c, 8.0%; fasting plasma glucose [FPG], 9.5 mmol/L; body mass index, 31.6 kg/m<sup>2</sup>) received CANA 100 or 300 mg or PBO once daily. Change in HbA1c from baseline to Week 26 was assessed in the overall modified intent-to-treat population and subsets of patients who were not on AHAs at screening (n = 303), or on AHAs (oral AHA monotherapy [except PPAR- $\gamma$  agonists] or low-dose combination metformin + sulphonylurea) and entered the AHA washout period (n = 281).

**Results:** Patients on AHAs at screening had a higher baseline mean age and T2DM duration, lower mean estimated glomerular filtration rate (eGFR), and higher HbA1c and FPG. Relative to PBO, CANA 100 and 300 mg lowered HbA1c in patients not on AHAs (differences of -0.72% and -1.05%) and on AHAs at screening (differences of -1.11% and -1.29%; Figure) at Week 26; changes were similar to those in the overall population. The overall incidence of adverse events (AEs) was higher with CANA 100 and 300 mg than PBO in patients not on AHAs (59% and 52% vs 46%) and on AHAs at screening (62% and 68% vs 52%), but the incidence of serious AEs and AEs leading to discontinuation were low across groups in both subsets.

**Conclusion:** CANA treatment lowered HbA<sub>1c</sub> and was generally well tolerated in patients with T2DM who were, or were not, on prior AHA therapy at screening.

Figure. Change in HbA<sub>1c</sub> at Week 26 in patients who were, or were not, on AHAs at screening.

AHA, antihyperglycaemic agent; LS, least squares; SE, standard error; CI, confidence interval; PBO, placebo; CANA, canagliflozin.

**Canagliflozin reduces both HbA<sub>1c</sub> and body weight in patients with type 2 diabetes mellitus on background metformin**

G. Langslet<sup>1</sup>, J.A. Davidson<sup>2</sup>, V. Valentine<sup>3</sup>, U. Vijapurkar<sup>4</sup>, W. Canovatchel<sup>4</sup>, G. Meininger<sup>4</sup>;

<sup>1</sup>Lipid Clinic, Oslo University Hospital, Norway, <sup>2</sup>Touchstone Diabetes Center, The University of Texas Southwestern Medical Center, Dallas,

<sup>3</sup>Northside Family Medicine, Albuquerque,

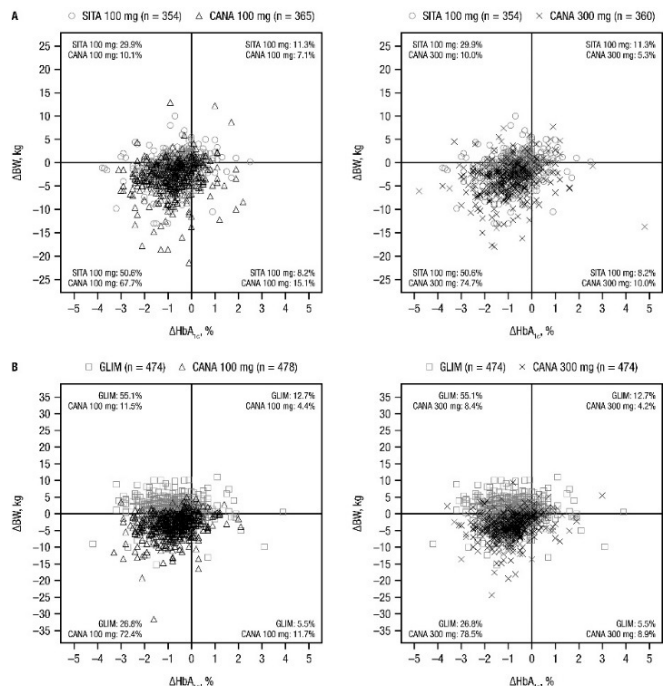

<sup>4</sup>Janssen Research & Development, LLC, Raritan, USA.

**Background and aims:** Canagliflozin (CANA), a sodium glucose co-transporter 2 (SGLT2) inhibitor, is approved for the treatment of adults with type 2 diabetes mellitus (T2DM). Reductions in HbA<sub>1c</sub> and body weight (BW) have been observed with CANA in 2 studies as add-on to metformin over 52 weeks. This post hoc analysis describes the distribution of change from baseline in HbA<sub>1c</sub> and BW in these studies at Week 52.

**Materials and methods:** This analysis used data from 2 separate randomised, double-blind, active-controlled Phase 3 studies of CANA 100 and 300 mg versus either sitagliptin (SITA) 100 mg (Study 1: N = 1,284; HbA<sub>1c</sub>, 7.9%; BW, 87.2 kg) or glimepiride (GLIM; Study 2: N = 1,450; HbA<sub>1c</sub>, 7.8%; BW, 86.6 kg). Study 1 included a treatment arm where patients received placebo during the 26-week core period and switched to SITA during the 26-week extension period (n = 183); this arm was excluded from the current analysis. **Results:** In Study 1, least squares (LS) mean HbA<sub>1c</sub> changes from baseline were -0.73%, -0.88%, and -0.73%, and LS mean BW changes from baseline were -3.8%, -4.2%, and -1.3% with CANA 100 and 300 mg and SITA 100 mg, respectively. In Study 2, LS mean HbA<sub>1c</sub> changes from baseline were -0.82%, -0.93%, and -0.81%, and LS mean BW changes from baseline were -4.2%, -4.7%, and 1.0% with CANA 100 and 300 mg and GLIM, respectively. A greater proportion of patients had reductions in both HbA<sub>1c</sub> and BW with CANA 100 and 300 mg compared with SITA 100 mg (67.7%, 74.7%, and 50.6%, respectively) or GLIM (72.4%, 78.5%, and 26.8%, respectively; Figure). More patients had a decrease in HbA<sub>1c</sub> with either no change or an increase in BW with SITA or GLIM versus CANA 100 and 300 mg in both studies.

**Conclusion:** CANA provided reductions in both HbA<sub>1c</sub> and BW versus SITA 100 mg or GLIM in most patients with T2DM as add-on to metformin at 52 weeks.

Figure. Change from baseline in HbA<sub>1c</sub> and BW at Week 52 in individual patients with CANA 100 and 300 mg versus (A) SITA and (B) GLIM.

BW, body weight; CANA, canagliflozin; SITA, sitagliptin; GLIM, glimepiride.

**Glycaemic efficacy of canagliflozin is largely independent of baseline beta cell function or insulin sensitivity**

D. Matthews<sup>1</sup>, B. Zinman<sup>2</sup>, C. Tong<sup>3</sup>, G. Meininger<sup>3</sup>, D. Polidori<sup>4</sup>;

<sup>1</sup>The Oxford Centre for Diabetes, Endocrinology and Metabolism, UK,

<sup>2</sup>Lunenfeld-Tanenbaum Research Institute, Mount Sinai Hospital, University of Toronto, Canada, <sup>3</sup>Janssen Research & Development, LLC, Raritan, USA,

<sup>4</sup>Janssen Research & Development, LLC, San Diego, USA.

**Background and aims:** Canagliflozin (CANA), a sodium glucose co-transporter 2 (SGLT2) inhibitor, lowers plasma glucose and HbA<sub>1c</sub> in patients with type 2 diabetes mellitus (T2DM) by increasing urinary glucose excretion. Because CANA's mechanism of action is insulin-independent, it was hypothesised that the glycaemic efficacy of CANA would be independent of baseline beta-cell function (BCF) or insulin sensitivity (IS). This hypothesis was tested using data from 4 placebo (PBO)- and 2 active-controlled studies to measure BCF (HOMA-%B) and IS (HOMA2-%S).

**Materials and methods:** The first analysis pooled data from 26-week PBO-controlled studies (N = 2,313; baseline HbA<sub>1c</sub> = 8.0%, HOMA2-%B = 49, HOMA2-%S = 60). Patients were divided into tertiles of HOMA2-%B or HOMA2-%S and, given the potential impact of baseline HbA<sub>1c</sub>, further divided based on baseline HbA<sub>1c</sub> (HbA<sub>1c</sub> <7.5%, 7.5% ≤ HbA<sub>1c</sub> <8.5%, HbA<sub>1c</sub> ≥8.5%). Change in HbA<sub>1c</sub> from baseline with CANA 100 and 300 mg and PBO was evaluated for each subgroup. A second analysis included 52-week studies comparing CANA 300 mg with sitagliptin (SITA) 100 mg (N = 1,488; baseline HbA<sub>1c</sub> = 8.0, HOMA2-%B = 49, HOMA2-%S = 59). Patients were divided into the same HOMA2-%B, HOMA2-%S, and baseline HbA<sub>1c</sub> subgroups described in the first analysis.

**Results:** Overall, reductions in HbA<sub>1c</sub> from baseline were greater in patients with higher baseline HbA<sub>1c</sub> (Figures A and B). Within each baseline HbA<sub>1c</sub> range, the HbA<sub>1c</sub> decrease seen with CANA was generally similar across tertiles of HOMA2-%B (as shown for the PBO-controlled studies in Figure A; similar results for CANA were also observed in the active-controlled studies) and HOMA2-%S (as shown for the active-controlled studies in Figure B; similar results for CANA were also observed in the PBO-controlled studies). Greater reductions in HbA<sub>1c</sub> were observed with CANA than with SITA,

with the biggest differences seen in patients with higher baseline HbA1c and in patients with lower HOMA2-%S (Figure B).

**Conclusion:** Consistent with expectations based on the insulin-independent mechanism of action of CANA, the glycaemic efficacy of CANA is largely independent of baseline measures of BCF or IS.

### Effects of sodium glucose co-transporter 2 inhibitors in patients with type 2 diabetes: a systematic review with meta-analysis of randomised clinical trials

H. Storgaard<sup>1</sup>, L.L. Gluud<sup>2</sup>, M. Christensen<sup>1,3</sup>, F. Knop<sup>1</sup>, T. Vilsbøll<sup>1</sup>; <sup>1</sup>Diabetes Research Division, Department of Medicine, Gentofte Hospital, University of Copenhagen, Hellerup, <sup>2</sup>Gastrounit, Hvidovre Hospital, University of Copenhagen, <sup>3</sup>Department of clinical pharmacology, Bispebjerg Hospital, University of Copenhagen, Denmark.

**Background and aims:** Several randomised clinical trials (RCTs) have assessed the effects of sodium glucose co-transporter 2 inhibitors (SGLT-2i) for patients with type 2 diabetes. We performed a systematic review with meta-analyses of RCTs on SGLT-2i for ≥12 weeks. The primary outcomes were changes in HbA1c, body weight and adverse events.

**Materials and methods:** Random effects meta-analysis was performed. Bias and heterogeneity were assessed in subgroup, sensitivity, regression and sequential analyses. We included 24 placebo-controlled RCTs on 12-102-week treatment with canagliflozin 300 mg (7 trials), dapagliflozin 10 mg (13 trials) or empagliflozin 25 mg (4 trials) and 7 trials with active controls.

**Results:** Random effects meta-analysis of 3,425 patients randomised to SGLT-2i and 3,234 patients randomised to placebo found that SGLT-2i reduced HbA1c (mean difference -0.71%; CI -0.80 to -0.63) and body weight (-2.0 kg; -2.2, -1.9). The analysis was stable to assessments of bias and the results were confirmed in sequential analyses. Beneficial effects in favour of SGLT2i on fasting plasma glucose (-1.6 mM; CI -1.9 to -1.4), systolic blood pressure: (-4.4 mmHg; -5.2 to -3.6) and diastolic blood pressure: (-1.6 mmHg; CI -2.1 to -1.1) were detected. Analyses on adverse events showed that 6% of patients randomised to SGLT-2i developed genital or urinary tract infections (relative risk 1.7; CI 1.4 to 2.1); number needed to harm 50).

**Conclusion:** We conclude that SGLT-2i have clinically relevant effects on glycaemic control and body weight and should be considered as second line treatment after metformin in obese patients with type 2 diabetes. The risk benefit balance may not be favourable in patients prone to genital or urinary tract infections.

#### Pharmacokinetics of once weekly dulaglutide in patients with type 2 diabetes mellitus

A. de la Peña<sup>1</sup>, C. Loghin<sup>2</sup>, X. Cui<sup>3</sup>, X. Zhang<sup>1</sup>, J.S. Geiser<sup>1</sup>, J. Martin<sup>1</sup>, J.Y. Chien<sup>1</sup>;

<sup>1</sup>Eli Lilly and Company, <sup>2</sup>Clinical Pharmacology, Eli Lilly and Company, Indianapolis, <sup>3</sup>inVentiv Health Clinical, Burlington, USA.

**Background and aims:** The aim of these analyses was to characterize the pharmacokinetics (PK) of once weekly dulaglutide in patients with type 2 diabetes mellitus (T2DM).

**Materials and methods:** PK meta-analysis of Phase 1 data and population PK modeling of Phase 2 and Phase 3 studies were used in order to perform this characterization.

**Results:** The PK of dulaglutide was well described by a 2-compartment model with first-order absorption. After subcutaneous (SC) administration, dulaglutide was slowly absorbed. Time to reach maximum concentration ( $C_{max}$ ) at steady state ranged from 24 to 72 hours (median = 48 hours); absolute bioavailability was 47% and half-life was 4.7 days. Steady state was achieved between 2 and 4 weeks of dosing. At steady state for dulaglutide 1.5 mg, the mean peak ( $C_{max}$ ) and total area under the concentration-time curve (AUC) exposures of dulaglutide were 114 ng/mL (range 56 to 231 ng/mL) and 14000 ng·h/mL (range 6940 to 26000 ng·h/mL), respectively; the accumulation ratio was approximately 1.56. Intra-patient variability was <17% for both AUC and  $C_{max}$ . Mean volume of distribution after intravenous administration was 5.32 L, showing dulaglutide distributes primarily in the blood volume. Apparent clearance in patients with T2DM after multiple 1.5 mg dosing was 0.107 L/hr. Body weight influenced dulaglutide PK, however weight explained <6% of the inter-patient variability. Effects of age, weight, sex, race and ethnicity on dulaglutide PK were not clinically relevant and generally less than the inter-patient variability of dulaglutide exposure (AUC,  $C_{max}$ ) (≤35%). Injection site (abdomen, upper arm, thigh) had no statistically significant effect on exposure.

**Conclusion:** The PK of dulaglutide 1.5 mg supports once weekly administration in patients with T2DM. No dose adjustment is needed based on body weight, sex, age, race or ethnicity, or injection site.

#### A multicentric, double-blind, randomised-controlled trial (RCT) of carnitine orotate complex in diabetic patients with non-alcoholic fatty liver disease (NAFLD)

J. Bae<sup>1</sup>, W. Lee<sup>2</sup>, K. Yoon<sup>3</sup>, J. Park<sup>4</sup>, H. Son<sup>4</sup>, K. Han<sup>5</sup>, K. Lee<sup>6</sup>, J.-T. Woo<sup>4</sup>, M.-K. Lee<sup>7</sup>;

<sup>1</sup>Division of Endocrinology and Metabolism, Department of Internal Medicine, Samsung Changwon Hospital, <sup>2</sup>Division of Endocrinology and Metabolism, Department of Internal Medicine, Kangbuk Samsung Hospital, <sup>3</sup>Division of Endocrinology and Metabolism, Department of Internal Medicine, Kangnam St Mary's Hospital, <sup>4</sup>Division of Endocrinology and Metabolism, Department of Internal Medicine, Eulji Hospital, Seoul, <sup>5</sup>Division of Endocrinology and Metabolism, Department of Internal Medicine, Suwon, <sup>6</sup>Division of Endocrinology and Metabolism, Department of Internal Medicine, Samsung Medical Center, Seoul, Republic of Korea.

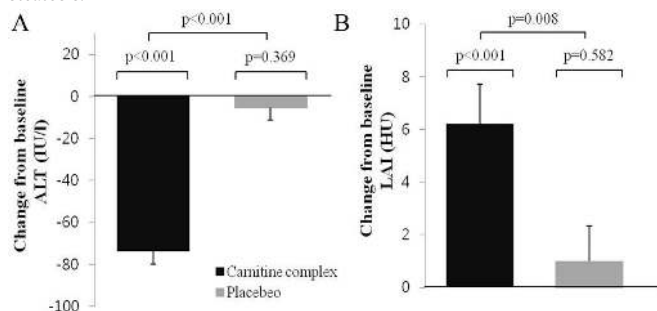

**Background and aims:** We aimed to evaluate the effects of carnitine orotate complex (Godex<sup>®</sup>, 412mg/capsule, Celltrion Pharm, Seoul, Korea) on non-alcoholic fatty liver disease in diabetic patients. In addition, we also evaluated whether carnitine orotate have effect on the glucose metabolism, particularly, in relation to improvement of hepatic steatosis.

**Materials and methods:** Seventy-eight outpatients with NAFLD, who were receiving medical treatment for type 2 diabetes, were randomly assigned to receive double-blind oral carnitine orotate 900mg (GODEX<sup>®</sup>) daily (n=39) or placebo (n=39) for 3 months. Hepatic steatosis was assessed by using hepatic computed tomography (CT) attenuation values (Hounsfield units) obtained by unenhanced low-dose CT at baseline and 3 months after initiation of treatment. Also, biochemical marker for liver function and glycemic control were measured.

**Results:** There was no difference in the baseline mean liver attenuation between carnitine-treated and control groups. On the Hepatic CT analysis,

participants treated with carnitine orotate complex showed increase in mean liver attenuation values and liver attenuation index (LAI) after 12 weeks treatment ( $p < 0.008$  vs. placebo). Mean changes in LAI level from baseline at week 12 was  $6.21 \pm 8.51$  in carnitine orotate complex group ( $p < 0.001$ ) while it was  $0.74 \pm 8.05$  in placebo group ( $p = 0.582$ ). Both serum aspartate aminotransferase ( $P < 0.001$ ) and alanine aminotransferase ( $P < 0.001$ ) level were also reduced significantly in the carnitine-treated group. Those on treatment with carnitine showed improvement in HbA1c level with 0.33% decrease from baseline ( $P < 0.007$ ). When subjects were classified into tertiles by LAI changes from baseline at 12 weeks, participants in the highest tertile of LAI changes showed significant decrease in fasting glucose, HbA1c, and HOMA IR from baseline.

**Conclusion:** Three months of treatment with carnitine improved hepatic steatosis and liver enzymes levels in diabetic patients with NAFLD. Carnitine also improved glycemic control in relation to improvement of hepatic steatosis.

Clinical Trial Registration Number: KCT0000505

## 859

### Sulforaphane reduces hepatic glucose production in liver cells and improves glucose tolerance in diabetic animal models

A.S. Axelsson, Y. Tang, A.H. Rosengren;  
Department of Clinical Sciences, Lund University, Malmö, Sweden.

**Background and aims:** Novel means to treat type 2 diabetes are needed. One strategy for expanding the therapeutic options is drug repositioning, i.e. finding new indications for old drugs. The aim of this study was to employ a new method for drug repositioning combining gene network analysis of metabolic tissues and comprehensive public data on “drug signatures”. A drug signature denotes gene expression traits affected by a particular compound. Thus, we analysed gene co-expression networks in liver from different rodent models and identified a “disease signature” that predicts diabetes status. Next, we interrogated a library with >1000 drug signatures to identify drugs that can revert the aberrantly expressed genes in diabetes and improve metabolic control.

**Materials and methods:** A diabetes signature consisting of 50 genes was derived from rodent liver microarray data using co-expression analyses and causality tests. This signature was matched with publically available drug signatures using Gene Set Enrichment Analysis. The findings were validated by oral and intraperitoneal (i.p.) glucose tolerance tests (GTT) in Wistar rats and C57Bl6 mice with diet-induced glucose intolerance, as well as in clonal H-4-II-E liver cells.

**Results:** We identified sulforaphane (SFN) as the top candidate compound. SFN is an isothiocyanate contained in cruciferous vegetables. It is known to induce an anti-oxidant response by nuclear translocation of NRF2 and has recently been suggested to have anti-cancer effects and improve diabetic complications. First, we incubated hepatic H-4-II-E cells with 10 micromol/l SFN for 28 h. This decreased basal glucose output by 49% ( $p = 0.002$ ). Pre-incubation with palmitate (0.25 mmol/l) for 16 h elevated glucose output by 34% compared with non-treated control cells ( $p = 0.006$ ). Interestingly, SFN not only prevented the palmitate-induced increase of glucose production but led to a net reduction of glucose output by 45% compared with the control cells ( $p = 0.006$ ). SFN also improved the insulin-mediated inhibition of glucose production in these cells ( $p = 0.0003$ ). Next, Wistar rats with diet-induced insulin resistance were treated with 2.5 mg/kg SFN three times a week during 4 months, which improved insulin sensitivity as measured by an ip insulin tolerance test (AUC  $p = 0.0038$ ) and tended to decrease fasting glucose ( $p = 0.055$ ). Microarray analysis of liver from these rats revealed that a major fraction of the genes in the diabetic signature was reversed by SFN treatment ( $p < 0.0001$ , Fisher’s exact test). Treatment of rats with higher doses

of SFN (5 mg/kg daily) over shorter periods of time (2 weeks) improved glucose tolerance assessed by an oral GTT ( $p = 0.049$  at 60 min; AUC=0.093). Furthermore, mice with diet-induced diabetes demonstrated improved fasting glucose ( $p = 0.044$ ) and glucose tolerance measured by an i.p. GTT (AUC  $p = 0.011$ ) after 4-week treatment with 10 mg/kg SFN.

**Conclusion:** Through a new method for network-based drug repositioning we have identified SFN as a potential new anti-diabetic compound. Our results show that SFN improves diet-induced insulin resistance in vivo, reverses aberrantly expressed genes and reduces glucose output from H-4-II-E liver cells. The observed effects, in combination with the documented ability of SFN to protect tissues from diabetic complications and low toxicity, make SFN a promising new drug for future treatment of T2D.

### Timed daily bromocriptine mesylate (BC) administration improves glucose disposal in a canine diet-induced model of impaired glucose tolerance

M.C. Moore, M. Smith, B. Farmer, A.D. Cherrington;  
Molecular Physiology & Biophysics, Vanderbilt University, Nashville, USA.

**Background and aims:** We previously showed that 4 wk of high-fat diet (HFD; 52% of energy) blunts net hepatic glucose (glc) uptake (NHGU) during a hyperinsulinemic hyperglycemic (HIHG) clamp in dogs. Here we examined the impact of BC treatment upon glucose disposal during an OGTT and a HIHG clamp in HFD-fed dogs.

**Materials and methods:** After an initial OGTT (0.9 g/kg), 10 dogs began the HFD. After 4 wk of HFD, 5 dogs received subcutaneous BC injections (15 µg/kg/d) and 5 (CTR) received vehicle for 26d (rx period) at the onset of locomotor activity, while continuing the HFD. Surgery for placement of hepatic balance catheters was performed ~16d before the end of rx. Dogs underwent OGTT2 ~5d before rx ended and a HIHG clamp (4x basal insulin, 2x basal glc) at the end of rx. During the 1st 90 min of the clamp (P1), glc was infused via peripheral vein; during the last 90 min (P2), glc was also infused via the hepatic portal vein at  $22.2 \mu\text{mol} \times \text{kg}^{-1} \times \text{min}^{-1}$ .

**Results:** By 4 wk of HFD, dogs had gained  $4 \pm 1$  kg (mean  $\pm$  SEM); CTR and BC dogs lost  $0.3 \pm 0.2$  and  $0.9 \pm 0.4$  kg, respectively, during rx ( $P = 0.4$ ). In OGTT2 vs OGTT1, the  $\Delta\text{AUC}_{0-120 \text{ min}}$  for glucose increased 58% (CTR) and 26% (BC;  $P < 0.05$  vs CTR), while that of insulin was increased 68% and 95% (CTR vs BC;  $P = 0.4$ ). The C-peptide response increased nearly 2-fold in CTR (OGTT2 vs OGTT1;  $P < 0.05$ ) but did not change in BC, suggesting that BC might decrease insulin clearance. In the clamp studies, there were no significant group differences during the basal or P1 periods. Nonhepatic glucose uptake was greater in BC vs CTR during P2, and total body glucose disposal (GIR) showed a strong tendency to be enhanced in BC (Table 1). There was no significant correlation between plasma insulin concentrations and net hepatic or nonhepatic glucose uptake.

**Conclusion:** BC rx of HFD-fed dogs improves glucose tolerance and glucose disposal during a HIHG clamp primarily by enhancing nonhepatic glucose disposal.

### Prevention of diet-induced hepatic insulin resistance by antisense oligonucleotides targeted to mINDY

D. Pesta<sup>1</sup>, R. Perry<sup>1</sup>, D. Zhang<sup>1</sup>, M. Jurczak<sup>1</sup>, A. Birkenfeld<sup>1</sup>, S. Bhanot<sup>2</sup>, V. Samuel<sup>1</sup>, G. Shulman<sup>1</sup>;

<sup>1</sup>Yale University, New Haven, <sup>2</sup>Isis Pharmaceuticals, Inc, Carlsbad, USA.

**Background and aims:** INDY as part of the SLC13 protein family is a high-affinity di- and tricarboxylate plasma membrane transporter involved in citrate import. In Drosophila, genetic deletion of INDY alters energy metabolism and extends lifespan. Mice lacking INDY are protected from both

diet-induced and age-associated hepatic insulin resistance. Here, we examined the impact of selective hepatic knockdown of mammalian Indy protein (mINDY) expression using anti-sense oligonucleotides (ASOs).

**Materials and methods:** We studied the effect of mINDY knockdown on hepatic glucose metabolism in 4 week high fat fed rats (n=15 per group) assessed by hyperinsulinemic-euglycemic (HEC) clamp studies.

**Results:** After 4 weeks of ASO treatment, mINDY mRNA expression was reduced by 91% ( $P<0.001$ ) in the treatment group. The mINDY ASO treated rats showed a 34% reduction in fasting plasma insulin concentrations compared to the control group (14.5 vs. 9.6  $\mu\text{U/ml}$ ,  $P<0.05$ ) and was associated with ~30% reduction in basal rates of endogenous glucose production [ $5.9 \pm 0.6$  vs.  $8.4 \pm 0.8$  mg/(kg·min)]. Furthermore hepatic insulin responsiveness was increased in the mINDY ASO rats as reflected by increased suppression of hepatic glucose production during the HEC [19.7 vs. 61.6%,  $P<0.05$ ].

**Conclusion:** Taken together these data suggest that hepatic mINDY may be a novel therapeutic target for the treatment of hepatic insulin resistance and type 2 diabetes.

### LX4211 improves glycaemic control in NOD mice with type 1 diabetes

D.R. Powell, D. Doree, S. Jeter-Jones, Z.-M. Ding, B. Zambrowicz, A. Sands; Lexicon Pharmaceuticals, Inc., The Woodlands, USA.

**Background and aims:** There is a need for oral agents that improve glycaemic control without increasing hypoglycemia (hypoG) events in patients with type 1 diabetes (T1D). LX4211 is a compound that may meet this need, as it lowers blood glucose (G) by the dual insulin (Ins)-independent mechanisms of inhibiting intestinal sodium-glucose cotransporter (SGLT)1 to delay G absorption and inhibiting kidney SGLT2 to decrease G reabsorption. We tested if LX4211 can improve the poor glycaemic control of NOD mice receiving low daily insulin doses for their T1D, and if LX4211 treatment of these mice is accompanied by a decrease in hypoG events.

**Materials and methods:** NOD mice receiving only 0.05 U Ins/day for their T1D served as a model of poor glycaemic control, while NOD mice receiving 0.2 U Ins/day for their T1D served as a model of improved glycaemic control. T1D, defined as fed blood G > 300 mg/dL on 2 consecutive samples, was induced in 11 week old NOD mice using IP cyclophosphamide (200 mg/kg x2, separated by 2 weeks). Ins was delivered SC by Alzet pump (Model 1004, 4 week duration). The day after pump implantation, mice received the first of 22 once-daily oral doses of LX4211 or vehicle. Glycaemic control was monitored by measuring blood A1C (A1C Now+ kit) and fed blood G (ACCU-CHEK Aviva glucometer). HypoG was defined as a fed blood G < 50 mg/dL.

**Results:** As is shown in the table below, 1) LX4211 significantly improved glycaemic control in NOD mice with poorly controlled T1D, as evidenced by the rapid and sustained lowering of blood G levels, and the delayed rise in A1c levels, in LX4211-treated mice receiving 0.05 U Ins/day; 2) the glycaemic control of LX4211-treated mice receiving 0.05 U Ins/day was similar to that of vehicle-treated mice receiving 0.2 U Ins/day; and 3) hypoG was less frequent in LX4211-treated mice receiving 0.05 U Ins/day than in vehicle-treated mice receiving 0.2 U Ins/day.

**Conclusion:** LX4211 significantly improved glycaemic control in NOD mice with poorly controlled T1D, and this improvement was associated with a marked decrease in the frequency of hypoG events.

| N  | Group   |                | G (mg/dL)    |                |                 | $\Delta$ A1C (%) | HypoG   |

### Berberine increases serum osteocalcin levels and improves early phase of insulin secretion in non-alcoholic fatty liver disease patients with impaired glucose metabolism

H. Yan<sup>1</sup>, M. Xia<sup>1</sup>, X. Chang<sup>1</sup>, H. Bian<sup>1</sup>, L. Zhang<sup>1</sup>, H. Lin<sup>1</sup>, X. Yao<sup>2</sup>, S. Rao<sup>2</sup>, M. Zeng<sup>3</sup>, Y. Tu<sup>3</sup>, W. Jia<sup>3</sup>, W. Deng<sup>4</sup>, X. Gao<sup>1</sup>;

<sup>1</sup>Department of Endocrinology and Metabolism, <sup>2</sup>Department of Radiology, Zhongshan Hospital, Fudan University, Shanghai, China, <sup>3</sup>Department of Endocrinology and Metabolism, The Sixth People's Hospital, Jiao Tong University, <sup>4</sup>School of Public Health, Fudan University, Shanghai, China.

**Background and aims:** Increasing evidences have shown that osteocalcin participate in the glycaemic control and energy metabolism. Positive modulation of serum osteocalcin concentrations could be valuable for the prevention, delay and treatment of diabetes. Berberine is the active phytochemical that has potential to treat diabetes and diabetic complications. We aim to observe the effect of berberine on serum osteocalcin levels in patients with non-alcoholic fatty liver disease (NAFLD) and impaired glucose metabolism. **Materials and methods:** We randomly assigned 124 adults with NAFLD and impaired glucose metabolism to 16 weeks of treatment with lifestyle intervention (LSI) (a reduction of 500 kcal in daily intake and exercise) or berberine (1.5g daily) plus LSI. Before and after treatment, we assessed serum glucose and lipid metabolism, insulin, osteocalcin levels, liver enzymes, and hepatic fat content by proton magnetic resonance spectroscopy.

**Results:** Berberine plus LSI treatment, as compared with LSI control, was associated with a significantly higher increasing in early phase insulin secretion ( $\Delta\text{I30}/\Delta\text{G30}$ ) [ $6.47 \pm 13.86$  vs  $-0.06 \pm 10.56$ ,  $p=0.011$ ] and serum osteocalcin levels [ $4.54 \pm 4.55$  vs  $0.85 \pm 3.62$  ug/L,  $p<0.001$ ], and a significantly higher reduction in 2 hour blood glucose, HOMA-IR, total cholesterol, triglyceride, alanine aminotransferase, body weight, waist circumference and hepatic fat content (all  $p<0.05$ ). Although these data had higher improvement in berberine plus LSI than in LSI group, such as fasting glucose, 30 minute glucose, HbA1c, LDL-c, aspartate aminotransferase and glutamyltransferase, the differences of them were insignificant. Spearman's correlation analysis demonstrated that the difference of osteocalcin before and after treatment was significantly positively associated with the difference of  $\Delta\text{I30}/\Delta\text{G30}$ , and negatively associated with the differences of 30 minute blood glucose, HbA1c, total cholesterol, BMI, waist circumference, and hepatic fat content before and after treatment in the two groups. A stepwise multiple linear regression analysis demonstrated that the difference of osteocalcin was the only variable independently associated with the difference of  $\Delta\text{I30}/\Delta\text{G30}$  ( $p=0.045$ ), the other variables excluded from the regression equation including differences of HbA1c, total cholesterol, triglyceride, HDL-c, LDL-c, BMI, waist circumference, WHR, blood pressure and hepatic fat content. The incidence of adverse events between groups were significantly different ( $p<0.001$ ), with no serious adverse events occurred.

**Conclusion:** For NAFLD patients with abnormal glucose metabolism, Berberine can increase serum osteocalcin levels, improve early phase insulin secretion and decrease 2 hour blood glucose. Elevated levels of osteocalcin may be one of the mechanisms of berberine improving glucose metabolism.

### Proteinuric nephropathy in acquired and congenital generalised lipodystrophy: baseline and after recombinant leptin therapy

L. Major<sup>1</sup>, C. Musso<sup>2</sup>, E. Cochran<sup>3</sup>, M. Toniatti<sup>4</sup>, C. Mussin<sup>5</sup>, R. Brown<sup>3</sup>, L. Trifone<sup>4</sup>, F. Grabois<sup>4</sup>, E. Andres<sup>6</sup>, M. Ferraro<sup>6</sup>, P. Gorden<sup>3</sup>;

<sup>1</sup>Nutrition, Hospital San Isidro, Buenos Aires, <sup>2</sup>Endocrinology and Metabolism, Hospital Milstein, Capital Federal, Argentina, <sup>3</sup>NIH, NIDDK, Bethesda, USA, <sup>4</sup>Nutrition, Hospital Dr. R Gutierrez, <sup>5</sup>Nutrition, Hospital Cutral Co, Neuquen, <sup>6</sup>Nutrition, Hospital Dr P Elizalde, Buenos Aires, Argentina.

**Background and aims:** Lipodystrophies, acquired and congenital, are syndromes characterized by absence of body fat, low levels of the adipocyte-derived hormone/cytokine leptin, severe hypertriglyceridemia, insulin resistance associated with diabetes, hepatomegaly and hepatic steatosis. Nephropathy has been previously reported but it is not a feature of the syndrome, but proteinuria was common and very high in this group of young patients. Aim: Evaluate basal renal disease in patients with lipodystrophy and modifications 3 and 6 months after r-metHuLeptin therapy.

**Materials and methods:** We studied 6 patients with lipodystrophy, 4 generalized (2 congenital generalized lipodystrophy CGL, and 2 acquired generalized lipodystrophy, AGL) and the other 2 with familial partial lipodystrophy (FPL). We determined basal, and after 3 and 6 month of leptin therapy: Creatinine, urea, microalbuminuria, proteinuria and % HbA1c. We evaluate which patients were on Angiotensin-converting enzyme (ACE) inhibitors therapy. In 2 of the 6 patients renal biopsy was done. We performed percutaneous renal biopsies in 2 patients.

**Results:** HbA1c and proteinuria improved after leptin therapy. Patient 2 didn't develop proteinuria. Four patients have proteinuria at baseline and after leptin improved significantly (patients 3, 5 and 6) or even turned negative (patient 1). Patients 1,3 and 5 were on enalapril. Renal Biopsy: patient 1 has diagnosis of mesangial proliferative glomerulosclerosis and Patient 3 developed focal segmental glomerulosclerosis (FSGS)

**Conclusion:** Renal function was evaluated in a group of patients with lipodystrophy during the course of a therapeutic trial of recombinant human leptin. It was describe that in some cases treated with recombinant human leptin there was an exacerbation of their underlying renal disease. In our patients we demonstrated efficacy of leptin to improved renal disease.

### Ranolazine induces skeletal muscle hypertrophy activating Ca<sup>2+</sup>/calmodulin pathway

I. Terruzzi<sup>1</sup>, P. Senesi<sup>2,3</sup>, A. Montesano<sup>2</sup>, L. Luzi<sup>2,3</sup>,

<sup>1</sup>Div. Metabolic and Cardiovascular Sciences, Metabolism, Nutrigenomics and Cellular Differentiation, San Raffaele Scientific Institute, <sup>2</sup>Department of Biomedical Sciences for Health, University of Milan, <sup>3</sup>Metabolism Research Centre and Department of Endocrinology and Metabolic Diseases, San Donato Hospital and Scientific Institute, Milan, Italy.

**Background and aims:** The underlying causes of type 2 diabetes are a combination of a defect in insulin secretion from pancreatic  $\beta$  cells and an impairment in insulin-mediated glucose disposal (insulin resistance) in insulin target tissues, such as skeletal muscle. Ranolazine (RAN) is a novel anti-ischemic and antianginal drug that reduces angina frequency in patients with chronic stable angina, a manifestation of coronary artery disease. RAN decreases myocardial ischemia by improving sodium-calcium homeostasis via inhibition of the late phase of the inward sodium current (late INa). Recently, RAN has been shown to lower haemoglobin A1c (HbA1c) in patients with diabetes mellitus. The mechanism by which RAN improves glycaemic control is unknown. Previous studies in isolated human and murine  $\beta$  cell showed that RAN preserves pancreatic cells mass and promotes glucose-stimulated insulin secretion. However, RAN hypoglycaemic mechanisms in skeletal muscle is jet not studied. Objective of the present study was to determine the effect of RAN on skeletal muscle metabolism and differentiation.

**Materials and methods:** We examined RAN action on skeletal muscle using C2C12 murine myoblastic cell. After treatment of C2C12 with 1, 10 or 25 $\mu$ M RAN for 24 hours to study the RAN dose-response relationship: 10 $\mu$ M RAN was considered the dose able to stimulate morphological changes and hypertrophic process in neo-formed myotubes. 10 $\mu$ M RAN was added to C2C12 during proliferation, differentiation and neo formed myotubes to assess RAN possible interference in insulin pathway.

**Results:** RAN enhanced myoblasts proliferative capacity decreasing the expression of cell cycle inhibitors (p21 protein/cyclins). Interestingly, RAN did not modify p70S6 kinase activation showing it did not modulate the classic signaling pathways involved in cell growth. Western and Immunofluorescence studies revealed that during differentiation, RAN improved neo myotubes formation, but did not stimulate kinases involved in skeletal muscle differentiation and glucose uptake (ERKs and AKT pathways). Neo formed myotubes analysis showed that RAN activated Ca<sup>2+</sup>/calmodulin dependent protein kinase (CaMKII), which plays an important role in GLUT4 upregula-

tion and in myotube differentiation, confirming that RAN improved skeletal muscle metabolism a without affecting p70S6 and ERKs pathway.

**Conclusion:** Taken together, our results demonstrate that RAN have a positive action on skeletal muscle cells differentiation and metabolism, activating not AKT insulin mediated pathway, but Ca<sup>2+</sup>/calmodulin signaling pathway. This finding provides interesting evidence on the innovative use of RAN in diabetic condition, not only to improve insulin secretion of  $\beta$  cell but also insulin sensitivity in skeletal muscle.

## 866

### Lipolytic and insulinotropic effects of HM12525A, a novel long-acting GLP-1/glucagon dual agonist

<sup>1</sup>Hanmi Pharmaceutical, Seoul, Republic of Korea,

<sup>2</sup>Profil Institute, Chula Vista, USA.

**Background and aims:** Oxyntomodulin, an alternative cleavage product of proglucagon, is a gut hormone which shows enhanced body weight loss and improved glycemic control by activating GLP-1 (GLP-1R) and glucagon receptor (GCGR), respectively. But its clinical application is limited due to a short half-life. We have developed the long acting GLP-1/glucagon dual agonist, HM12525A, by conjugating a novel GLP-1/glucagon dual agonist with constant region of human immunoglobulin via non-peptidyl linker. In a previous study, we demonstrated that once weekly administration of HM12525A exerted potent body weight loss and improved glycemic control in obese and diabetic animal models. However, the underlying modes of action for HM12525A are still poorly defined. The aim of this study was to investigate the molecular basis for the beneficial effects of HM12525A in vitro and in vivo system.

**Materials and methods:** To evaluate the effect of HM12525A on lipid droplet formation, 3T3-L1 cells were incubated with HM12525A during adipogenic differentiation. After 10–14days, the cells were stained with Oil-red O to determine triglyceride content. Fully differentiated 3T3-L1 adipocytes were treated with HM12525A, and the phosphorylation of hormone-sensitive lipase (HSL) was evaluated through western blot analysis. To measure lipolytic activity, conditioned medium was collected following HM12525A treatment for 4hr, and the amount of glycerol was quantified. Serum concentration of insulin in normal mice during ipGTT was quantified to evaluate the insulinotropic and insulin sensitizing potency of HM12525A.

**Results:** Consistent with *in vivo* results in which HM12525A administration significantly reduced the fat mass of diet-induced obesity (DIO) mice, HM12525A inhibited the lipid droplet formation in 3T3-L1 adipocytes in a dose-dependent manner. Of note, these inhibitory effects were partially reserved by either GLP-1R or GCGR antagonist, suggesting that the dual agonism of HM12525A synergistically exerts its lipolytic action. At the molecular level, phosphorylation of HSL, a key marker for the activation of lipolysis, and the following glycerol release were increased upon HM12525A treatment in 3T3-L1 adipocytes. As to the insulinotropic effects in pancreatic  $\beta$ -cells, HM12525A increased insulin secretion in RINm5F cells. In line with *in vitro* results, HM12525A administration significantly increased insulin secretion as well as insulin sensitivity, thereby attenuating the glucose excursion during ipGTT in normal mice.

**Conclusion:** Our results indicate that a well balanced dual agonism of HM12525A mediates synergistic effects on lipolysis of adipocytes. Moreover, HM12525A improves glucose tolerance by enhancing both insulin secretion and insulin sensitivity in  $\beta$ -cells and normal mice. Therefore, our results collectively demonstrate that a novel GLP-1/glucagon dual agonist HM12525A mediated lipolytic and insulinotropic effects through which anti-obesity and anti-diabetic potentials were conferred.

### Renoprotective effect of gemigliptin, dipeptidyl peptidase 4 inhibitor, on streptozotocin-induced type 1 diabetic model

M.-K. Kim<sup>1</sup>, Y.-A. Jung<sup>1</sup>, G.-S. Jung<sup>2</sup>, Y.-K. Choi<sup>2</sup>, K.-H. Bae<sup>2</sup>, I.-K. Lee<sup>2</sup>, K.-G. Park<sup>2</sup>, J.-E. Lee<sup>3</sup>, E. Jung<sup>4</sup>, M.-J. Kim<sup>5</sup>, E. Kim<sup>6</sup>;

<sup>1</sup>Department of Internal Medicine, Keimyung University School of Medicine, <sup>2</sup>Department of Internal Medicine, Kyungpook National University School of Medicine, Daegu, <sup>3</sup>Department of Internal Medicine, CHA Gumi Medical Center, Gumi, <sup>4</sup>Department of Internal Medicine, Catholic University of Daegu School of Medicine, <sup>5</sup>Pooreen Meerae Internal Medicine Clinic, <sup>6</sup>Department of Internal Medicine, Daegu Fatima Hospital, Republic of Korea.

**Background and aims:** Gemigliptin is a dipeptidyl peptidase 4 (DPP4) inhibitor, which is currently used in the treatment of patients with type 2 diabetes through augmentation of GLP-1 activity. In addition to GLP-1 activity, growing body of evidence shows that DPP4 play various roles in metabolism and inflammation through enzymatic activity and non-enzymatic activity. Some studies reported that DPP 4 activity increased in the urine and kidney of the diabetic patients and inhibition of DPP 4 activity attenuated diabetic neuropathy, retinopathy and renal ischemia-reperfusion injury. Therefore, the aim of this study was to determine whether gemigliptin has renoprotective effects on the kidney of streptozotocin (STZ)-induced type 1 diabetic mice model.

**Materials and methods:** Diabetes was induced by single intraperitoneal injection of streptozotocin (150 mg/kg/body weight). Diabetic mice was treated without or with an oral dose of gemigliptin 300mg/kg/ day for 8 weeks. Renal injury was observed by electron microscopy and light microscopy. We also measured serum glucose and urinary albumin excretion and evaluated fibrotic markers using immunohistochemical staining, qRT-PCR and western blot analysis.

**Results:** Blood glucose was significantly higher in diabetic mice than control mice, and gemigliptin did not reduce blood glucose levels of STZ-induced diabetic mice. Diabetic mice exhibited marked increased kidney/body weight ratio and urinary albumin excretion, but gemigliptin treatment significantly reduced kidney/body weight ratio and albuminuria. Moreover, gemigliptin treatment significantly reduced glomerular basement membrane thickness of kidney compared with STZ-induced diabetic mice. Histological examination showed renal fibrosis was induced by STZ, but gemigliptin treatment significantly attenuated STZ-induced renal fibrosis. In addition, immunohistochemical staining showed decrease of type 1 collagen and fibronectin in the kidney of STZ-induced diabetic mice treated with gemigliptin. To test whether attenuation of renal fibrosis by gemigliptin is GLP-1 dependent, we examined the effects of gemigliptin on TGF- $\beta$ -stimulated fibrotic gene expression in cultured renal cells. The results showed that gemigliptin-treated RMCs and NRK-52E cells showed markedly decrease in type 1 collagen and fibronectin expression through inhibition of smad3 activity.

**Conclusion:** In conclusion, our data showed that gemigliptin has renoprotective effect on diabetic nephropathy regardless of glucose lowering effect. The present study raises the possibility that gemigliptin could be used to prevent the progress of diabetic nephropathy including patients with type 1 diabetes.

### Pituitary adenylate cyclase-activating polypeptide, a substrate of DPP-4, protects glomerular podocytes from inflammatory injuries

K. Sakamoto, M. Takemoto, K. Kuno, T. Ishikawa, P. He, R. Ishibashi, K. Kobayashi, H. Kawamura, H. Tokuyama, Y. Maezawa, K. Yokote; Department of Clinical Cell Biology and Medicine, Chiba University Graduate School of Medicine, Japan.

**Background and aims:** Diabetic nephropathy (DN) is a leading cause of end-stage kidney disease; however, to date, there are few available treatment options. Although the mechanisms of DN are not well understood, inflammation plays a crucial role in the initiation and/or progression of DN. Dipeptidyl peptidase-4 inhibitors (DPP4i) have recently been introduced for use as oral hypoglycemic agents. In addition to reducing blood glucose levels, DPP4i have been found to possess pleiotropic actions, e.g. protecting the

kidney from injuries. Although the mechanisms underlying the pleiotropic effects of DPP4i are not clear, it has been speculated that substrates, including incretins, which are stabilized by DPP4i may play a role in these effects. Pituitary adenylate cyclase-activating polypeptide (PACAP) is a neuropeptide, which was originally isolated from the ovine hypothalamus and has diverse biological functions. PACAP is known to be one of the substrates of DPP4. Furthermore, in studies of kidney pathology, PACAP has been found to have renoprotective effects. However, the specific cell types within the kidney that are protected by PACAP have not yet been identified. In the present study, we investigated the effects of PACAP on kidney cells and the mechanisms by which PACAP decreases the expression of inflammatory cytokines.

**Materials and methods:** We used immunohistochemistry (IHC), western blotting (WB), and real-time polymerase chain reaction (RT-PCR) to evaluate the expressions of PACAP receptors in kidney tissue, isolated glomeruli and cultured podocytes. Next, we evaluated if PACAP induces the phosphorylation of cAMP response element-binding protein (CREB) in cultured podocytes using WB. In addition, podocytes were stimulated with lipopolysaccharide (LPS) and PACAP, and the effects of PACAP on the expression of inflammatory cytokines were examined using WB or RT-PCR. Activation of NF- $\kappa$ B and ERK were evaluated by nuclear localization of NF- $\kappa$ B and phosphorylation of ERK, respectively.

**Results:** We found that VPAC1, one of the PACAP receptors, is expressed in podocytes, a key player of glomerular filtration barrier. PACAP (10 nM) significantly increased the cellular contents of cAMP in cultured podocytes. In the presence of PACAP, CREB was increased by  $1.9 \pm 0.5$  fold (mean  $\pm$  SEM). In cultured podocytes, LPS increased the expression of interleukin-6 (IL-6) and monocyte chemo-attractant protein-1 (MCP-1) by  $4.2 \pm 0.6$  fold and  $32.8 \pm 3.3$  fold, respectively. In the presence of PACAP, the increased expression of IL-6 and MCP-1 was significantly attenuated by 20% and 25%, respectively, through the protein kinase A signaling pathway. In the presence of LPS, NF- $\kappa$ B transnuclear localization and phosphorylation of ERK were significantly increased, and PACAP significantly reduced these increases by 51% and 81%, respectively.

**Conclusion:** In the present study we demonstrated that PACAP has anti-inflammatory effects on glomerular podocytes. To date, treatment options for DN are limited and PACAP may be useful in the prevention/attenuation of DN.

### Effect of two years of sitagliptin treatment on renal function in elderly patients with type 2 diabetes mellitus

S. Kurioka;

Komatsu Hospital, Neyagawa, Japan.

**Background and aims:** Many elderly patients with type 2 diabetes suffer from complications of chronic kidney disease and diabetic nephropathy. In this study, we examined the effect of a DPP-4 inhibitor, sitagliptin, on renal function in elderly patients with type 2 diabetes.

**Materials and methods:** A total of 70 patients aged  $\geq 65$  years with type 2 diabetes mellitus, which included 42 males (60%), were examined. Patients had the following characteristics: age (mean  $\pm$  SD) was  $74 \pm 5$  years, BMI  $24.5 \pm 3.5$  kg/m<sup>2</sup>, duration of diabetes  $14 \pm 10$  years, HbA1c  $8.3 \pm 1.0\%$ , serum creatinine  $0.82 \pm 0.27$  mg/dl, eGFR  $69.3 \pm 23.9$  ml/min/1.73m<sup>2</sup>, and an urine albumin-to-creatinine ratio (UACR) of  $94.1 \pm 172.0$  mg/gCr. Patients had been treated with either 25 mg (n = 6 [9%]) or 50 mg (n = 64 [91%]) of sitagliptin over a two-year period. HbA1c, eGFR and UACR were assessed yearly. eGFR data had been collected 1 year before commencement of sitagliptin. Of the 70 patients, 22 (31%) had eGFR  $< 60$  ml/min/m<sup>2</sup> and 28 (40%) had UACR  $> 30$  mg/gCr. All endpoints were evaluated by ANOVA.

**Results:** HbA1c values before treatment, 1 year, and 2 years after sitagliptin treatment were 8.3, 7.5, and 7.3, respectively (before vs. after treatment,  $p < 0.0001$ ). Gradually decreasing eGFR values were noted, as evidenced by values of 71.0, 69.3 ( $p < 0.05$  when compared with eGFR 1 year before treatment), 65.6 ( $p < 0.05$  when compared with eGFR before treatment), and 63.0 ( $p < 0.005$  when compared with eGFR before treatment) at 1 year before treatment, before treatment, 1 year, and 2 years after treatment, respectively, while eGFR values were not decreased in patients with reduced renal function (eGFR  $< 60$  ml/min/m<sup>2</sup>), as evidenced by values of 52.5, 47.6 ( $p < 0.05$  when compared with eGFR 1 year before treatment), 47.8 ( $p = 0.88$  when compared with eGFR before treatment), and 45.5 ( $p = 0.54$  when compared with eGFR before treatment), respectively. UACR values were significantly decreased in patients with micro- or macroalbuminuria (UACR  $> 30$  mg/gCr), as evidenced by values of 207.3, 136.5 ( $p = 0.27$  when compared with

UACR before treatment), and 106.6 ( $p < 0.05$  when compared with UACR before treatment) before treatment, 1 year, and 2 years after treatment, respectively.

**Conclusion:** Despite the gradual decline in eGFR values in patients with normal renal function, eGFR did not decrease in patients with reduced renal function. These findings suggest that sitagliptin exhibits a renal protective effect, and is effective in maintaining long-term glycemic control in elderly patients with type 2 diabetes.

### A DPP-4 inhibitor suppresses atherosclerotic lesions in the aorta and coronary arteries with decrease of macrophage infiltration in cholesterol-fed rabbits

T. Hirano<sup>1,2</sup>, S. Yamashita<sup>2</sup>, M. Takahashi<sup>2</sup>, H. Hashimoto<sup>2</sup>, M. Goto<sup>2</sup>;

<sup>1</sup>Diabetes, Metabolism, and Endocrinology, Showa University School of Medicine, Tokyo, Japan, <sup>2</sup>Sanwa Kagaku Lab., Mie, Japan.

**Background and aims:** Several studies have demonstrated suppression of atherosclerosis by dipeptidyl peptidase-4 (DPP-4) inhibitors in hypercholesterolemic mice. However, it remains unknown whether DPP-4 inhibitors might also exert anti-atherogenic effects in bigger animals. We examined the effect of anagliptin, a DPP-4 inhibitor, on the development of atherosclerosis in the aorta and coronary arteries in cholesterol-fed rabbits.

**Materials and methods:** Japanese white rabbits were fed either a normal diet or a diet containing 0.5% cholesterol. The cholesterol-fed rabbits were given drinking water not mixed ( $n = 18$ ) or mixed with 3 mg/mL of anagliptin ( $n = 16$ ) for 12 weeks. The lipoprotein fractions were measured by high-performance liquid chromatography. The serum oxidative stress markers 8-hydroxy-2'-deoxyguanosine (OHdG) and malondialdehyde (MDA) were measured by ELISA and TBARS, respectively. Inflammatory cytokine gene expressions in the carotid artery were quantified by real time-qPCR. We measured the lesion area in the aorta and the coronary arteries in seven cross-sections of the heart. Values were expressed as mean  $\pm$  SE.

**Results:** Dietary cholesterol intake led to a marked increase of the serum total-cholesterol (TC) level ( $37.9 \pm 3.9$  vs.  $0.59 \pm 0.04$  mmol/L), with the most striking increase seen in the VLDL fraction (30–80 nm) among the major lipoproteins. No significant changes of the body weight, water intake, HbA1c, serum lipids and lipoproteins, or glucose response to intravenous glucose loading were observed following the administration of anagliptin. The plasma DPP-4 activity was suppressed by 86%, and the plasma active GLP-1 levels doubled. Dietary cholesterol intake resulted in the development of severe atherosclerosis in the aorta, with a ratio of the lesion area to the total aortic surface areas of  $22.0 \pm 2.3\%$ , and anagliptin treatment induced marked suppression of the percent lesion area to  $8.6 \pm 2.1\%$  ( $p < 0.001$ ). Atherosclerotic lesions were also observed in the coronary arteries. The four major coronary arteries increased in area with cholesterol feeding ( $1.14 \pm 0.12$  vs.  $0.81 \pm 0.06$  mm<sup>2</sup>), while anagliptin treatment attenuated this change ( $0.87 \pm 0.07$  mm<sup>2</sup>). The intimal formation in the coronary arteries in the cholesterol-fed mice was attenuated by anagliptin treatment ( $0.04 \pm 0.02$  vs.  $0.13 \pm 0.05$  mm<sup>2</sup>). The alpha-SMA-positive and macrophage-positive areas in the coronary arteries were suppressed 54 and 78% respectively, by anagliptin treatment ( $p < 0.05$ ). Notably, the ratio of the macrophage area to the plaque area was substantially decreased by 83%. The serum 8-OHdG and MDA showed no significant changes following the anagliptin treatment. However, the arterial gene expressions of the inflammatory cytokines TNF-alpha and interleukin-6 were markedly reduced by approximately 90% ( $p < 0.001$ – $0.05$ ), and the expressions of macrophage chemoattractant protein-1 and CD26 in the carotid arteries were partially reduced (by about 30%) following the anagliptin administration.

**Conclusion:** Our study demonstrated for the first time that a DPP-4 inhibitor suppressed the development of atherosclerosis in the aorta and coronary arteries in bigger animals than rodents, by inhibiting the inflammatory responses in the vessels.

### A DPP-4 inhibitor remarkably suppresses foam cell formation in peritoneal macrophages obtained from db/db diabetic mice, comparison with a SGLT2 inhibitor and pioglitazone

M. Terasaki, M. Nagashima, M. Hiromura, K. Notomi, T. Hirano; Department of Medicine, Showa University School of Medicine, Tokyo, Japan.

**Background and aims:** We reported that a dipeptidyl peptidase-4 inhibitor (DPP-4i) confer an anti-atherosclerotic effect in diabetic apolipoprotein-E null mice with significant suppression of foam cell formation in macrophages (M $\phi$ ). However, it remains to be elucidated whether a DPP-4i exerts anti-atherogenic properties beyond glycaemic control. We evaluated the suppressive effect of DPP-4i on foam cell formation in M $\phi$  obtained from db/db diabetic mice, and compared with other glucose-lowering agents, a sodium-glucose co-transporter (SGLT)2-inhibitor and pioglitazone.

**Materials and methods:** Male db/db mice at 9-week-old were fed normal diet containing none ( $n=23$ ), alogliptin (0.02% w/w,  $n=12$ ), pioglitazone (0.02%,  $n=12$ ), or ipragliflozin (0.0014%,  $n=13$ ) for 4 weeks. In subset of animals at age of 13 weeks, glucose (0.5g/kg body weight) was administered orally, and bled 0, 15, 30, 60, and 120 min thereafter (OGTT). Peritoneal M $\phi$  were obtained from mice at age of 13 weeks after the injection of thioglycollate. Foam cell formation was determined by the incorporation of [<sup>3</sup>H]-oleate into cholesteryl-oleate stimulated by oxidized-LDL in M $\phi$ . CD36 and Acetyl-CoA acetyltransferase (ACAT)-1 gene expression was measured by RT-PCR.

**Results:** Food and water intakes were comparable among treated groups, whereas final body weight was increased in pioglitazone group by 6% and decreased in ipragliflozin group by 5% compared with non-treated control group. Pioglitazone and ipragliflozin decreased fasting blood glucose (FBG), HbA1c and glucose-AUC in OGTT compared with control group (FBG:  $6.1 \pm 0.4$ ,  $10.0 \pm 1.6$ , and  $19.4 \pm 1.8$  mmol/l, HbA1c:  $5.2 \pm 0.2$ ,  $5.7 \pm 0.3$ , and  $8.4 \pm 0.2\%$ , AUC:  $790 \pm 280$ ,  $2123 \pm 260$ ,  $4183 \pm 293$  mmol/l $\times$ min, respectively). Alogliptin group exhibited mild reductions of FBG, HbA1c, and AUC ( $16.0 \pm 1.3$  mmol/l,  $7.0 \pm 0.4\%$ , and  $3413 \pm 463$  mmol/l $\times$ min). Despite mild amelioration of glycemic control with alogliptin, the M $\phi$  foam cell formation was 36% decreased, which was comparable to those with pioglitazone or ipragliflozin (35 and 30%, respectively). Foam cell formation was critically regulated by glycemic control (HbA1c) in each group ( $r=0.70$ – $0.94$ ,  $p < 0.02$ ). The linear regression curves were similar between control and ipragliflozin groups. Alogliptin group distributed below the regression curves made by control and ipragliflozin groups, indicating that foam cell formation of alogliptin group is further suppressed than corresponded HbA1c. Gene expressions of CD36 and ACAT-1 were upregulated in db/db mice. Alogliptin treatment decreased gene expression of CD36 and ACAT-1.

**Conclusion:** A pioglitazone and a SGLT2-inhibitor both suppress foam cell formation in obese diabetic mice by substantial glucose-lowering effect, whereas DPP-4inhibitor remarkably suppresses foam cell formation despite mild amelioration of glycaemic control, suggesting a pleiotropic effect of DPP-4 inhibitor on atherogenesis beyond glucose.

## 872

**Increase in beta cell function and improvement in HOMA-2beta index induced by saxagliptin in patients with latent autoimmune diabetes in adults**R. Buzzetti<sup>1</sup>, P. Pozzilli<sup>2</sup>, R. Frederich<sup>3</sup>, N. Iqbal<sup>3</sup>, B. Hirshberg<sup>4</sup>;<sup>1</sup>Department of Experimental Medicine, Sapienza University of Rome,<sup>2</sup>Department of Endocrinology and Diabetology, Policlinico Universitario Campus Bio-Medico, Rome, Italy, <sup>3</sup>Bristol-Myers Squibb, Princeton,<sup>4</sup>AstraZeneca, Wilmington, USA.

**Background and aims:** We used the presence of glutamic acid decarboxylase antibodies (GADA) to identify patients with latent autoimmune diabetes of adults, a population which typically responds poorly to oral antidiabetic medications. We previously reported that saxagliptin (SAXA; 2.5, 5, and 10 mg/d) was generally well tolerated and produced greater reductions vs placebo (PBO) in HbA<sub>1c</sub> and fasting and postprandial plasma glucose, with consistent treatment effects in GADA-positive and GADA-negative patients.

**Materials and methods:** In this analysis, we assessed the effects of SAXA on  $\beta$ -cell function (postprandial C-peptide AUC and HOMA-2 $\beta$ ) in GADA-positive (n=133) and GADA-negative (n=2576) patients from 5 placebo-controlled clinical trials.

**Results:** There were little or no changes from baseline to week 24 in fasting C-peptide concentrations across patient and treatment groups (Table). SAXA produced similar increases relative to PBO in C-peptide AUC and HOMA2- $\beta$  in GADA-positive and GADA-negative patients, with no evidence of an interaction of GADA status on treatment effects, although the number of GADA-positive patients limits this interpretation.

**Conclusion:** These results suggest that SAXA improves  $\beta$ -cell function over 24 weeks in patients with and without GADA at baseline.

## 873

**Efficacy of DPP-4 inhibitors and their effect on blood cyclosporine levels in patients with post-transplantation diabetes**E. Kang<sup>1</sup>, J. Bae<sup>1</sup>, Y. Lee<sup>1</sup>, C. Ahn<sup>1</sup>, B. Cha<sup>1</sup>, H. Lee<sup>1</sup>, K. Huh<sup>2</sup>, M. Kim<sup>2</sup>, Y. Kim<sup>2</sup>;<sup>1</sup>Internal Medicine, <sup>2</sup>Transplantation Surgery, Yonsei University Health System, Seoul, Republic of Korea.

**Background and aims:** Dipeptidyl peptidase-4 (DPP-4) inhibitors have been widely used in kidney-transplant patients with diabetes. However the efficacy and interactions with immunosuppressants according to individual DPP-4 inhibitors are not widely studied. Therefore we tried to compare the glucose-lowering efficacy of DPP-4 inhibitors in patients with post-transplantation diabetes and evaluate the drug interaction with immunosuppressant, cyclosporine.

**Materials and methods:** A total of 91 renal allograft recipients with diabetes who began to take DPP-4 inhibitors after transplantation were enrolled. The glucose-lowering efficacy of three DPP-4 inhibitors, vildagliptin, sitagliptin, and linagliptin were compared using glycosylated hemoglobin (HbA<sub>1c</sub>) after treatment for three months. Changes in blood cyclosporine levels were also assessed in 48 patients treated with cyclosporine.

**Results:** There were no significant differences in HbA<sub>1c</sub> levels among vildagliptin, sitagliptin, and linagliptin treatment (-0.29±1.71% vs. -0.40±1.87% vs. -0.82±1.32%, *P*=0.559). However, blood cyclosporine level was significantly increased in the sitagliptin group, compared with vildagliptin and linagliptin group after three months of treatment (*P*=0.005). Difference in cyclosporine blood level was significant between vildagliptin group and sitagliptin group (*P*=0.004).

**Conclusion:** There were no significant difference in glucose-lowering efficacy among vildagliptin, sitagliptin, and linagliptin in kidney-transplant recipients with diabetes. However, drug interaction between cyclosporine was significant in patients with sitagliptin treated group. Physicians should consider drug interaction when prescribing sitagliptin in kidney-transplant patients receiving cyclosporine as an immunosuppressant.

## 874

**A comparison of the effects of the DPP-4 inhibitor sitagliptin and the sulfonylurea glimepiride on metabolic parameters and endothelial function**H. Nomoto<sup>1</sup>, H. Miyoshi<sup>1</sup>, A. Nakamura<sup>1</sup>, T. Kondo<sup>1</sup>, N. Manda<sup>2</sup>, Y. Kurihara<sup>3</sup>, T. Atsumi<sup>1</sup>, S. Aoki<sup>4</sup>;<sup>1</sup>Medicine II (Immunology and Metabolism), Hokkaido University, <sup>2</sup>Manda Memorial Hospital, <sup>3</sup>Kurihara Clinic, Sapporo, <sup>4</sup>Aoki Clinic, Sapporo, Japan.

**Background and aims:** DPP-4 inhibitors improve hyperglycemia in a glucose-dependent manner, and have been reported to possess favorable effects on atherosclerosis in animal experiments. However, it has not been elucidated whether DPP-4 inhibitors are able to improve endothelial function in patients with type 2 diabetes. Therefore, we investigated the efficacy of the DPP-4 inhibitor, Sitagliptin (Sita) on endothelial function and glycemic metabolism compared with Glimepiride (Gli) therapy.

**Materials and methods:** This study was a multicenter, prospective, randomized parallel-group comparison. Study inclusion criteria were current metformin treatment and inadequate glycemic control (HbA<sub>1c</sub> levels of 6.9% to 8.4%) with sufficient control of blood pressure and lipid profile. Patients who suffered severe atherosclerosis, liver damage and renal dysfunction were excluded. Flow mediated dilation (FMD), Endo PAT, a comprehensive panel of hemodynamic parameters (Task Force<sup>®</sup> Monitor), and serum metabolic markers were assessed before and after the 26 week treatment period. All FMD assessments were performed by the same individual in a quiet, temperature-controlled setting. Patients were randomly assigned to once daily Sita (50mg) or Gli (0.5 to 2mg) therapy according to age, body mass index and baseline FMD values. Statistical analysis was performed using a Mann-Whitney U test and a *p* value < 0.05 was considered significant.

**Results:** Forty-six men and thirty-three women aged 59.0 ± 10.4 years with HbA<sub>1c</sub> levels of 7.1 ± 0.4 % were enrolled. After 26 weeks, improvements in HbA<sub>1c</sub> levels were similar between the Sita and the Gli group (*p* = 0.48). Contrary to expectations, the observed improvements in %FMD and Endo PAT were not statistically different between groups (%FMD; Sita 5.9 to 6.0 %, Gli 5.7 to 6.1 %, RHI; Sita 1.9 to 2.3, Gli 2.1 to 2.3). Plasma HDL-cholesterol, adiponectin and TNF- $\alpha$  levels were significantly improved in the Sita group (*p* < 0.05) and LDL-cholesterol also tended to be improved (*p* = 0.07). Blood

pressure, cardiac index, total peripheral resistance index and most other metabolic parameters were not different.

**Conclusion:** In type 2 diabetic patients without advanced atherosclerosis, changes in endothelial function were similar between Sita and Gli groups after 26 weeks. However, early Sita therapy was associated with more favorable effects on adipokine and lipid profiles compared with Gli therapy. Therefore, it is probable that over the long term these beneficial changes in glycemic and lipid control will aid in the prevention of atherosclerosis.

## 875

**Co-administration of the DPP-4 inhibitor linagliptin and native GLP-1 induce synergistic body weight loss and appetite suppression in DIO rats**  
M. Feighl<sup>1</sup>, H.B. Hansen<sup>1</sup>, G. Hansen<sup>1</sup>, S. Paulsen<sup>1</sup>, M. Mark<sup>2</sup>, N. Vrang<sup>1</sup>, T. Klein<sup>2</sup>;

<sup>1</sup>Gubra, Hørsholm, Denmark, <sup>2</sup>Boehringer Ingelheim, Biberach, Germany.

**Background and aims:** Linagliptin is a dipeptidyl peptidase (DPP)-4 inhibitor approved for the treatment of type 2 diabetes. DPP-4 inhibitors are weight-neutral, suggesting that elevation of endogenous incretin (GLP-1) levels is not sufficient to promote weight loss *per se*. However, it may be possible that long-term exogenous GLP-1 treatment in the context of concurrent DPP-IV inhibition may yield synergistic effects on appetite and body weight regulation. Hence, we evaluated the chronic metabolic effects of linagliptin and native GLP-1(7-36) co-administration in DIO rats.

**Materials and methods:** Male diet-induced obese (DIO) rats (n= 8-10 per group) were treated with either linagliptin (1.5 mg/kg, PO, BID; 0.5 mg/kg, SC, BID) or native GLP-1 (0.4 mg/kg, SC, BID) as monotherapy, and compared to co-administration of linagliptin and GLP-1 for a total of 28 days. Body weight, food intake and body composition was measured. Also, forebrain preprodynorphin gene expression levels were analyzed to assess for potential central effects on central endogenous opioidergic neurotransmission.

**Results:** In DIO rats, monotherapy with linagliptin did not significantly influence Food intake, body weight and adiposity during the study period. In contrast, combined linagliptin and GLP-1 treatment induced a reduction in food intake in conjunction with a pronounced body-weight (~8% compared with baseline) and whole-body fat mass (~20% vehicle-corrected) lowering effect at study end, which was superior to GLP-1 administration *per se*. Notably, the anorexigenic effect of linagliptin and GLP-1 co-administration was associated with a marked increase in chow preference at the expense of palatable high-fat carbohydrate diet intake. Interestingly, combined linagliptin and GLP-1 treatment increased preprodynorphin mRNA levels in the caudate-putamen, an effect not obtained with administration of the compounds individually.

**Conclusion:** These data demonstrate that combined treatment with linagliptin and GLP-1 synergistically reduces body weight in obese rats. This anti-obesity effect is caused by appetite suppression and change in diet preference, presumably associated with increased dynorphin activity in dopaminergic forebrain regions involved in reward anticipation and habit learning. In conclusion, linagliptin and GLP-1 co-administration may therefore hold promise as a novel therapeutic principle for combined weight and diabetes management in obese patients.

**Effects of sitagliptin on body fat and intrahepatic lipid content in Japanese overweight patients with type 2 diabetes**

Y. Nagai, H. Kato, Y. Sada, S. Asai, A. Ohta, Y. Tanaka;

Metabolism and Endocrinology, Internal Medicine, St. Marianna University School of Medicine, Kawasaki, Japan.

**Background and aims:** Previous studies showed that human hepatocyte and adipocyte have the receptor of glucagon-like peptide-1 (GLP-1). Actually, GLP-1 analog, exendin-4 decreases intrahepatic lipid (IHL) and body fat in obese patients with type 2 diabetes. However, concrete changes of body fat and IHL by DPP-IV inhibitors were not fully evaluated. Thus, the aim of this study was to evaluate the effect of DPP-IV inhibitor, sitagliptin on body fat and IHL in overweight Japanese patients with type 2 diabetes.

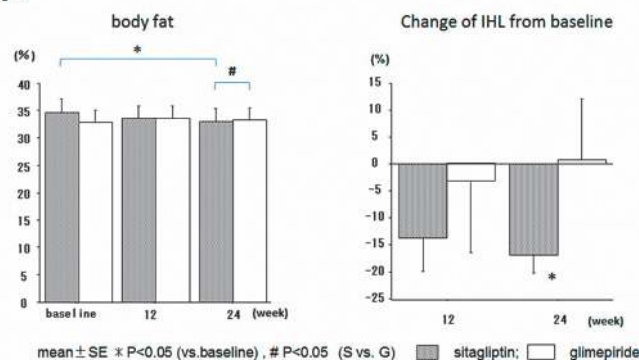

**Materials and methods:** This was a prospective, 24-week, single center, open labeled comparison study. The subjects were 20 Japanese type 2 diabetic patients (male: 11, female: 9) with BMI>25 kg/m<sup>2</sup>. Nine of them were drug naïve

and the remaining 11 received metformin. After a 4 to 8 weeks period of instructing lifestyle modification (28 kcal/kg of ideal body weight and 150 - 200 kcal daily exercise), subjects were randomly assigned to receive sitagliptin 25mg titrated up to 50 mg (S) or glimepiride 0.5 mg titrated up to 1 mg (G). At the baseline, week 12 and week 24 after starting each treatment, body fat and IHL at segment 6 of the liver were evaluated by dual energy X-ray absorptiometry (DEXA) and <sup>1</sup>H-magnetic resonance spectroscopy (<sup>1</sup>H-MRS), respectively.

**Results:** Though HbA1c and GA levels were significantly decreased in both groups after 24 weeks (HbA1c; 7.3 ± 0.1 to 6.5 ± 0.1% (S) and 7.1 ± 0.2 to 6.6 ± 0.1% (G), GA; 18.2 ± 1.0 to 14.8 ± 1.0% (S) and 17.0 ± 0.5 to 15.7 ± 0.4% (G), all p<0.05 vs. baseline), no significant differences were observed between the two groups (p=0.15). The body fat was not altered in G, but significantly decreased by 1.2% in S (p<0.05 vs. base line). Reduction of IHL at week 24 was -0.8 ± 11.4% (p=0.47 vs. baseline) in G and 16.8 ± 3.5% (p<0.01) in S. No severe hypoglycemia event occurred in both groups during the study period.

**Conclusion:** Our findings indicate that while sitagliptin and glimepiride achieve blood glucose control to the same degree, the effects on adiposity were different: sitagliptin might have a beneficial effect on body fat and IHL apart from glucose control.

### Efficacy and safety of saxagliptin in older participants in the SAVOR-TIMI 53 trial

L.A. Leiter<sup>1</sup>, H. Teoh<sup>2</sup>, D.L. Bhatt<sup>3</sup>, O. Mosenson<sup>4</sup>, B.M. Scirica<sup>3</sup>, P. Kumar<sup>5</sup>, A. Smahelova<sup>6</sup>, B. Hirshberg<sup>7</sup>, C. Stahre<sup>8</sup>, R. Frederick<sup>9</sup>, F. Bonnici<sup>10</sup>, I. Raz<sup>11</sup>;  
<sup>1</sup>Li Ka Shing Knowledge Institute and Keenan Research Centre for Biomedical Science, St. Michael's Hospital, University of Toronto, <sup>2</sup>St. Michael's Hospital, University of Toronto, Canada, <sup>3</sup>Brigham and Women's Hospital, Harvard Medical School, Boston, USA, <sup>4</sup>The Diabetes Unit, Hadassah Hebrew University - Medical Center, Jerusalem, Israel, <sup>5</sup>Bangalore Diabetes Hospital & Centre for Diabetes & Endocrine Care, Bangalore Diabetes Hospital, India, <sup>6</sup>Department of Internal Gerontometabolic Clinic, Charles University in Prague, Hradec Kralove, Czech Republic, <sup>7</sup>AstraZeneca, Wilmington, USA, <sup>8</sup>AstraZeneca, MÖLNDAL, Sweden, <sup>9</sup>Bristol-Myers Squibb, Princeton, USA, <sup>10</sup>UCT Private Academic Hospital, Cape Town, South Africa, <sup>11</sup>Hadassah Hebrew University - Medical Center, Jerusalem, Israel.

**Background and aims:** There are limited data from randomised clinical trials (RCT) on the efficacy and safety of antihyperglycaemic treatments in the elderly and very elderly despite the high prevalence of diabetes in these populations. The aim of this analysis was to examine the cardiovascular (CV) effects, glycaemic efficacy, and safety of saxagliptin (SAXA) in the elderly ( $\geq 65$  years, N=8,561) and very elderly ( $\geq 75$  years, N=2,330) participants in the SAVOR-TIMI 53 trial.

**Materials and methods:** Individuals  $\geq 40$  years old (N=16,492) with HbA<sub>1c</sub>  $\geq 6.5\%$  and  $\leq 12.0\%$  were randomised (1:1) to double-blind saxagliptin (5mg or 2.5mg OD) or placebo treatment for a median follow-up of 2.1 years.

**Results:** The exposure to study medication was similar in all age groups. The hazard ratio (HR) for SAXA vs. placebo for the primary CV endpoint (myocardial infarction, ischemic stroke, CV death) was 0.92 for those  $\geq 65$  years vs. 1.15 for those  $< 65$  years ( $p=0.058$ ), and 0.95 for those  $\geq 75$  years (nominal interaction  $p$ -value, 0.67). The HR for the secondary composite end point and total mortality in the elderly and very elderly was balanced and showed a similar pattern to that of the entire study population. There was no treatment interaction based on age in terms of the risk of hospitalization for heart failure ( $p$  for interaction with age, 0.34), a component of the secondary end point, which showed an imbalance in the overall trial population. The difference in HbA<sub>1c</sub> associated with the use of SAXA was comparable ( $-0.33\%$  vs.  $-0.36\%$ ) in those  $\geq$  and  $< 75$  years with a baseline HbA<sub>1c</sub> of 7.6%. The incidence of overall adverse events (AEs), serious AEs and discontinuations related to serious AEs was similar in the elderly, very elderly and the entire study population between SAXA and placebo.

**Conclusion:** The SAVOR-TIMI 53 trial provides efficacy and safety data from a RCT with a robust number of elderly and very elderly participants. The efficacy, CV safety, and overall safety of saxagliptin in this subset of patients are similar to those found in younger patients supporting the safety of SAXA in the older patient population.

### Effects of baseline glycaemic HbA1c on CV outcomes and blood glucose control during the EXAMINE trial in patients with type 2 diabetes and recent acute coronary syndrome

W.B. White<sup>1</sup>, S.R. Heller<sup>2</sup>, R.M. Bergenstal<sup>3</sup>, C. Wilson<sup>4</sup>, R. Oh<sup>4</sup>;  
<sup>1</sup>Calhoun Cardiology Center, University of Connecticut School of Medicine, Farmington, USA, <sup>2</sup>University of Sheffield, UK, <sup>3</sup>International Diabetes Center, Park-Nicollet Clinic, Minneapolis, USA, <sup>4</sup>Takeda Development Center Americas, Inc., Deerfield, USA.

**Background and aims:** EXAMINE was a randomized, double-blind cardiovascular (CV) outcomes safety trial in patients with diabetes and recent acute coronary syndromes (ACS) that showed similar rates of major adverse CV events (MACE) with the dipeptidyl peptidase 4 (DPP-4) inhibitor alogliptin compared with placebo. In this analysis, we investigated the effects of baseline

HbA1c on MACE and the effect of alogliptin vs placebo on HbA1c according to baseline HbA1c levels.

**Materials and methods:** EXAMINE randomized 5380 patients in 49 countries with type 2 diabetes and an ACS within 15 to 90 days to alogliptin or placebo in addition to both evidence-based CV prophylaxis and treatment for type 2 diabetes according to regional guidelines. The median follow-up period in the trial was 18 months. Events were prospectively adjudicated by an independent, blinded committee (C5, Cleveland Clinic). The relationship between MACE and baseline HbA1c was analyzed using Cox proportional hazards models without adjustment for multiple comparisons.

**Results:** The HbA1c at the final visit was lower in the alogliptin arm vs placebo for each level of baseline HbA1c (Table). These changes occurred despite greater intensification of all additional medications in the placebo group. There was no systematic change in MACE rates according to baseline HbA1c (Table),  $p = 0.971$  for interaction.

**Conclusion:** In patients with type 2 diabetes at high CV risk, there was no relationship between MACE and baseline HbA1c; the highest event rates were seen at an HbA1c of between 8 and 9%. Participants in the alogliptin arm achieved a lower HbA1c than those on placebo at all levels of baseline HbA1c. Of note, clinician investigators did not add sufficient additional therapy in those taking placebo to match HbA1c levels by the end of this double-blind randomized trial.

### Efficacy of vildagliptin and sitagliptin in patients with type 2 diabetes and severe renal impairment

W. Kothny<sup>1</sup>, J. Foley<sup>2</sup>, A. Schweizer<sup>1</sup>, M.S. Rendell<sup>3</sup>, V. Lukashevich<sup>2</sup>;  
<sup>1</sup>Novartis Pharma AG, Basel, Switzerland,  
<sup>2</sup>Novartis Pharmaceuticals Corporation, East Hanover,  
<sup>3</sup>Creighton University School of Medicine, Omaha, USA.

**Background and aims:** There are limited clinical data comparing DPP-4 inhibitors directly. Here we present the efficacy data from a 24-week study in patients with type 2 diabetes mellitus (T2DM) and severe renal impairment (RI) comparing vildagliptin (VILDA) and sitagliptin (SITA). VILDA is mostly hydrolyzed to inactive metabolites; approximately 20% is excreted as unchanged drug. In patients with severe RI slower elimination effectively doubles the period of time that VILDA prevents GLP-1 and GIP degradation. Therefore, a 50 mg dose once daily provides full efficacy. SITA is essentially excreted unchanged by the kidney. In patients with severe RI, C<sub>max</sub> increases four-fold, requiring dose reduction. Thus, the expected maximal effective dose and the dose mandated in the label in patients with severe RI is 50 mg qd for VILDA and 25 mg qd for SITA, which have been compared in this study. **Materials and methods:** Patients with T2DM (N=148), drug-naïve or on treatment (HbA1c 6.5%-10%), and severe RI [eGFR (MDRD)  $< 30$  ml/min/1.73m<sup>2</sup>], including patients on haemodialysis (N=12), were randomized in this multicenter, double-blind, parallel-group study to receive VILDA 50 mg qd (N=83) or SITA 25 mg qd (N=65) for 24 weeks in addition to their continued background antidiabetic therapy. Changes in HbA1c and fasting plasma glucose (FPG) from baseline to study endpoint were compared between treatments using an ANCOVA model. Hypoglycaemia was defined as

symptoms suggestive of hypoglycaemia confirmed by a self-monitored blood glucose measurement of <3.1 mmol/l plasma glucose equivalent.

**Results:** Mean age of the randomized patients was 66.8 years, BMI 33.2 kg/m<sup>2</sup> and T2DM duration 19.2 years; 80% of the patients were receiving insulin therapy alone or in combination with oral antidiabetic drugs. Mean eGFR was 19.7 and 20.4 ml/min/1.73m<sup>2</sup> in the VILDA and SITA groups, respectively. At the end of treatment, mean HbA1c was reduced by 0.54% from a lower baseline of 7.52% with VILDA and by 0.56% from a baseline of 7.80% with SITA (p=NS between treatments). Twice as many patients in the VILDA group achieved an HbA1c target ≤6.5% compared with SITA (29.0% vs 14.3%, p=0.050). FPG was reduced by 0.47 mmol/l with VILDA compared to a slight increase of 0.16 mmol/l with SITA (between-group difference: -0.63 mmol/l; p=0.185). While the incidence of hypoglycaemia was similar between treatments (15.7% vs 15.4%), adverse events likely related to hypoglycaemia (hyperhidrosis, tremor, asthenia) as well as asymptomatic low blood glucose were markedly less frequent with VILDA than SITA (7.2% vs 13.8%; 8.4% vs 16.9%; 6.0% vs 21.5%; and 4.9% vs 9.2%, respectively). Overall safety was similar between the two treatments.

**Conclusion:** In patients with T2DM and severe RI, VILDA and SITA produced similar and clinically relevant HbA1c reductions. However, more patients achieved an HbA1c goal ≤6.5% with VILDA compared to SITA which was not associated with an increase in confirmed (<3.1 mmol/l) hypoglycaemia. The lower levels of glycaemia achieved with VILDA may have been due to the lower rate of symptoms suggestive of hypoglycaemia which typically occur at plasma glucose >3.1 mmol/l, where glucagon counter-regulation is most important. This may be attributed to the previously described effect of VILDA to improve glucagon counter-regulation by maintaining meal-induced increases in GIP during inter-meal periods.

### Pharmacokinetics of once weekly dulaglutide in special populations

C. Loghin<sup>1</sup>, A. de la Peña<sup>2</sup>, X. Cui<sup>3</sup>, X. Zhang<sup>2</sup>, J.S. Geiser<sup>2</sup>, J.Y. Chien<sup>2</sup>; <sup>1</sup>Clinical Pharmacology, Eli Lilly and Company, <sup>2</sup>Eli Lilly and Company, Indianapolis, <sup>3</sup>BioStatistics, inVentiv Health Clinical, Burlington, USA.

**Background and aims:** For use in a broad type 2 diabetes mellitus (T2DM) population, dulaglutide pharmacokinetics (PK) were characterized in subjects with renal or hepatic impairment.

**Materials and methods:** Two separate open-label, single-dose studies assessed dulaglutide 1.5 mg PK in subjects with hepatic (n=15) or renal impairment (n=32), relative to healthy subjects (n=11 and 16, respectively). Both studies included mild, moderate and severe impairment; the renal study also included end stage renal disease.

**Results:** Dulaglutide exposure (area under concentration-time curve [AUC] and maximum concentration [C<sub>max</sub>]) was <30% higher in renal impairment groups versus controls. There was no relationship between PK parameters and renal function based on estimated glomerular filtration rate. In addition, there was no statistically significant linear relationship at the 5% significance level between exposure and creatinine clearance (CrCL). A statistically significant linear relationship was observed between CrCL and dulaglutide apparent clearance (CL/F); however the relationship was weak based on its small slope (p=0.0133) and goodness of fit (r<sup>2</sup>=0.1315). Across all hepatic groups, impaired subjects had lower exposure compared to controls. There was no trend in exposure relative to degree of hepatic impairment, with the largest difference observed in subjects with moderate impairment (C<sub>max</sub> and AUC values approximately 70% and 67% of controls, respectively). No notable differences in safety profiles were seen between subjects with hepatic or renal impairment and healthy subjects.

**Conclusion:** There were no clinically relevant effects of renal or hepatic impairment on dulaglutide PK. Dulaglutide can be administered once weekly to patients with renal or hepatic impairment, without dose adjustment.

*Clinical Trial Registration Number: NCT01253304*

### Liraglutide 3.0 mg improves insulin secretion and action in overweight/obese adults without type 2 diabetes: the SCALE obesity and prediabetes trial

D.C.W. Lau<sup>1</sup>, J.P.H. Wilding<sup>2</sup>, A. Astrup<sup>3</sup>, K. Fujioka<sup>4</sup>, F. Greenway<sup>5</sup>, A. Halpern<sup>6</sup>, M. Krempf<sup>7</sup>, C. le Roux<sup>8</sup>, R. Violante Ortiz<sup>9</sup>, R.V. Overgaard<sup>10</sup>, C.B. Jensen<sup>10</sup>, X. Pi-Sunyer<sup>11</sup>; <sup>1</sup>University of Calgary, Canada, <sup>2</sup>University of Liverpool, UK, <sup>3</sup>University of Copenhagen, Denmark, <sup>4</sup>Scripps Clinic, La Jolla, <sup>5</sup>Louisiana State University, Baton Rouge, USA, <sup>6</sup>University of São Paulo Medical School, Brazil, <sup>7</sup>Université de Nantes, France, <sup>8</sup>University College Dublin, Ireland, <sup>9</sup>Instituto Mexicano del Seguro Social, Ciudad Madero, Mexico, <sup>10</sup>Novo Nordisk A/S, Søborg, Denmark, <sup>11</sup>Columbia University, New York, USA.

**Background and aims:** Obesity is commonly associated with impaired insulin sensitivity and pancreatic beta-cell dysfunction; both implicated in the pathogenesis of type 2 diabetes (T2D). This trial investigated the effects of liraglutide 3.0 mg, as adjunct to diet and exercise, on weight loss (primary endpoint) and insulin secretion and action in overweight/obese individuals with and without prediabetes at screening.

**Materials and methods:** Adults (BMI ≥27 kg/m<sup>2</sup> with ≥1 comorbidity or ≥30 kg/m<sup>2</sup>) were advised on a 500 kcal/day deficit diet and exercise programme and randomised 2:1 to once-daily s.c. liraglutide 3.0 mg or placebo. Randomisation was stratified by prediabetes status (ADA 2010) and BMI at screening. AUCs for glucose, insulin and C-peptide during a 75-g 120 min OGTT at week 0 and 56 were estimated (least square [LS] means, full analysis set [FAS] with LOCF), as were indices of insulin secretion (IS, C-peptide deconvolution method), insulin sensitivity (SI, Matsuda index) and beta-cell function (disposition index [DI], IS\*SI) (completers, exploratory analyses).

**Results:** Baseline characteristics: age 45.1 years, 79% female, weight 106.2 kg, BMI 38.3 kg/m<sup>2</sup>, 61.2% with prediabetes. At week 56, individuals on liraglutide 3.0 mg (n=2437) had weight loss of 8.0% vs 2.6% with placebo (n=1225) (estimated treatment difference [ETD] -5.4%, p<0.0001, LSmeans, FAS with LOCF, ANCOVA). Fasting and post-load glycaemia was improved with liraglutide 3.0 mg, as both FPG and glucose AUC were lower with liraglutide 3.0 mg vs placebo (ETD -0.38 mmol/L and -2.02 h\*mmol/L, respectively; p<0.0001, ANCOVA). Post-load insulin and C-peptide were also improved with liraglutide 3.0 mg vs placebo (estimated treatment ratios 1.10 and 1.07, respectively; p<0.0001, ANCOVA on log scale). Improvements applied to individuals both with and without prediabetes, but glucose-lowering was most prominent in individuals with prediabetes (p<0.0001). Improved post-load glucose with liraglutide 3.0 mg vs placebo, was accompanied by increased IS (11% vs 1%), increased SI (21% vs 10%) and improved beta-cell function (35% vs 11%) (all p<0.0001, ANOVA). Similar effects were seen in individuals both with and without prediabetes.

**Conclusion:** Liraglutide 3.0 mg, as adjunct to diet and exercise, led to weight loss and improvements in insulin secretion and action, all of which likely explain the observed improvements in fasting and post-load glycaemia in overweight and obese individuals with and without prediabetes.

### Pharmacokinetics and tolerability of a single dose of semaglutide, a once-weekly human GLP-1 analogue, in subjects with and without renal impairment

T.C. Marbury<sup>1</sup>, A. Flint<sup>2</sup>, S. Segel<sup>2</sup>, M. Lindegaard<sup>2</sup>, K.C. Lasseter<sup>3</sup>; <sup>1</sup>Orlando Clinical Research Center, Orlando, USA, <sup>2</sup>Novo Nordisk, Søborg, Denmark, <sup>3</sup>Clinical Pharmacology of Miami, Inc., USA.

**Background and aims:** The pharmacokinetics and tolerability of semaglutide, a once-weekly, human GLP-1 analogue in development for treatment of type 2 diabetes, were investigated in subjects with and without renal impairment.

**Materials and methods:** Using the Cockcroft-Gault formula, 56 subjects were assigned to one of five renal function groups and received a single dose of 0.5 mg s.c. semaglutide. In the end-stage renal disease (ESRD) group, semaglutide was given 1-24 h after haemodialysis, with no haemodialysis for 48 h post dose. Semaglutide plasma concentration was assessed regularly up to 480 h (~20 days) post dose; the primary endpoint was area under the semaglutide time-concentration curve from time zero to infinity (AUC<sub>0-∞</sub>).

Secondary endpoints included other pharmacokinetic parameters ( $C_{max}$ ,  $t_{max}$  and  $t_{1/2}$ ), safety and tolerability of semaglutide.

**Results:** Exposure of semaglutide in subjects with mild or moderate renal impairment or ESRD was similar to that in subjects with normal renal function (Table). Subjects with severe renal impairment had a 22% higher exposure of semaglutide than those with normal renal function and the 95% CI (1.02, 1.47) exceeded the 'no effect' limits (0.70, 1.43). One subject with severe renal impairment reported two major hypoglycaemic events. There were no appreciable changes in laboratory safety parameters or vital signs; no serious adverse events (AEs) were noted. One subject withdrew due to gastrointestinal AEs.

**Conclusion:** In three of four groups with renal impairment, there was no effect on semaglutide exposure. In the severe renal impairment group, semaglutide exposure was increased. Semaglutide was well tolerated. The long-term effect of semaglutide on renal impairment will be investigated in future trials.

| Pharmacokinetic endpoints for semaglutide in subjects with and without renal impairment <sup>a</sup> |  |  |  |  |   |

### VIRTUE study: effects of vildagliptin versus sulphonylureas as monotherapy or combined with metformin in Muslim patients with type 2 diabetes fasting during Ramadan

I. Shaltout<sup>1</sup>, F. Pathan<sup>2</sup>, R. Medlej<sup>3</sup>, M. Al-Arouj<sup>4</sup>, A.A.K. Hassoun<sup>5</sup>, M.S. Chawla<sup>6</sup>, D. Knap<sup>7</sup>, J.A. Vaz<sup>8</sup>;

<sup>1</sup>Cairo University, Cairo, Egypt, <sup>2</sup>BIRDEM Hospital, Dhaka, Bangladesh,

<sup>3</sup>Chronic Care Center, Saint Joseph University, Beirut, Lebanon, <sup>4</sup>Dasman

Diabetes Institute, Dasman, Kuwait, <sup>5</sup>Dubai Diabetes Center, United Arab

Emirates, <sup>6</sup>Lina Diabetes Care Center, Mumbai, India, <sup>7</sup>Novartis Pharma

AG, Basel, Switzerland, <sup>8</sup>Novartis Healthcare Pvt. Ltd., Hyderabad, India.

**Background and aims:** For Muslim patients with type 2 diabetes mellitus (T2DM), fasting during Ramadan can increase the risk of serious complications such as hypoglycaemia. This post-hoc analysis of the VIRTUE study assessed, in routine clinical practice, the effectiveness and safety of vildagliptin relative to sulphonylureas (SUs) as monotherapy or when combined with metformin in Muslim patients with T2DM fasting during Ramadan.

**Materials and methods:** VIRTUE was a multicentre, prospective, 16-week, observational study conducted in the Middle East and Asia, and included adult Muslim patients with T2DM who were receiving vildagliptin or SUs (either as monotherapy or combined with metformin as per routine care) for ≥4 weeks and <3 years prior to the start of fasting. The primary endpoint was the proportion of patients with ≥1 hypoglycaemic event (HE) during Ramadan. Secondary endpoints included change from baseline in HbA<sub>1c</sub> and body weight, and safety assessments.

**Results:** Overall, 145 patients received monotherapy (vildagliptin, N=62; SU, N=83) and 1,148 received dual therapy (vildagliptin + metformin, N=607; SU + metformin, N=541). Fewer patients experienced ≥1 HE with vildagliptin

compared with SUs, both as monotherapy and when combined with metformin, the latter achieving statistical significance (p<0.001; Table). No grade 2 (severe) HEs were reported with vildagliptin therapy, compared with four patients receiving SU + metformin (p=0.048 vs vildagliptin + metformin). Pre- to post-Ramadan changes in HbA<sub>1c</sub> and body weight were also assessed in vildagliptin and SU treatment groups (Table). Vildagliptin therapy was generally well tolerated. The incidence of adverse events with vildagliptin compared with SUs was 9.7% vs 18.1%, respectively, for monotherapy and 10.2% vs 23.5% for combination with metformin. The most common AEs were hypoglycaemia, pyrexia and nausea.

**Conclusion:** In this post-hoc analysis, fewer patients experienced HEs with vildagliptin compared with SUs; this achieved significance in patients receiving combination therapy with metformin. In addition, vildagliptin +/- metformin was associated with good glycaemic and weight control, and was well tolerated in this population. As such, vildagliptin may be a useful treatment option for patients with T2DM fasting during Ramadan.

**Table. Effects of vildagliptin versus SU monotherapy and in combination with metformin on incidence of HEs, HbA<sub>1c</sub> and body weight**

|   | Monotherapy  |      | Combination with metformin |       |
|---|--------------|------|----------------------------|-------|
|   | Vildagliptin | SU   | Vildagliptin               | SU    |
| Patients with ≥1 HE during fasting (%)              | 6.5          | 14.5 | 5.3*                       | 20.6  |

### Enhanced glucose-lowering effect of dipeptidyl peptidase-4 inhibitor in subjects with type 2 diabetes who have a history of gastrectomy

Y. Wada<sup>1</sup>, Y. Hamamoto<sup>1</sup>, S. Honjo<sup>1</sup>, K. Fujimoto<sup>1</sup>, H. Tatsuoka<sup>1</sup>,

A. Matsuoka<sup>1</sup>, H. Ikeda<sup>2</sup>, J. Fujikawa<sup>3</sup>, H. Koshiyama<sup>1</sup>;

<sup>1</sup>Center for Diabetes and Endocrinology, The Tazuke Kofukai Foundation

Medical Research Institute Kitano Hospital, <sup>2</sup>Ikeda Hospital, Amagasaki,

Japan, <sup>3</sup>Laboratory Medicine, The Tazuke Kofukai Foundation Medical

Research Institute Kitano Hospital, Osaka, Japan.

**Background and aims:** It has been reported that glucagon like peptide-1 (GLP-1) exhibits its effects not only directly through its receptor on the target cell membrane but also via central nervous system. Hepatic branch vagotomy reportedly decreases insulin secretion in rodents. On the other hand, accelerated gastric excretion in subjects with gastrectomy affects postprandial absorption of nutrients and secretion pattern of GLP-1 and glucose-dependent insulinotropic polypeptide (GIP). In this study, we investigated whether the effect of dipeptidyl peptidase-4 (DPP-4) inhibitor is different between the subjects with and without the history of gastrectomy.

**Materials and methods:** Among patients with type 2 diabetes who were prescribed with DPP-4 inhibitor during 2010 to 2013 at our clinic, those who have the history of gastrectomy more than 6 months before (50±11.4 months) the administration of DPP-4 inhibitor were retrospectively identified from our database (gastrectomy group). Also, patients without the history of gastrectomy who were prescribed with DPP-4 inhibitor (n=20; male: n=13) were randomly selected as a control group. The HbA<sub>1c</sub> levels measured before and three and six months after DPP-4 inhibitor administration were evaluated. Each value is shown in mean ± SE.

**Results:** A total of 10 subjects (male: n=8) were identified to meet the conditions (50mg of sitagliptin: n=6, 50mg of vildagliptin: n=4). Control group received 50mg of sitagliptin (n=18), 50mg of vildagliptin (n=1) and 5mg of linagliptin (n=1). The drugs used in combination were sulphonylureas (n=5), insulin (n=2), biganide (n=1), alpha-glucosidase inhibitor (n=1), glinide (n=1) in gastrectomy group, and sulphonylureas (n=11), insulin (n=4), biganides (n=5), and alpha-glucosidase inhibitor (n=1) in control group. Age (71.6±2.5 vs 69.1±2.7 years; gastrectomy group vs control group, p=0.50), body mass index (22.5±1.1 vs 24.1±0.7 kg/m<sup>2</sup>; p=0.22) and HbA<sub>1c</sub> levels before DPP-4 inhibitor administration (8.1±0.1 vs 7.9±0.1 %; p=0.18) were not different between two groups. DPP-4 inhibitor administration significantly decreased HbA<sub>1c</sub> levels in both groups by -1.11±0.20 % in gastrectomy group (p<0.01) and -0.88±0.11% in control group (p<0.01) at 3 months, and by -1.25±0.11

% ( $p < 0.01$ ) and  $-0.82 \pm 0.12$  % ( $p < 0.01$ ) at 6 months; however, gastrectomy group showed significantly greater reduction compared to control group at 6 months ( $p = 0.02$ ).

**Conclusion:** Our results suggest that glucose-lowering effect of DPP-4 inhibitor is enhanced in the patients who have a history of gastrectomy. Although the study with larger number of subjects will be needed to confirm our results, it is conceivable that enhanced secretion of incretins after gastrectomy might have contributed to the results.

## PS 069 Safety of DPP4 inhibitors

#### Safety of linagliptin in 8778 patients with type 2 diabetes mellitus: pooled analysis of 23 placebo-controlled randomised clinical trials

G. Scherthaner<sup>1</sup>, K. Khunti<sup>2</sup>, S. Patel<sup>3</sup>, K. Cheng<sup>4</sup>, M. Mattheus<sup>4</sup>, H.-J. Woerle<sup>4</sup>;

<sup>1</sup>Rudolfstiftung Hospital, Vienna, Austria,

<sup>2</sup>University of Leicester, <sup>3</sup>Boehringer Ingelheim Ltd, Bracknell, UK,

<sup>4</sup>Boehringer Ingelheim Pharma GmbH & Co. KG, Ingelheim, Germany.

**Background and aims:** Linagliptin is a DPP-4 inhibitor approved for the treatment of type 2 diabetes mellitus. A robust, global clinical trials program has investigated the efficacy and safety of linagliptin in adult patients. In these trials, linagliptin was given as monotherapy or as add-on to common antidiabetes drugs, such as metformin, sulphonylureas, thiazolidinediones, or insulin. This pooled analysis was undertaken to assess the overall safety of linagliptin in a larger group of patients than would be available in a single randomised trial.

**Materials and methods:** Tolerability was evaluated by incidence and intensity of adverse events (AEs), AEs of special interest (heart failure, pancreatitis, and pancreatic cancer), and incidence and intensity of hypoglycaemia. Data were analysed for 8778 patients (linagliptin,  $n = 5488$ ; placebo,  $n = 3290$ ) participating in 23 placebo-controlled randomised trials with durations  $\leq 54$  weeks. Data were assessed descriptively.

**Results:** Total exposure was 2883.6 patient years (mean,  $192 \pm 127$  days) and 1957.8 patient years (mean,  $217 \pm 151$  days) in the linagliptin and placebo groups, respectively. Linagliptin was well tolerated, with AEs occurring in a similar proportion of linagliptin and placebo patients (58.0% and 62.3%, respectively). Drug-related AEs were observed in 11.8% and 13.3% of patients, respectively. Heart failure was observed in 0.5% and 0.2% of patients, respectively. Pancreatitis was reported in 0.1% of both groups. One pancreatic carcinoma occurred in the linagliptin group. Investigator-defined hypoglycaemia occurred in 10.6% and 12.2% of linagliptin and placebo patients, respectively (linagliptin,  $n = 5303$ ; placebo,  $n = 3084$ ). Severe hypoglycaemia was experienced by 0.4% and 0.5% of patients, respectively. Most hypoglycaemia occurred in trials allowing sulphonylureas or insulin as background medications.

**Conclusion:** These findings provide further evidence for the safety and tolerability of linagliptin in a broad range of patients.

### 886

#### Lower risk of hypoglycaemia with vildagliptin versus low dose glimepiride in relation to the HbA1c level

B. Ahrén<sup>1</sup>, A. Schweizer<sup>2</sup>, M. Dworak<sup>3</sup>, J.E. Foley<sup>4</sup>, S. Dejager<sup>5</sup>, G. Heimann<sup>2</sup>, M. Akacha<sup>2</sup>, Q. Shao<sup>4</sup>;

<sup>1</sup>Lund University, Sweden, <sup>2</sup>Novartis Pharma AG, Basel, Switzerland,

<sup>3</sup>Novartis Pharma GmbH, Nürnberg, Germany, <sup>4</sup>Novartis Pharmaceuticals Corporation, East Hanover, USA, <sup>5</sup>Novartis Pharma SAS, Rueil Malmaison, France.

**Background and aims:** In a previously published study (mean HbA1c 7.3%;  $N = 3118$ ), vildagliptin (50 mg bid) showed a reduced risk of hypoglycaemia compared with glimepiride as add-on therapy to metformin after 52 (1.7/16.2%) and 104 (2.3/18.2%) weeks at similar efficacy. Glimepiride (starting dose 2 mg/day) could be titrated to a maximum dose of 6 mg/day. A limitation of the study was the perception that the hypoglycaemia difference was driven by high doses of glimepiride. It was therefore of interest to compare the risk of confirmed hypoglycaemia with vildagliptin to the subgroup of glimepiride patients remaining on the dose of 2 mg/day throughout the study, in addition to all glimepiride patients.

**Materials and methods:** Comparisons were done by modeling risk as a function of time and last measured HbA1c using discrete event time modelling, with treatment, age and gender as additional covariates. Hypoglycaemia was defined as symptoms suggestive of low blood glucose confirmed by self-monitored blood glucose measurement  $< 3.1$  mmol/l plasma glucose equivalent.

**Results:** The hypoglycaemia risk at week 18 was significantly lower with vildagliptin 50 mg bid compared to glimepiride 2 mg/day, with similar results unadjusted or adjusted for last HbA1c (adjusted HR = 0.05 [95% CI 0.03, 0.10]). The risk of hypoglycaemia was very low with vildagliptin over the full HbA1c

range while the risk with glimepiride 2 mg/day increased with lower HbA1c (Figure). The increase for lower levels of HbA1c was more pronounced in the glimepiride 2 mg/day subgroup than in the full set of patients treated with glimepiride (adjusted HR = 0.08 [95% CI 0.0, 0.15]).

**Conclusion:** Taken together, the data show a substantially lower risk of confirmed hypoglycaemia with vildagliptin compared to low dose (2 mg/day) glimepiride, and indicate that the previously reported results are not driven by high doses of glimepiride.

#### Risk of confirmed hypoglycaemia

### Incidence of fractures in patients with type 2 diabetes in the SAVOR-TIMI 53 trial

K. Strojek<sup>1</sup>, O. Mosenzon<sup>2</sup>, J. Davidson<sup>3</sup>, B.M. Scirica<sup>4</sup>, G. Leibowitz<sup>2</sup>, R.G. Bretzel<sup>5</sup>, J.E. Villena<sup>6</sup>, M. Alvarsson<sup>7</sup>, B. Hirshberg<sup>8</sup>, C. Stahre<sup>9</sup>, A. Parker<sup>10</sup>, D.L. Bhatt<sup>11</sup>, I. Raz<sup>12</sup>;

<sup>1</sup>Department of Internal Diseases Diabetology and Cardiometabolic Diseases, Silesian Medical University Zabrze, Poland, <sup>2</sup>The Diabetes Unit, Hadassah Hebrew University - Medical Center, Jerusalem, Israel, <sup>3</sup>The University of Texas Southwestern Medical Center, Dallas, <sup>4</sup>Brigham and Women's Hospital Harvard Medical School, Boston, USA, <sup>5</sup>St. Josefs Hospital Baleserische Stiftung, Giessen, Germany, <sup>6</sup>Hospital Nacional Cayetano Heredia, Lima, Peru, <sup>7</sup>Dept. of Endocrinology, Metabolism and Diabetes, Karolinska University Hospital, Stockholm, Sweden, <sup>8</sup>AstraZeneca, Wilmington, USA, <sup>9</sup>AstraZeneca, Mölndal, Sweden, <sup>10</sup>The Diabetes Unit, AstraZeneca LP, Wilmington, USA, <sup>11</sup>The Diabetes Unit, Brigham and Women's Hospital, Harvard Medical School, Boston, USA, <sup>12</sup>Diabetes Unit, Hadassah Hebrew University - Medical Center, Jerusalem, Israel.

**Background and aims:** Patients with type 2 diabetes have an increased risk of bone fractures, the predisposing factors for which in diabetes are unknown. In the SAVOR-TIMI 53 trial, fractures were considered an adverse event of special interest (AESI) and information regarding fractures was actively collected by the investigators.

**Materials and methods:** We compared the incidence of fractures among the 8,280 patients who were assigned to treatment with saxagliptin to the incidence in the 8,212 patients who were assigned to placebo.

**Results:** During the median follow-up of 2.1 years, 235 (2.8%) and 236 (2.9%) patients in the saxagliptin and placebo groups experienced a fracture; HR (95% CI) = 0.99 (0.83–1.19). The treatment exposure-adjusted rate of bone fracture (first event only) was 14 per 1000 patient-years of follow-up in both groups. Fracture risk was similar in patients treated with saxagliptin or placebo across different subgroups defined by race, cardiovascular risk, renal function and duration of diabetes. A multivariable analysis of the entire study population showed the risk of fracture was associated with older age

( $p=0.001$ ), female gender ( $p<0.0001$ ), longer diabetes duration ( $p<0.0001$ ), elevated HbA1c ( $p=0.03$ ) and treatment with TZDs ( $p=0.03$ ). Fracture risk was not associated with body mass index, estimated glomerular filtration rate, or the use of other anti-diabetic drugs.

**Conclusion:** The SAVOR TIMI 53 trial provides important data regarding the risk of fractures in a large population of patients with type 2 diabetes. Treatment with saxagliptin was not associated with an increased risk of fractures. The association between longer diabetes duration and poor glycemic control to increased risk of bone fracture is an intriguing finding.

### Assessment of heart failure risk with vildagliptin in diabetic patients: pooled analysis of safety data from approximately 17,000 patients

M. Evans<sup>1</sup>, G. McInnes<sup>2</sup>, M. Stumvoll<sup>3</sup>, S. Del Prato<sup>4</sup>, A. Schweizer<sup>5</sup>,

Q. Shao<sup>6</sup>, V. Lukashevich<sup>6</sup>, W. Kothny<sup>5</sup>;

<sup>1</sup>University Hospital Llandough, Cardiff, UK, <sup>2</sup>Institute of Cardiovascular

& Medical Sciences University of Glasgow, UK, <sup>3</sup>University of Leipzig,

Germany, <sup>4</sup>University of Pisa, Italy, <sup>5</sup>Novartis Pharma AG, Basel,

Switzerland, <sup>6</sup>Novartis Pharmaceuticals Corporation, East Hanover, USA.

**Background and aims:** Heart failure (HF) is an important and disabling complication of type 2 diabetes mellitus (T2DM). Two recently completed DPP4 inhibitor cardio-vascular (CV) outcome trials (SAVOR-TIMI-53 and EXAMINE) confirmed the overall CV safety of this class, but also triggered a discussion of a potential HF risk with these agents. We present a meta-analysis of prospectively adjudicated HF events from the vildagliptin pooled database with approximately 17,000 patients.

**Materials and methods:** Data from 40 randomized, double blind, placebo or active-controlled Phase III vildagliptin studies of  $\geq 12$ -week duration were pooled. Vildagliptin data on the approved doses of 50 mg qd or bid were considered and analysed consistent with FDA guidance on CV safety. Vildagliptin was used as a monotherapy or in combination with other anti-diabetic drugs in a broad T2DM population including patients with HF NYHA Class I-III. All reported HF events were prospectively adjudicated by independent experts as either 1) HF requiring hospitalization or 2) new onset of HF. The Mantel-Haenszel (M-H) relative risk (RR) of confirmed HF events with vildagliptin vs. comparators (all non-vildagliptin treatments) was calculated.

**Results:** There were 9599 patients exposed to vildagliptin (9250 subject year exposure [SYE]) compared to 7847 exposed to comparators (7317 SYE). Baseline demographic and clinical characteristics were comparable between treatment groups. Over 40% of patients had 2 or more CV risk factors and approximately 18% had a previous history of cardio-cerebro-vascular disease. Confirmed HF events were reported in 41 (0.43%) patients on vildagliptin 50 mg qd/bid dose and in 32 (0.45%) patients on comparators (Figure) with M-H RR of 1.08 (95% CI 0.68–1.70). No dose response was observed.

**Conclusion:** This analysis of prospectively adjudicated HF events from the large vildagliptin database indicated that vildagliptin is not associated with increased risk of HF in patients with T2DM relative to comparators.

FIGURE: Incidences and risk ratios for adjudicated heart failure events requiring hospitalization or new onset of heart failure events with vildagliptin vs. comparators

<sup>3</sup>Creighton University School of Medicine, Omaha, USA.

**Background and aims:** Therapeutic management of type 2 diabetes mellitus (T2DM) with declined kidney function is challenging especially in patients with severe renal impairment (RI). Since the actions of the incretin hormones GLP-1 and GIP are glucose-sensitive, hypoglycaemia secondary to increased drug exposure is unlikely to occur with DPP-4 inhibitors (DPP-4i), making this drug class very attractive in treating patients with RI. It has been suggested that safety profiles of DPP-4i may differ in patients with RI, driven by whether or not unchanged drug or metabolites are renally excreted. Here we present a large pooled analysis of safety data for two different DPP-4i eliminated via the kidney, vildagliptin (Vilda), which is primarily hydrolyzed, and sitagliptin (Sita), excreted as unchanged drug, from two studies in 368 patients with T2DM and severe RI.

**Materials and methods:** Data were pooled across two double-blind studies of similar design (a new study comparing Vilda and Sita at the doses recommended by label in severe RI and a previously reported study comparing Vilda and placebo [Pbo]). Patients with severe RI [eGFR (MDRD) <30 mL/min/1.73m<sup>2</sup>], including patients on haemodialysis (N=16) were treated with Vilda 50 mg qd (N=206), Pbo (N=97) or Sita 25 mg qd (N=65) for 24 weeks. Absolute incidence rates were calculated for all adverse events (AEs), serious AEs (SAEs), discontinuation due to AEs, and deaths. Laboratory data were also analyzed.

**Results:** Mean age of the patients was 65.3 years, BMI 31.3 kg/m<sup>2</sup>, HbA1c 7.7% and T2DM duration 18.5 years; 81.3% of patients were treated with insulin as monotherapy or in combination with oral antidiabetics. The incidence of AEs, SAEs, discontinuations due to AEs and deaths were overall comparable between Vilda, Sita and Pbo as shown in Table, which also presents the most commonly reported AEs. The incidence of cardiac events was also similar between treatments (12.6%, 15.4% and 12.4% with Vilda, Sita and Pbo, respectively). Hepatobiliary AEs were infrequent in all 3 groups (1.0%, 1.5% and 0% of patients, respectively) as were persistent elevations  $\geq 3 \times$ ULN of hepatic enzymes alanine or aspartate aminotransferase (0.5%, 0% and 1.1%, respectively). No cases of pancreatitis were reported in either group. There was no deterioration of renal function with Vilda or Sita compared with Pbo. While a limited number of patients with end stage renal disease on haemodialysis was included in the study (Vilda=8 and Sita=6), the safety data did not indicate that these patients were at increased risk compared to the population with severe RI.

**Conclusion:** Taken together, in a pooled analysis of patients with severe RI, Vilda and Sita had overall safety profiles comparable with Pbo, indicating that two different DPP-4i that are excreted via the kidney as unchanged drug or metabolites can be safely used in patients with T2DM and advanced RI at the doses recommended by the label.

**Table. Adverse events in patients with T2DM and severe renal impairment**

Sud, Santa Maria Imbaro, Italy, <sup>2</sup>Drug Safety Research Unit, Southampton,

UK, <sup>3</sup>RTI Health Solutions, Barcelona, Spain, <sup>4</sup>University Milano-Bicocca,

Italy, <sup>5</sup>Erasmus University Medical Center, Rotterdam, Netherlands.

**Background and aims:** In the framework of an EU funded study, the “Safety Evaluation of Adverse Reactions in Diabetes (SAFEGUARD) project”, a meta-analysis of randomized clinical trials (RCTs) to assess the cardiovascular (CV) safety of dipeptidyl peptidase-4 inhibitors (DPP-4i) was performed.

**Materials and methods:** Trials were identified through searches of MEDLINE, EMBASE and Cochrane databases (January 1966–September 2013) using standard search strategies. Reference lists of selected articles were also checked. Eligible studies included published RCTs that compared DPP-4i against placebo/no treatment, or another non-insulin blood glucose lowering agent in individuals with type 2 diabetes and reported major CV events (CV mortality, sudden death, myocardial infarction, stroke, or heart failure). Two reviewers independently assessed trials for inclusion and extracted data. Effect estimates were pooled using fixed or random effects meta-analysis based on exact bivariate non-linear mixed models. Results are reported as relative risks (RR) with 95% confidence intervals (CI).

**Results:** The electronic search identified 8,168 citations on all non-insulin blood glucose lowering agents, of which 334 were selected. Out of 140 RCTs on DPP-4i, 70 reported at least one CV event. When DPP-4i were compared with placebo/no treatment, no association was suggested with CV mortality (27 studies, 43,381 participants; RR=0.85; 0.71–1.02), sudden death (15 studies, 23,494 participants; RR=1.17; 0.90–1.51), myocardial infarction (20 studies, 27,553 participants; RR=0.95; 0.84–1.09), and ischemic stroke (15 studies, 27,224 participants; RR=1.04; 0.84–1.29). There was an increase in the risk of heart failure in patients treated with DPP-4i compared to placebo (9 studies, 20,349 participants; RR=1.24, 1.03–1.49). For active comparator studies no association was found for CV mortality (24 studies, 22,064 participants; RR=0.92; 0.50–1.70), sudden death (8 studies, 7,130 participants; RR=0.83; 0.23–3.00), myocardial infarction (12 studies, 5,453 participants; RR=0.70; 0.34–1.43), or heart failure (6 studies, 6,180 participants; RR=1.31; 0.50–3.43). DPP-4i reduced the risk of ischemic stroke when compared to active comparator (8 studies, 7,777 participants; RR=0.33; 0.14–0.79).

**Conclusion:** These results, based on publicly available data, suggest that DPP-4i did not influence the risk of CV mortality or other CV events in comparison with placebo/no treatment, except for an increased risk of heart failure. However, the results are driven by the findings from the “Saxagliptin Assessment of Vascular Outcomes Recorded in Patients with Diabetes Mellitus (SAVOR)-Thrombolysis in Myocardial Infarction (TIMI) 53” study and the finding needs to be confirmed by pooling these data with those of other ongoing studies specifically designed to assess the effect on CV end-points. Furthermore, DPP-4i showed a lower risk of ischemic stroke than active comparators. Additional trial data are required before definitively draw conclusions on CV safety of DPP-4i.

### Cardiovascular safety of vildagliptin: an adjudicated meta-analysis of 40 studies

G. McInnes<sup>1</sup>, S. Del Prato<sup>2</sup>, M. Evans<sup>3</sup>, M. Stumvoll<sup>4</sup>, A. Schweizer<sup>5</sup>,

V. Lukashevich<sup>6</sup>, Q. Shao<sup>6</sup>, W. Kothny<sup>5</sup>;

<sup>1</sup>Institute of Cardiovascular & Medical Sciences University of Glasgow, UK,

<sup>2</sup>University of Pisa, Italy, <sup>3</sup>University Hospital, Llandough, Cardiff, UK,

<sup>4</sup>University of Leipzig, Germany, <sup>5</sup>Novartis Pharma AG, Basel, Switzerland,

<sup>6</sup>Novartis Pharmaceuticals Corporation, East Hanover, USA.

**Background and aims:** Since the previous assessment of the cardiovascular (CV) safety profile of the DPP-4 inhibitor vildagliptin, a considerable number of additional studies have completed, including trials in high risk patients, such as with congestive heart failure or moderate/several renal impairment. It was therefore important to re-assess the CV safety of vildagliptin in this enlarged pool of studies.

**Materials and methods:** Patient-level data were pooled from 40 double-blind, controlled studies of vildagliptin, used either as monotherapy or combination therapy, ranging in duration from 12 to  $\geq 104$  weeks. A retrospective meta-analysis of prospectively adjudicated CV events by a blinded independent expert committee was performed using Mantel-Haenszel risk ratios (RR) to compare the vildagliptin treatment group (approved doses of 50 mg bid and qd) to the comparators groups (placebo and active comparators). The primary endpoint was a major adverse CV events (MACE) composite of myocardial infarction, stroke and CV death. Additional assessments included the individual components of the composite endpoint.

**Results:** Patients included in the pooled dataset [treated with vildagliptin (N=9599; 9250 subject year exposure [SYE]) or comparators (N=7847; 7317 SYE)] had a mean age of  $\sim 57$  years, slight male predominance ( $\sim 55/45\%$ ), mean BMI of  $30.5 \text{ kg/m}^2$  (nearly 50% obese), mean HbA1c of 8.1%, and a mean T2DM duration of 5.6 years; 46% of patients had dyslipidemia, 58% hypertension and 27% were 65 years or older. The incidences and risk ratios for the MACE composite endpoint as well as the individual components are shown in the Figure below. A MACE occurred in 111 (1.16%) patients receiving vildagliptin and 108 (1.52%) patients receiving comparators, the resulting RR being 0.86 (95% CI 0.66, 1.11), indicating no increased risk of MACE with vildagliptin. Similar risk ratios were also seen for each individual component of the composite endpoint (Figure).

**Conclusion:** This large meta-analysis demonstrates that vildagliptin is not associated with an increased risk for adjudicated MACE events relative to comparators, confirming the CV safety profile of the drug in a largely expanded pooled population.

**FIGURE** Incidences and risk ratios for adjudicated major adverse CV (MACE) composite endpoint (consisting of CV death, MI and stroke) and its individual components with vildagliptin vs. comparators

## 892

### Lower respiratory tract infections and the use of dipeptidyl peptidase-4 inhibitors: a population-based matched cohort study

J.-L. Faillie<sup>1</sup>, L. Azoulay<sup>2</sup>, K. Filion<sup>2</sup>, V. Patenaude<sup>2</sup>, S. Suissa<sup>2</sup>, P. Ernst<sup>2</sup>; <sup>1</sup>Department of Medical Pharmacology, Montpellier University Hospital, France, <sup>2</sup>Centre for Clinical Epidemiology, Lady Davis Institute, Montreal, QC, Canada.

**Background and aims:** It is hypothesized that dipeptidyl peptidase-4 (DPP-4) inhibitors, also known as gliptins, may alter the immune response and play a role in the occurrence of infections. The aim of this study was to determine whether the use of DPP-4 inhibitors is associated with an increased risk of community-acquired lower respiratory tract infection, when compared to sulfonylureas.

**Materials and methods:** A population-based matched cohort study was conducted among linkable patients with records in both the United Kingdom Clinical Practice Research Datalink (CPRD) and the Hospital Episodes Statistics (HES) database. Between January 1, 2007 and March 31, 2012, each new user of DPP-4 inhibitors was matched to two patients prescribed sulfonylureas either in monotherapy or in combination, on three variables: age, duration of treated diabetes (defined as the time between a first ever non-insulin prescription and cohort entry) and use of sulfonylurea in the prior year. Cox proportional hazards models were used to estimate hazard ratios (HRs) and 95% confidence intervals (CIs) of community-acquired lower respiratory tract infection, comparing DPP-4 inhibitors users to sulfonylurea users. In secondary analyses, types of DPP-4 inhibitors, and the outcome of hospitalization for community-acquired pneumonia were assessed. All models were adjusted for comorbidities and diabetes-related variables (such as hemoglobin A1c and previous use of anti-diabetic drugs).

**Results:** Overall, 6933 new users of DPP-4 inhibitors were compared to 17,026 users of sulfonylureas. The crude incidence rates of community-acquired lower respiratory tract infection was 8.44 per 100 person-years (95% CI: 7.71 - 9.23) for DPP-4 inhibitors users and 7.54 (95% CI: 7.21 - 7.89) for

sulfonylurea users. Compared to sulfonylureas, the use of DPP-4 inhibitors was not associated with an increased risk of community-acquired lower respiratory tract infection and hospitalization for community-acquired pneumonia (0.90, 95% CI: 0.78 - 1.04 and 0.76, 95% CI: 0.44 - 1.31, respectively) (table 1). In the subgroup analysis by type of DPP-4 inhibitors, the risk of community-acquired lower respiratory tract infection ranged from a 17% decreased risk (HR: 0.83, 95% CI: 0.71 - 0.97) for sitagliptin, to a 31% increased risk for vildagliptin (HR: 1.31, 95% CI: 1.00 - 1.72).

**Conclusion:** Overall, the use of DPP-4 inhibitors as a class does not appear to be associated with an increased risk of community-acquired lower respiratory tract infections or hospitalization for community-acquired pneumonia. Additional research is needed to determine whether there is a within-class effect.

**Table 1.** Crude and adjusted hazard ratios of community-acquired lower respiratory tract infections associated with the use of DPP-4 inhibitors compared to sulfonylureas\*

| Exposure group   | No.    | Events | Person-years | Incidence rate per 1000 person-years (95% CI) | Crude HR (95% CI)  | Adjusted <sup>†</sup> HR (95% CI) |
|------------------|--------|--------|--------------|---|--------------------|-----------------------------------|
| Sulfonylureas    | 13,866 | 1514   | 20,846       | 72.63 (69.06 - 76.38)                         | 1.00 (Reference)   | 1.00 (Reference)                  |
| DPP-4 inhibitors | 6933   | 471    | 5,582        | 84.37 (77.09 - 92.35)                         | 1.03 (0.93 - 1.15) | 0.90 (0.78 - 1.04)                |

HR: hazard ratio, CI: confidence interval

\*Patients were matched on age, duration of treated diabetes (defined as the time between a first ever non-insulin prescription and cohort entry) and use of sulfonylurea in the prior year.

<sup>†</sup>Adjusted for age, sex, body mass index, HbA1c categories, smoking status, year of cohort entry, duration of treated diabetes, alcohol use, prior use of insulin, metformin, sulfonylurea, thiazolidinediones and other anti-diabetic drug, number of anti-diabetic drug ever used, lower respiratory tract infection, asthma, chronic obstructive pulmonary disease, bronchiectasis,  $\geq 4$  physician visits in the year prior to cohort entry, use of immunosuppressive agents, inhaled bronchodilators, inhaled corticosteroids, non-topical antibiotics, non-topical corticosteroids, use of influenza or pneumococcal vaccines.

### Pregnancy outcomes after unintentional exposure to vildagliptin

C. McNeill<sup>1</sup>, C. Chu<sup>1</sup>, P.M. Paldanius<sup>2</sup>, W. Kothny<sup>2</sup>;

<sup>1</sup>Novartis Pharmaceuticals Corporation, East Hanover, USA,

<sup>2</sup>Novartis Pharma AG, Basel, Switzerland.

**Background and aims:** Type 2 diabetes mellitus (T2DM) is increasingly diagnosed in younger adults and as the population of women with diabetes becomes younger, T2DM and pregnancy increasingly co-exist. Pregnancies complicated by diabetes are associated with an increased risk of adverse outcomes such as preterm delivery, abortions, congenital abnormalities and neonatal mortality. However, data on outcomes in women exposed to newer oral anti-diabetes drugs (OADs), including vildagliptin, are limited. In the absence of adequate studies, most OADs carry warnings against use during pregnancy. Nevertheless, some use of these drugs occurs during pregnancy, either accidentally or intentionally. This analysis was performed to evaluate outcomes in pregnant women exposed to vildagliptin treatment.

**Materials and methods:** The Novartis Safety Database was searched to identify all known records (cut-off date: 30 September 2013) of exposure to vildagliptin ( $\pm$  metformin) during pregnancy. The database includes clinical study and post-marketing surveillance reports, as well as spontaneous reports. Maternal outcomes (number of live births, pre-term deliveries, abortions or caesarean sections) and neonatal outcomes (number of congenital anomalies or deaths) were analysed and presented as descriptive data when available.

**Results:** A total of 32 pregnancies in 31 women with T2DM were identified from the database: 14 cases from controlled clinical trials, 15 spontaneous reports and 3 cases from post-marketing studies. The availability of demographic and baseline characteristics data was limited. The mean age was 33.9 (range 19 - 44) years and 29.0% of women had a previous history of an abortion (elective or spontaneous). Limited information was available on cumulative vildagliptin dose or trimester(s) of exposure. 23 out of 32 pregnancies (71.9%) resulted in a live birth and more than half of all the pregnancies (n=18, 56.3%) had an unremarkable outcome of normal newborns without complications. Three (9.4%) pregnancies resulted in normal newborns with pregnancy complications (one case of gestational hypertension, haemorrhage during pregnancy and placenta previa) and two (6.3%) resulted in preterm deliveries. Four caesarean sections were reported (all live births), one in the preterm and three in term pregnancies. There were eight (24.9%) spontaneous or missed abortions, but their relationship to vildagliptin was unclear. Additionally one case of therapeutic abortion was reported. No congenital abnormalities or neonatal deaths were reported.

**Conclusion:** Although the numbers are low, this analysis provides preliminary information on pregnancy outcomes in T2DM after exposure to vildagliptin. No prospective studies of vildagliptin have been performed in pregnant women with T2DM. As with most OADs, vildagliptin is also not recommended for use during pregnancy.

#### Oral glucose lowering with linagliptin plus metformin is a viable initial treatment strategy in patients with newly diagnosed type 2 diabetes and marked hyperglycaemia

B. Gallwitz<sup>1</sup>, S.A. Ross<sup>2</sup>, A.E. Caballero<sup>3</sup>, S. Del Prato<sup>4</sup>, D. Lewis-D'Agostino<sup>5</sup>, Z. Bailes<sup>6</sup>, S. Thiemann<sup>7</sup>, S. Patel<sup>6</sup>, H.-J. Woerle<sup>7</sup>, M. von Eynatten<sup>5</sup>;

<sup>1</sup>Dept. Medicine IV, Universitätsklinikum Tübingen, Germany, <sup>2</sup>LMC Endocrinology Centres, University of Calgary, Canada, <sup>3</sup>Joslin Diabetes Center and Harvard Medical School, Boston, USA, <sup>4</sup>Department of Endocrinology and Metabolism, Section of Diabetes, University of Pisa, Italy, <sup>5</sup>Boehringer Ingelheim Pharmaceuticals, Inc., Ridgefield, USA, <sup>6</sup>Boehringer Ingelheim Ltd, Bracknell, UK, <sup>7</sup>Boehringer Ingelheim Pharma GmbH & Co. KG, Ingelheim, Germany.

**Background and aims:** Newly diagnosed type 2 diabetes (T2D) patients commonly present with marked hyperglycaemia. This condition has rarely been studied for novel oral diabetes drugs and insulin is often proposed as the preferred starting therapy.

**Materials and methods:** We explored oral glucose-lowering combination therapy in newly diagnosed ( $\leq 12$  months) T2D patients with marked hyperglycaemia ( $n=316$ ) utilising prespecified exploratory subgroup analyses from a randomised double-blind study of initial combination of linagliptin+metformin versus linagliptin. Baseline mean $\pm$ SD age and HbA1c was 48.8 $\pm$ 11.0 years and 9.8 $\pm$ 1.1%, respectively. The primary endpoint was HbA1c change from baseline to week 24.

**Results:** Mean $\pm$ SE HbA1c reduction was -3.4 $\pm$ 0.2% versus -2.5 $\pm$ 0.2% with linagliptin+metformin and linagliptin, respectively, in patients with baseline HbA1c  $\geq 9.5\%$ , and -2.1 $\pm$ 0.2% versus -1.4 $\pm$ 0.2% in patients with baseline HbA1c  $< 9.5\%$ . Similar HbA1c reductions occurred in all subgroups of age, body-mass index (BMI), renal function, race, and ethnicity (table). Hypoglycaemia was rare (1.9% and 3.2% of patients, respectively) with no severe episodes.

**Conclusion:** In our analysis of newly diagnosed T2D patients presenting with marked hyperglycaemia, initial linagliptin+metformin elicited consistent HbA1c reductions across different subgroups. Oral glucose-lowering combination therapy may be a viable initial alternative to insulin for effective treatment of these patients.

| Table. Adjusted* mean HbA1c (%) change from baseline at week 24 (per protocol completers cohort**, last observation carried forward; n=245) |  |                |                     |                |  |            |

#### Vildagliptin versus insulin as add-on therapy to glimepiride in type 2 diabetes mellitus: results from a randomised controlled trial

H.-J. Strotmann<sup>1</sup>, D. Goetze<sup>2</sup>, C. Koch<sup>3</sup>, T. Forst<sup>4</sup>;

<sup>1</sup>Hausarztpraxis, Neubukow, Germany, <sup>2</sup>Internistische Facharztpraxis, Magdeburg, Germany, <sup>3</sup>Novartis Pharma GmbH, Nuernberg, Germany, <sup>4</sup>Profil Mainz GmbH & Co. KG, Germany.

**Background and aims:** The study was designed to compare the effects of the dipetidyl-peptidase 4 (DPP-4) inhibitor vildagliptin and insulin, in addition to glimepiride, in patients with type 2 diabetes mellitus (T2DM) who do not receive metformin.

**Materials and methods:** This was a multicenter, randomized, parallel-group controlled study to evaluate the occurrence of hypoglycemic events (HE) and treatment success on treatment with vildagliptin vs. NPH insulin, each in addition to background therapy with glimepiride. T2DM patients with intolerance or contraindications to metformin therapy, and who did not have adequate glycemic control on their previous sulfonylurea monotherapy, were eligible for inclusion. Vildagliptin 50 mg once daily was compared in an open-label design with NPH insulin once daily, in an individually titrated dose, over 24 weeks. Primary efficacy endpoints were a combination of HbA1c target  $< 7.0\%$  without HE ( $< 3.9$  mmol/L) and bodyweight gain ( $> 3\%$ ), and rate of confirmed HEs. Secondary efficacy variables, amongst others, included assessment of the Treatment Satisfaction Questionnaire for Medication (TSQM-9).

**Results:** 162 patients with T2DM and a mean age of 67.7 (SD 10.8) years were enrolled at 47 centers in Germany (83 patients in the vildagliptin group vs. 79 patients in the insulin group). Mean HbA1c at baseline was 7.6% (SD 0.5; 7.61  $\pm$  0.47% in the vildagliptin group, 7.67  $\pm$  0.52% in the insulin group;  $p=0.510$ ). After 24 weeks, 13.4% in the vildagliptin group and 29.1% in the insulin group had confirmed HEs, while 11.0% of patients in the vildagliptin group and 23.8% in the insulin group experienced a bodyweight gain  $> 3\%$ . 48.8% patients in the vildagliptin group and 60.8% patients in the insulin group achieved the HbA1c target level of  $< 7.0\%$  at Week 24. Overall, the rate of patients fulfilling the combined criteria was similar in the two treatment groups: 35.4% in the vildagliptin group vs. 34.2% in the NPH insulin group achieved an HbA1c level of  $< 7.0\%$  without HEs and bodyweight gain  $> 3\%$  (OR=0.985, 95% CI for OR: [0.507; 1.915],  $p=0.9646$ ). Patients' satisfaction

with medication, assessed as TSQM-9 scores for “convenience”, showed an increase from baseline to week 24 for the vildagliptin group and a decrease in the insulin group ( $9.6 \pm 19.1$  score points vs.  $-5.6 \pm 22.0$  score points;  $p < 0.001$ ). Scores for “effectiveness” and “global satisfaction” increased similarly for both treatment groups.

**Conclusion:** In the treatment of T2DM in patients with insufficient glycaemic control on sulfonylurea monotherapy, addition of vildagliptin or insulin resulted in a similar number of patients reaching target HbA1c without HEs or bodyweight change  $>3\%$ . That more patients achieved the HbA1c target of  $<7.0\%$  with insulin treatment was expected because of individualized dose titration, but was associated with a doubling of confirmed HEs in this group. Vildagliptin was associated with greater convenience and treatment satisfaction scores compared with insulin. In these patients, the addition of vildagliptin to glimepiride could be considered as a treatment option prior to escalation to insulin treatment, with the advantages of a lower HE rate and greater patient convenience.

### Efficacy of vildagliptin and sitagliptin in reducing fasting plasma glucose in type 2 diabetes mellitus: results from a randomised controlled trial

R. Göke<sup>1</sup>, E.D. Dütting<sup>2</sup>;

<sup>1</sup>Diabetologische Schwerpunktpraxis, Marburg,

<sup>2</sup>Novartis Pharma GmbH, Nuremberg, Germany.

**Background and aims:** This study was designed to compare the effects of dipetidyl-peptidase 4 (DPP-4) inhibitors vildagliptin and sitagliptin, in addition to metformin, on fasting plasma glucose (FPG) levels in patients with type 2 diabetes mellitus (T2DM).

**Materials and methods:** This study applied a randomized cross-over, open-label, active-controlled design to assess the FPG-lowering abilities of a single pill combination (SPC) of vildagliptin and metformin (50/1000 mg bid) compared to sitagliptin/metformin SPC (50/1000 mg bid). Patients with type 2 diabetes mellitus (T2DM) insufficiently controlled by stable metformin therapy (1000–2000 mg/day) were included. FPG was assessed twice, after 2 weeks' treatment with either medication: on day 14, and again on day 15 after a missed dose the previous evening.

**Results:** 99 patients with T2DM (35.4% female) and a mean age of 61.2 years (SD 10.1) were enrolled at 15 centers in Germany. Mean HbA1c on screening was 7.5 % (SD 0.68), and mean FPG was 164.3 mg/dL (SD 30.9). After 14 days of treatment, mean FPG was 137.8 mg/dL (SD 28.5) on vildagliptin and 140.1 mg/dL (SD 26.5) on sitagliptin ( $p < 0.05$ , Wilcoxon). Change of FPG from baseline to day 14 was significantly greater under vildagliptin [ $-21.9$  mg/dL (SD 27.0)] as compared to sitagliptin [ $-14.5$  mg/dL (SD 23.0)] ( $p = 0.0196$ , Wilcoxon). After a missed evening dose, FPG increased slightly at day 15 in both treatment groups, with a greater increase on vildagliptin than sitagliptin treatment [day 15 FPG: 147.6 mg/dL (SD 29.2) vs. 143.4 mg/dL (SD 27.9), respectively;  $p = 0.0473$ , Wilcoxon]. Adverse events were infrequent, and were mainly of mild or moderate intensity in both treatment groups.

**Conclusion:** Both DPP-4 inhibitors, given as SPC with metformin bid, lowered FPG after 14 days of treatment. Vildagliptin produced a significantly greater reduction in FPG versus baseline compared with sitagliptin, and this may have clinical relevance.

### Improvement in postprandial glucose after 2-year treatment with alogliptin in patients with type 2 diabetes inadequately controlled with metformin

J. Liu<sup>1</sup>, R. Oh<sup>1</sup>, C. Wilson<sup>1</sup>, R. Camisasca<sup>2</sup>;

<sup>1</sup>Takeda Development Center Americas, Inc., Deerfield, USA,

<sup>2</sup>Takeda Development Centre Europe, London, UK.

**Background and aims:** Increased postprandial glucose (PPG) contributes to hyperglycemia in patients with type 2 diabetes (T2D), and may be associated with an increased risk of cardiovascular disease. Alogliptin (ALO) is an oral anti-diabetic agent that improves glycaemic control by enhancing the incretin system in patients with T2D. Based on its mechanism of action, ALO may have a significant impact on PPG. The impact on PPG by ALO has only

been demonstrated in a short-term (16-week) study. In a sub-population of a large 2-year, multicenter, double-blind, randomized clinical trial examining the durability of glycaemic control of ALO compared to glipizide (GLIP), the long-term reduction in PPG by ALO was examined.

**Materials and methods:** A total of 2639 patients with T2D inadequately controlled by metformin alone were randomized to ALO 12.5mg (A12.5), ALO 25mg (A25) or GLIP (5mg titrating to 20mg) treatment groups. The primary endpoint was HbA1c reduction from baseline (BL) at 52 and 104 weeks. In study centers capable of measuring PPG, 2-hour PPG was measured after a standardized meal at BL, week 12, 26, 52, and 104 visits.

**Results:** A total of 1418 subjects had a BL PPG measurement. Mean 2-hour PPG levels were similar among treatment groups at BL: 207.5 mg/dL, 203.2 mg/dL, and 197.3 mg/dL in the A12.5 ( $n=470$ ), A25 ( $n=492$ ), and glipizide ( $n=456$ ) groups, respectively. Reduction of PPG occurred in all 3 groups at week 12 and lasted through week 104. At week 104, the LS mean reductions from BL in 2-hour PPG levels were significantly greater with A12.5 ( $n=230$ ,  $-12.9$  mg/dL;  $p=0.014$ ) and A25 ( $n=257$ ,  $-11.4$  mg/dL;  $p=0.027$ ) when compared with GLIP ( $n=214$ ,  $0.9$  mg/dL). The 2-hour PPG excursion was determined by the 120-min glucose value minus the 0-min glucose value at that visit. At week 104, the LS mean changes from BL in PPG excursions were 6.4 and  $-6.8$  mg/dL in the A12.5 and A25 treatment groups, respectively, vs 2.8 mg/dL in the GLIP treatment group; no statistically significant treatment-group differences were observed.

**Conclusion:** In this study, ALO reduced PPG over the 2-year treatment period, and this reduction appears to be more sustainable with ALO than that with GLIP.

### Assessing time to insulin use among type 2 diabetes patients treated with sitagliptin or sulfonylurea plus metformin dual therapy

S.E. Inzucchi<sup>1</sup>, Y. Qiu<sup>2</sup>, S. Rajpathak<sup>2</sup>, K.G. Brodovicz<sup>2</sup>, S.S. Engel<sup>2</sup>,

P. Mavros<sup>2</sup>, L. Radican<sup>2</sup>, P. Brudi<sup>2</sup>, K. Tunceli<sup>2</sup>, C.-P.S. Fan<sup>3</sup>, Z. Li<sup>3</sup>, J. Tang<sup>3</sup>, L. Blonde<sup>4</sup>;

<sup>1</sup>Yale University School of Medicine, New Haven, <sup>2</sup>Merck Sharp & Dohme Corp, Whitehouse Station, <sup>3</sup>Asclepius/JT LLC, New York, <sup>4</sup>Ochsner Medical Center, New Orleans, USA.

**Background and aims:** In type 2 diabetes mellitus (T2DM), decline of  $\beta$ -cell function over time leads to the need for treatment intensification and eventually initiation of insulin therapy in many patients (pts). Sitagliptin (SITA) and sulfonylureas (SU) are commonly prescribed after metformin as dual therapy in T2DM. This study assessed the time to insulin initiation among pts treated with MET+SITA in comparison to those treated with MET+SU.

**Materials and methods:** This retrospective cohort study used a sample from the GE Centricity database. Included were pts with T2DM,  $\geq 18$  years (yrs), with continuous medical records. Index was the date of the 1st prescription of SITA or SU used as dual therapy with metformin for  $\geq 90$  days in 2006–13. SITA and SU users were matched 1:1 using propensity score (PSM). Differences in time to insulin use (from index date) between SITA and SU users were assessed using Kaplan-Meier (KM) curves and Cox regression. Conditional logistic regression (CLR) examined the likelihood of insulin use in each of yrs 1–5 post index. Adjustments were made for baseline characteristics. Subgroup analyses for baseline A1C  $< 9\%$  or  $\geq 9\%$  were then conducted.

**Results:** PSM produced 3,862 matched pairs. The percent of pts progressing to insulin by yrs 1–6 were 3.6, 8.4, 12.9, 17.7, 22.4, 26.6 for SITA and 4.1, 9.4, 14.6, 21.0, 27.1, 34.1 for SU users, respectively. KM curves for SITA and SU users were significantly different ( $p=0.0034$ ) indicating that SITA users progressed more slowly to insulin initiation than SU users. This remained significant after adjusting for baseline characteristics (HR: 0.76, 95% CI: [0.464, 0.897]). CLR analyses confirmed the robustness of the results (ORs: 0.77; 0.79; 0.81; 0.57; 0.29; for yrs 1–5 respectively,  $p < .05$  for Yr 4 and Yr 5). The SITA vs. SU comparison in pts with baseline A1C  $< 9\%$  and  $\geq 9\%$  produced hazard ratios of: 0.77, 95% CI: [0.621, 0.945], and 0.75, 95% CI: [0.490, 1.145], respectively.

**Conclusion:** In this matched cohort study, pts with T2DM who started with MET+SITA dual therapy progressed to insulin therapy at a slower rate than those who started with MET+SU dual therapy.

### Combination with linagliptin improves the tolerability of metformin in type 2 diabetic patients previously labelled as intolerant to metformin

G. Gusmão, M. Moureira, F. Sosa;

Endocrinologia, Hospital Santa Helena, Jequié - Bahia, Brazil.

**Background and aims:** Metformin is the first-line drug for the treatment of type 2 diabetes but gastrointestinal intolerance to it is frequent. We sought to determine if patients withdrawn from metformin treatment due to intolerance would be able to tolerate it when rechallenged, and if the addition of linagliptin would improve the probability of tolerating metformin.

**Materials and methods:** From the clinical records of our Diabetes Clinic, we identified type 2 diabetic patients aged 30 to 80 with HbA1c > 7% who had withdrawn from metformin due to gastrointestinal intolerance but had presented no serious adverse effects and had no significant renal insufficiency or other contraindications for metformin use, were not taking incretin-based therapy and were possible candidates for treatment with metformin and/or linagliptin. After at least 6 months from withdrawal, they were randomised to treatment with metformin alone (500 mg twice daily for 2 weeks, then 1000 mg twice daily for 10 additional weeks if the previous dose was tolerated), or with metformin (same pattern) plus linagliptin 5 mg daily, in an open fashion. Tolerance was assessed at weeks 2 and 12 by questionnaire performed by personnel blinded to the treatment status. Fasting glucose and HbA1c were measured at baseline and 12 weeks

**Results:** We found 84 consecutive patients who were offered to participate. 25 declined, 30 received metformin plus linagliptin (ML) and 29 metformin alone (M). Their age was  $63.2 \pm 7.6$  years, 56% were female; at baseline their fasting plasma glucose (FPG) was  $9.2 \pm 1.6$  mmol/l and their HbA1c was  $8.2 \pm 0.9\%$ . There were no significant differences between the groups for any of these variables. In the M group, 8 patients (28%) tolerated the low-dose and 5 (17%) the full-dose metformin (odds/ratio 3.94; 95% CI 1.32–11.76,  $p=0.014$ ). In the ML group, 18 patients (60%) tolerated the low-dose and 14 (47%) the full-dose metformin (odds/ratio 4.20; 95% CI 1.26–13.96,  $p=0.019$ ). By intention to treat, at week 12 the FPG in the M group was reduced by  $1.1 \pm 0.5$  mmol/l and HbA1c was reduced by  $0.2 \pm 0.1\%$ . In the ML group FPG was reduced by  $2.7 \pm 1.2$  mmol/l and HbA1c was reduced by  $0.9 \pm 0.3\%$  (both  $p < 0.001$  between groups, non-paired t-test). By protocol (patients that tolerated at least low-dose metformin), at week 12 the FPG in the M group was reduced by  $2.5 \pm 0.9$  mmol/l and HbA1c was reduced by  $0.5 \pm 0.2\%$ . In the ML group FPG was reduced by  $3.2 \pm 1.3$  mmol/l ( $p=0.020$ ) and HbA1c was reduced by  $1.1 \pm 0.4\%$  ( $p < 0.001$ ). Apart from minor gastrointestinal disturbances, the patients did not report any side effects that could be attributed to the studied drugs.

**Conclusion:** A significant proportion of patients labelled as intolerant to metformin could be successfully rechallenged with it, although only a fraction of them tolerated the full-dose treatment. The addition of linagliptin improved very significantly the probability of a successful rechallenge with metformin, resulting in a clear improvement in glycemic control, without additional tolerability issues.

### Real life effectiveness and safety of vildagliptin compared with other OADs in European type 2 diabetes mellitus patients: results from the EDGE study

P.M. Nilsson<sup>1</sup>, H. Brath<sup>2</sup>, A. Penforinis<sup>3</sup>, J.J. de Castro<sup>4</sup>, I. Conget<sup>5</sup>, R. Göke<sup>6</sup>, E. Pagkalos<sup>7</sup>, N.C. Schaper<sup>8</sup>, P. Geransar<sup>9</sup>, G. Bader<sup>10</sup>, P.M. Paldánus<sup>10</sup>, A.H. Barnett<sup>11</sup>, C. Mathieu<sup>12</sup>;

<sup>1</sup>Skåne University Hospital, Malmö, Sweden, <sup>2</sup>Health Center South, Vienna, Austria, <sup>3</sup>Jean Minjoz Hospital, Besançon, France, <sup>4</sup>Armed Forces University Hospital, Lisboa, Portugal, <sup>5</sup>Hospital Clinic i Universitari, Barcelona, Spain, <sup>6</sup>University of Marburg, Germany, <sup>7</sup>Private Hospital "Thermi", Kalamaria Thessaloniki, Greece, <sup>8</sup>University Hospital Maastricht, Netherlands, <sup>9</sup>Novartis Pharmaceuticals UK Ltd, Frimley/Camberley, UK, <sup>10</sup>Novartis Pharma AG, Basel, Switzerland, <sup>11</sup>Heart of England NHS Foundation Trust and University of Birmingham, UK, <sup>12</sup>Catholic University of Leuven, Belgium.

**Background and aims:** Stepwise treatment intensification is necessary in type 2 diabetes mellitus (T2DM) due to progressive loss of  $\beta$ -cell function. European societies (ESC/EASD) provide algorithms for improving glycaemic and risk factor control with a holistic approach in the management of T2DM and cardiovascular disease; HbA1c goal of  $\leq 7\%$ , avoiding hypoglycaemia and individualising therapy and glycaemic targets. The purpose of the observational EDGE study was to prospectively evaluate the effectiveness and safety of vildagliptin vs other oral antidiabetes drugs (OADs) in T2DM patients inadequately controlled with monotherapy. Here, we present the post-hoc analysis results for the 12 participating European countries.

**Materials and methods:** Patients receiving physician-prescribed add-on OAD treatment were assigned to: (i) vildagliptin or (ii) other OADs (except other incretin-based therapies). The primary composite endpoint was the proportion of patients with HbA1c drop  $>0.3\%$ , without peripheral oedema, hypoglycaemia, discontinuation due to a gastrointestinal event or weight gain  $\geq 5\%$  at 1 year. A secondary composite endpoint was attainment of HbA1c  $<7.0\%$  at 1 year without hypoglycaemia or weight gain  $\geq 3\%$ .

**Results:** In Europe, 23038 patients receiving mostly metformin monotherapy were enrolled (total intention to treat: 22073; vildagliptin: 15582; other OADs: 6491). The mean baseline HbA1c was  $7.9 \pm 1.3\%$ , mean T2DM duration was  $6.3 \pm 5.6$  years and 52.0% were male. Prevalence of risk factors such as hypertension (68.5%) and lipid disorders (50.0%) was high. Micro- and macrovascular complications were present in 9.6% and 18.4% of patients. Reflecting real life setting, there was heterogeneity in patient characteristics among different countries and imbalances between treatment cohorts. Patients in the vildagliptin cohort were younger at baseline ( $61.8 \pm 11.0$  years vs  $63.4 \pm 10.5$  years) with slightly higher BMI ( $30.5 \pm 5.3$  vs  $29.9 \pm 4.9$ ) while the cohorts had comparable mean baseline HbA1c ( $7.9 \pm 1.3\%$  vs  $7.8 \pm 1.2\%$ ). Both the primary (49.3% vs 46.5%; OR 1.11, 95% CI: 1.05; 1.18;  $p < 0.001$ ) and secondary (34.6% vs 28.5%; OR 1.32, 95% CI: 1.23; 1.42;  $p < 0.001$ ) composite endpoints were reached more often in patients receiving vildagliptin than other OADs. Between-country variability was substantial for both endpoints. The percentage of patients reporting adverse events was low and similar, 5.8% in each cohort. Also hypoglycaemia rates were low, 0.2% for vildagliptin vs 0.8% for other OADs.

**Conclusion:** In addition to confirming the real world effectiveness and safety of vildagliptin, EDGE highlights the sustained need for improvement in adherence to Europe-specific guidelines (ESC/EASD) for optimised management of glycaemic targets.

**Duration of maintenance of dual therapy with metformin and sitagliptin in type 2 diabetes: the Odyssee observational study**

P. Valensi<sup>1</sup>, G. De Pourville<sup>2</sup>, N. Benard<sup>3</sup>, C. Chanut-Vogel<sup>3</sup>, C. Kempf<sup>4</sup>, C. Moisan<sup>3</sup>, J. Dallongeville<sup>5</sup>;

<sup>1</sup>Department of Endocrinology Diabetology Nutrition-Jean Verdier Hospital, CRNH-IdF, CINFO, Bondy, <sup>2</sup>ESSEC, Paris, <sup>3</sup>MSD, Courbevoie, <sup>4</sup>CSD, PARIS, <sup>5</sup>Institut Pasteur, Lille, France.

**Background and aims:** Sulfonylurea and DPP-4 inhibitors are usually prescribed for T2DM patients in combination with metformin. Odyssee, a prospective, real-world, observational study conducted in France in primary care practices, compared the duration of maintenance of treatment without modification (withdrawal, substitution, or add-on therapy) in T2DM patients in whom dual therapy with metformin + sitagliptin (MetSita) or metformin + sulfonylurea (MetSu) was initiated.

**Materials and methods:** Odyssee was a multicenter, longitudinal study. It was conducted in a randomly selected sample of general practitioners in France. Patients were not randomized and were followed for a period of up to three years. Treatments were prescribed at the discretion of the physician. Physicians were expected to include all patients who met the eligibility criteria: Adult (aged ≥18 years) patients with type 2 diabetes who had initiated a de novo treatment with metformin and sitagliptin dual therapy or metformin and sulfonylurea dual therapy within the previous eight weeks were eligible for the study. Patient follow-up and changes to treatment were performed according to the physician's clinical practice and were not specified in the study protocol.

**Results:** At baseline, differences between the two arms (MetSita [n = 1874] and MetSu [n = 733]) were modest (mean age: 62.4 vs 64.2 years, BMI: 30.3 vs 29.6 kg/m<sup>2</sup>, diabetes duration: 6.4 vs 7 years, respectively). Mean HbA1c levels were similar (7.5 vs 7.6%). The median treatment duration for patients in the MetSita group was longer than the MetSu group (median treatment duration 43.2 vs 20.2 months, respectively; between-group difference 23 months, log-rank p <0.0001). This difference persisted after adjustment for baseline differences and confounders using propensity score methods and application of maximum bias statistical methodology for missing data (42.4 vs 20.2 months). A similar reduction in HbA1c was noted in both arms (-0.6%) and the incidence of hypoglycemia (prior to treatment modification) was lower in the MetSita arm than the MetSu arm (9.7% vs 21.0%). 130 (6.9%) and 58 (7.9%) patients presented a total of 159 and 79 (AEs) during follow-up in the MetSita and MetSU group, respectively. According to the investigating physicians, 60 AEs potentially related to treatment occurred in 52 (2.8%) patients in the MetSita group, and 24 AEs potentially related to treatment occurred in 20 (2.7%) patients in the MetSU group.

**Conclusion:** Conducted under real-life conditions, the Odyssee study showed that combined therapy with MetSita is maintained without treatment modification longer than combined therapy with MetSu. In addition, the study showed that the glycemic effect is similar, with a lower incidence of symptomatic hypoglycemia, with MetSita compared to MetSu.

**Figure 1:** Maintenance duration for dual therapy initiated at inclusion for patients receiving metformin + sitagliptin or metformin + sulfonylurea

**Efficacy and safety of a fixed-dose combination of vildagliptin and metformin (LMF237) in Japanese patients with type 2 diabetes**

M. Yoshiki<sup>1</sup>, M. Odawara<sup>2</sup>, M. Sano<sup>1</sup>, I. Hamada<sup>1</sup>, V. Lukashevich<sup>3</sup>, W. Kothny<sup>4</sup>;

<sup>1</sup>Novartis Pharma KK, Tokyo, <sup>2</sup>Tokyo Medical University, Japan, <sup>3</sup>Novartis Pharmaceuticals Corporation, East Hanover, USA, <sup>4</sup>Novartis Pharma AG, Basel, Switzerland.

**Background and aims:** The use of DPP-4 inhibitor and metformin combination therapy has been increasing in Japanese patients with type 2 diabetes mellitus (T2DM), but no single-pill combination (SPC) of a DPP-4 inhibitor and metformin is currently available in Japan. This clinical study aimed to evaluate the efficacy and safety of an SPC of vildagliptin and metformin (LMF237), in Japanese patients with T2DM inadequately treated with vildagliptin monotherapy. There is limited data assessing the benefit of adding metformin at the doses used in Japan to a DPP-4 inhibitor.

**Materials and methods:** In a 14-week, multicenter, randomized, double-blind, parallel-group, placebo-controlled study, 171 patients with T2DM were randomized to LMF237 bid (N=115) or placebo (vildagliptin monotherapy) (N=56) in a ratio of 2:1. In addition, patients in the LMF237 group were further randomized to receive either LMF237 (vildagliptin/metformin) 50/250 mg bid (N=56) or 50/500 mg bid (N=59) in a 1:1 ratio. The primary efficacy variable included change from baseline to endpoint (Week 14 or final study visit) in HbA1c. The incidence of adverse events (AEs) during the treatment period was also assessed.

**Results:** Treatment groups were well-balanced for baseline demographic and background characteristics. Patients had a mean age of 57.0 years (73.1% were <65 years old) and a mean T2DM duration of 7.0 years. A higher percentage of male patients (71.3%) was randomized compared to female patients (28.7%). Mean baseline values of HbA1c, FPG and BMI were 7.9%, 158.7 mg/dL and 25.8 kg/m<sup>2</sup>, respectively. The change in mean HbA1c was -0.83% in the LMF237 group (both doses combined) and 0.14% in the placebo group. The between-group difference in HbA1c change (LMF237 - placebo) of -0.98% was clinically relevant and statistically significant (p<0.001) (Table). In addition, clinically and statistically significant reductions in HbA1c from baseline to endpoint were observed for the subgroups of patients receiving LMF237 50/250 mg bid or 50/500 mg bid (-0.61% and -1.04%, respectively; both p<0.001). The overall incidences of AEs were 43.5% in the LMF237 (both doses combined) and 67.9% in the placebo. In the LMF237 subgroups, the incidence of AEs was similar (44.6% in 50/250 mg bid and 42.4% in 50/500 mg bid). The incidences of serious AEs were low in both treatment groups (0.9% vs 3.6%, respectively). No deaths or hypoglycemic AEs were reported in either group.

**Conclusion:** Treatment with LMF237 (vildagliptin + metformin SPC) demonstrated a significantly greater reduction in HbA1c compared to placebo (vildagliptin monotherapy), without an increase in hypoglycemia incidence, and was well-tolerated in Japanese patients with T2DM inadequately controlled with vildagliptin alone. Thus, LMF237 is an attractive treatment option for Japanese patients with T2DM.

Table. ANCOVA results for change in HbA1c (NGSP, %) from baseline to endpoint by treatment (FAS)

| Treatment | n   | Baseline mean (SE) | Adjusted mean change (SE) | Difference in adjusted mean change (LMF - placebo) |                |         |
|-----------|-----|--------------------|---------------------------|--|----------------|---------|
|           |     |                    |                           | mean (SE)  | (95% CI)       | p value |
| LMF237    | 115 | 7.91 (0.08)        | -0.83 (0.06)              |  |                |         |
| Placebo   | 56  | 7.97 (0.11)        | 0.14 (0.08)               | -0.98 (0.10)                                       | (-1.17, -0.79) | <0.001  |

#### Liraglutide 3.0 mg reduces body weight and improves cardiometabolic risk factors in overweight/obese adults: the SCALE obesity and prediabetes randomised trial

M. Krempf<sup>1</sup>, A. Astrup<sup>2</sup>, C. le Roux<sup>3</sup>, K. Fujioka<sup>4</sup>, F. Greenway<sup>5</sup>, A. Halpern<sup>6</sup>, D.C.W. Lau<sup>7</sup>, R. Violante Ortiz<sup>8</sup>, J.P.H. Wilding<sup>9</sup>, C.B. Jensen<sup>10</sup>, S.K. Lilleore<sup>10</sup>, X. Pi-Sunyer<sup>11</sup>;

<sup>1</sup>Clinique d'endocrinologie, CHRU Nantes, France,

<sup>2</sup>University of Copenhagen, Denmark, <sup>3</sup>University College Dublin, Ireland,

<sup>4</sup>Scripps Clinic, La Jolla, <sup>5</sup>Louisiana State University, Baton Rouge, USA,

<sup>6</sup>University of São Paulo Medical School, Brazil, <sup>7</sup>University of Calgary,

Canada, <sup>8</sup>Instituto Mexicano del Seguro Social, Ciudad Madero, Mexico,

<sup>9</sup>University of Liverpool, UK, <sup>10</sup>Novo Nordisk A/S, Søborg, Denmark,

<sup>11</sup>Columbia University, New York, USA.

**Background and aims:** A 5–10% weight loss has been shown to improve the multiple cardiometabolic comorbidities associated with chronic obesity. This phase 3 trial investigated the effects of liraglutide 3.0 mg, as adjunct to diet and exercise, on weight loss (primary endpoint) and cardiometabolic risk factors (waist circumference, BP, lipids and other biomarkers).

**Materials and methods:** Individuals (BMI  $\geq 27$  kg/m<sup>2</sup> with  $\geq 1$  comorbidity or  $\geq 30$  kg/m<sup>2</sup>) were advised on a 500 kcal/day deficit diet and exercise programme and randomised 2:1 to once-daily s.c. liraglutide 3.0 mg (n=2487) or placebo (n=1244). Randomisation was stratified by prediabetes status (ADA 2010 criteria) and BMI. Data are shown for the full analysis set (exposed individuals with  $\geq 1$  post-baseline assessment) with LOCF. The trial has an ongoing 2-year extension for participants with prediabetes.

**Results:** Baseline characteristics were: age 45.1 years, 78.5% female, body weight 106.2 kg, BMI 38.3 kg/m<sup>2</sup>, 61.2% with prediabetes. At week 56, individuals on liraglutide 3.0 mg achieved more weight loss (8.0%) than those on placebo (2.6%) (estimated treatment difference [ETD] -5.4% [95% CI 5.8; -5.0];  $p < 0.0001$ ) (Table). Weight loss was accompanied by reductions in waist circumference (ETD 4.2 [-4.7; -3.7] cm), systolic BP (ETD -2.8 [3.6; -2.1] mmHg) and diastolic BP (ETD 0.9 [-1.4; -0.4] mmHg) for liraglutide vs placebo (all  $p < 0.001$ ). Mean pulse was increased at week 56 with liraglutide 3.0 mg vs placebo (ETD 2.4 [1.9; 3.0] bpm,  $p < 0.0001$ ). Improvements in all fasting lipids were seen with liraglutide 3.0 mg vs placebo. Improvements in hsCRP (% relative difference -30% [34; 26]), PAI-1 (-21% [-26; -17]) and adiponectin (+8% [5; 12]) (all  $p < 0.0001$ ) were also observed with liraglutide 3.0 mg vs placebo. Liraglutide 3.0 mg reduced net use of anti-hypertensive (OR 1.7,  $p < 0.0001$ ) and lipid-lowering (OR 1.5,  $p = 0.02$ ) medications at week 56 vs placebo, while maintaining greater beneficial effects on BP and lipids.

**Conclusion:** Weight loss with liraglutide 3.0 mg, as adjunct to diet and exercise, produced improvements in a wide range of cardiometabolic risk factors, including inflammatory markers, in overweight or obese individuals, which if sustained in the long term may be associated with reduced cardiovascular events.

**Table.** Effects of liraglutide 3.0 mg on cardiometabolic risk factors after 56 weeks of treatment

<sup>9</sup>Instituto Mexicano del Seguro Social, Ciudad Madero, Mexico, <sup>10</sup>Novo

Nordisk A/S, Søborg, Denmark, <sup>11</sup>Columbia University, New York, USA.

**Background and aims:** Obesity is associated with prediabetes, which is a high risk factor for development of T2D. This trial investigated the effects of liraglutide 3.0 mg, as adjunct to diet and exercise, on weight loss (co-primary endpoints: mean change in body weight [BW] and proportions of individuals losing  $\geq 5\%$  and  $> 10\%$  of BW), safety and tolerability in overweight and obese adults without T2D over 56 weeks.

**Materials and methods:** Individuals (BMI  $\geq 27$  kg/m<sup>2</sup> with  $\geq 1$  comorbidity or  $\geq 30$  kg/m<sup>2</sup>) were advised on a 500 kcal/day deficit diet and exercise programme and randomised 2:1 to once daily sc liraglutide 3.0 mg (n=2487) or placebo (n=1244). Randomisation was stratified by prediabetes status (ADA 2010 criteria) and BMI. Data are shown for FAS (exposed individuals with  $\geq 1$  post-baseline assessment) with LOCF.

**Results:** Baseline characteristics: age 45.1  $\pm$  12.0 years, 78.5% female, BW 106.2  $\pm$  21.4 kg, BMI 38.3 kg/m<sup>2</sup>, 61.2% with prediabetes) completed 56 weeks (71.9% on liraglutide 3.0 mg; 64.4% on placebo). At week 56, individuals on liraglutide 3.0 mg had lost 8.0% (8.4 kg) of BW vs 2.6% (2.8 kg) on placebo (estimated treatment difference [ETD] -5.4% [5.6 kg],  $p < 0.0001$ , ANCOVA) (Fig). Proportion of individuals achieving a BW loss  $\geq 5\%$  was 64% with liraglutide 3.0 mg and 27% with placebo (estimated OR 4.8,  $p < 0.0001$ , logistic regression). The proportion achieving BW loss  $> 10\%$  was 33% and 10%, respectively (OR 4.3,  $p < 0.0001$ ). BW loss was independent of prediabetes status at screening (Fig). Consistent with BW loss, liraglutide 3.0 mg also reduced waist circumference (ETD -4.2 cm) and BMI (-2.0 kg/m<sup>2</sup>) (both  $p < 0.0001$  vs placebo, ANCOVA), and improved glycaemia, blood pressure and lipids (not shown). The most common AEs with liraglutide 3.0 mg were nausea and diarrhoea, with onset in week 1–4. Most events were mild/moderate and transient. AE withdrawal was 9.9% with liraglutide 3.0 mg (mostly due to gastrointestinal AEs) and 3.8% with placebo. The incidences of gallbladder disorders and pancreatitis were low, although events were reported more frequently with liraglutide 3.0 mg (2.7 and 0.3 events/100 patient years of exposure [PYE], respectively) than with placebo (1.1 and 0.1 events/100 PYE, respectively). Two individuals (1 in each group) co-reported gallbladder-related AEs and pancreatitis.

**Conclusion:** Liraglutide 3.0 mg, as adjunct to diet and exercise, was superior to placebo on all co-primary endpoints and generally well tolerated.

### Liraglutide improves carotid intima-media thickness in patients with type 2 diabetes and non-alcoholic fatty liver disease: an 8-month prospective pilot study

R.V. Giglio, M. Rizzo, A.M. Patti, D. Nikolic, V. Di Bartolo, G. Castellino, G. Pecoraro, C. Rinaudo, F. Emanuele, A. Bonfiglio, M. Soresi, G. Montalto; Biomedical Department of Internal Medicine and Medical Specialties, University of Palermo, Italy.

**Background and aims:** It has been shown in the last years that GLP-1 analogues, such as liraglutide, have several anti-atherogenic properties beyond their effects on glucose metabolism, including that on subclinical atherosclerosis. Yet, the effects of liraglutide in subjects with non-alcoholic fatty liver disease (NAFLD) are largely unknown.

**Materials and methods:** We included in a 8-month prospective study 29 subjects with type-2 diabetes and NAFLD (16 men and 13 women, mean age:  $61 \pm 10$  years), who were matched for age and gender with another group of 29 subjects with type-2 diabetes (T2DM) but without NAFLD (16 men and 13 women, mean age:  $61 \pm 8$  years). The diagnosis of NAFLD was based on ultrasonographic and biochemical data. All subjects were naïve to incretin-based therapies and treated with metformin only. Liraglutide was given, on top of metformin, at a dosage of 0.6 mg/day for two weeks, followed by a dose of 1.2 mg/day for the rest of the study. At baseline and every 4 months fasting plasma samples were taken for laboratory analyses and carotid-intima media thickness (IMT) was assessed by B-mode real-time ultrasound. Statistical analysis was performed by ANOVA and the Spearman correlation method.

**Results:** From baseline to 4 months and 8 months of liraglutide therapy we found significant reductions in HbA1c in both groups of patients (from  $8.9 \pm 1.5$  to  $6.6 \pm 1.2$  to  $6.5 \pm 1.1\%$  in subjects with T2DM and NAFLD, and from  $8.7 \pm 0.6$  to  $7.1 \pm 1.1$  to  $6.9 \pm 0.9\%$  in subjects with T2DM only,  $p < 0.0001$  for both groups). By contrast, no significant changes were found in body weight, waist circumference, body mass index as well as in plasma lipids for both groups of subjects; yet, it should be noted that some differences approached the statistical significance but probably did not reach it because of the small study groups. Carotid IMT significantly decreased only in the group of patients with T2DM and NAFLD (from  $0.96 \pm 0.27$  to  $0.82 \pm 0.17$  to  $0.85 \pm 0.12$  mm,  $p = 0.0325$ ). Correlation analysis revealed that changes in carotid IMT

after 8 months of therapy were not associated with changes in any other evaluated parameter, including fasting glycemia or HbA1c.

**Conclusion:** Liraglutide significantly reduced carotid IMT in patients with T2DM and NAFLD, and this beneficial effect was present beyond glycemic control. Yet, whether these findings may translate into a better cardio-metabolic outcome is still unknown.

**Background and aims:** Transient worsening of diabetic retinopathy (DR) with rapid and significant improvement in glycaemic control with GLP-1 agonist therapy has already been well documented. This phenomenon is more common with longer duration of diabetes and pre-existing DR with an inherent risk of maculopathy. The aim of our study was to assess the incidence and outcomes of diabetic maculopathy with sustained GLP-1 therapy in type 2 diabetes.

**Materials and methods:** A retrospective observational analysis was conducted on all patients who continued on GLP-1 therapy (Exenatide or Liraglutide) beyond 2 years. Retinal screening data at baseline (INITIAL), closest to the lowest HbA1c (INTERIM) and 2 years after initiation (FINAL) were derived from the regional DR screening database. Maculopathy was diagnosed based on referral criteria of UK National screening committee guidelines. HbA1c at baseline, lowest HbA1c achieved on treatment (within the first 12 months) and HbA1c at the latest DR screening were recorded.

**Results:** 125 patients were included in the analysis. Mean of various parameters were: Duration of diabetes 12.4 years (1-32); Baseline HbA1c 83mmol/mol (45-132); reduction in HbA1c at INTERIM phase was  $-19$  mmol/mol (0 to  $-70$ ); duration of follow up 933 days (407-1760); HbA1c at FINAL analysis 73mmol/mol (30-143). 82 patients had HbA1c lesser than or equal to their INITIAL value, mean difference being  $-23$  mmol/mol (0 to  $-68$ ). 72 patients had DR at baseline of whom 49 showing evidence of maculopathy. 3 had resolution of maculopathy at INTERIM study (without Laser) and a further 30 had resolution by the FINAL study (4 of them resolved likely with laser treatment). New onset of maculopathy was noted in 16 patients at INTERIM study. 9 of the 16 patients had no DR at INITIAL study and their duration of diabetes and reduction of HbA1c achieved at INTERIM study was similar to rest of the group. By the FINAL study, maculopathy had spontaneously resolved in 13 of the 16 without any Laser treatment. 9 of the 13 patients had sustained reduction in HbA1c [FINAL HbA1c still being lower than INITIAL HbA1c- mean  $-34$ mmol/mol ( $-3$  to  $-68$ )]

**Conclusion:** Pre-existing maculopathy improves in a significant proportion of patients with improvement in glycaemic control. Worsening of DR with intensification of diabetes control could lead to development of maculopathy but sustained improvement of glycaemic control could potentially reverse this transient complication. Patients with pre-existing DR may be at higher risk of continued progression of maculopathy. The retinal screening programme should have provisions to monitor this paradoxical phenomenon and refer to ophthalmologist if required.

### Patient-reported outcomes with once weekly dulaglutide 1.5 mg versus once daily liraglutide 1.8 mg (AWARD-6)

K.S. Boyle, M. Yu, K. Van Brunt, J.L. Fahrback; Eli Lilly and Company, Indianapolis, USA.

**Background and aims:** Patient-reported outcomes (PRO) were exploratory objectives in AWARD-6, a noninferiority study designed to compare the efficacy and safety of once weekly dulaglutide (DU), a long-acting GLP-1 receptor agonist, to once daily liraglutide (LIRA) in metformin-treated patients with type 2 diabetes.

**Materials and methods:** This was a Phase 3, randomised, open-label, parallel-arm study where 599 patients received once weekly DU 1.5 mg or once daily LIRA 1.8 mg for 26 weeks. PRO measures for health status (EQ-5D), impact of weight-related self-perception (IW-SP), and ability to perform physi-

cal activities of daily living questionnaire (APPADL) were administered at baseline and 26 weeks. Analysis of covariance models were fitted with factors of pooled country, baseline score, HbA<sub>1c</sub> strata ( $\leq 8.5$ ,  $> 8.5$ ) and treatment.

**Results:** DU 1.5 mg was noninferior to LIRA 1.8 mg in HbA<sub>1c</sub> change from baseline. Significant reductions in weight were observed with both DU 1.5 mg and LIRA 1.8 mg (LS mean [SE]: -2.90 [0.22] and -3.61 [0.22] kg, respectively;  $p=0.01$  DU 1.5 mg vs LIRA 1.8 mg). Both groups had significant improvements from baseline in IW-SP, with no between-group differences. Only DU-treated patients had significant improvements from baseline in APPADL ( $p=0.014$ ); between-group differences were not significant. Both groups had significant improvements from baseline in EQ-5D VAS with no between-group differences. In the EQ-5D UK population index score, patients treated with DU 1.5 mg had significant improvements from baseline ( $p=0.031$ ), while there was no significant change with LIRA 1.8 mg and no significant between-group difference.

**Conclusion:** Both once weekly DU 1.5 mg- and once daily LIRA 1.8 mg-treated patients experienced glycaemic and weight benefits. Significant improvements from baseline were observed in all PRO measures for DU 1.5 mg; significant improvements were only observed in the EQ-5D VAS and IW-SP for LIRA 1.8 mg. There were no significant between-group differences observed in any PRO measures.

### Results of the albiglutide HARMONY program prospective major adverse cardiovascular event (MI, stroke, cardiovascular death, and unstable angina) meta-analysis

P.D. Ambery<sup>1</sup>, J. Donaldson<sup>2</sup>, J. Ye<sup>3</sup>, J. McMurray<sup>4</sup>;

<sup>1</sup>MedImmune, Cambridge, <sup>2</sup>GlaxoSmithKline, Uxbridge, UK,

<sup>3</sup>GlaxoSmithKline, Research Triangle Park, USA,

<sup>4</sup>University of Glasgow, UK.

**Background and aims:** In keeping with guidance issued by the FDA in 2008 requiring demonstration of the cardiovascular (CV) safety of new glucose-lowering agents for type 2 diabetes, GSK conducted a meta-analysis of CV events for albiglutide.

**Materials and methods:** Possible CV events were collected prospectively across 1 Phase II and 8 Phase III albiglutide studies for blinded adjudication by an independent Clinical Endpoint Committee. Subjects were randomized to albiglutide or to placebo or active comparators (sitagliptin, insulin lispro, insulin glargine, pioglitazone, liraglutide, and glimepiride). Five of the Phase III studies were up to 3 years in duration. There were 5107 subjects in the safety population of whom 2524 were exposed to albiglutide (4870 person-yrs) and 2583 to comparators (5213 person-yrs).

**Results:** The primary endpoint was the first occurrence of MACE+ (MACE + unstable angina) for albiglutide versus all comparators. MACE (CV death, non-fatal myocardial infarction, or non-fatal stroke) was a pre-defined secondary endpoint. Results are shown in the table.

**Conclusion:** Although the upper bound of the 95% CI for MACE+ events in this prospective adjudicated metaanalysis was below 1.8, because it is above 1.3, a cardiovascular endpoint study is required for albiglutide. No difference was seen in heart failure events or all-cause mortality for albiglutide versus comparators in this meta-analysis.

**Table**

### Safety and efficacy of liraglutide in patients with type 2 diabetes and end-stage renal disease: an investigator-initiated, randomised, placebo-controlled trial

T. Idorn<sup>1</sup>, F.K. Knop<sup>2,3</sup>, M.B. Jørgensen<sup>1</sup>, T. Jensen<sup>4</sup>, M. Resuli<sup>5</sup>, P.M. Hansen<sup>5</sup>, K.B. Christensen<sup>6</sup>, J.J. Holst<sup>3</sup>, M. Hornum<sup>1</sup>, B. Feldt-Rasmussen<sup>1</sup>;

<sup>1</sup>Department of Nephrology, Copenhagen University Hospital, <sup>2</sup>Diabetes Research Division, Department of Internal Medicine, Gentofte Hospital, Hellerup, <sup>3</sup>Department of Biomedical Sciences, The NNF Center for Basic Metabolic Research, Faculty of Health Sciences, University of Copenhagen, <sup>4</sup>Department of Endocrinology, Copenhagen University Hospital, <sup>5</sup>Department of Internal Medicine, Hillerød Hospital, <sup>6</sup>Department of Biostatistics, Institute of Public Health, University of Copenhagen, Denmark.

**Background and aims:** Diabetes is the leading cause of end-stage renal disease (ESRD), however, few antidiabetic agents are available to these patients. We evaluated safety and efficacy of liraglutide treatment in patients with type 2 diabetes (T2D) and dialysis-dependent ESRD.

**Materials and methods:** 24 patients with T2D and ESRD and 23 patients with T2D and normal kidney function (71% and 74% treated with insulin, respectively) were randomly allocated to 12 weeks of double-blinded liraglutide (titrated dose of 0.6 mg, 1.2 mg or 1.8 mg) or placebo treatment (1:1) injected subcutaneously once-daily. 20 participants (1:1) in each group completed the study period. Dose-corrected plasma trough liraglutide concentration was evaluated at the final trial visit as the primary outcome measure. Additional safety and efficacy parameters were assessed.

**Results:** Liraglutide-treated ESRD patients were titrated slower than liraglutide-treated controls, but ended at comparable doses at 12 weeks ( $1.33 \pm 0.13$  and  $1.26 \pm 0.06$  mg/day, respectively;  $p=0.61$ ). Dose-corrected plasma trough liraglutide concentrations at the final trial visit were increased by 49% (confidence interval: 6-109%,  $p=0.02$ ) in liraglutide-treated ESRD patients compared with liraglutide-treated controls (plasma concentrations 11,975 [9,379-15,289] and 8,057 [6,306-10,293] pmol/l/mg, respectively) (see Figure). Nausea and vomiting were more frequent in liraglutide-treated ESRD patients compared with liraglutide-treated controls. Severe adverse events were more frequent in the ESRD group ( $n=7$ , including  $n=6$  during liraglutide treatment) compared with controls ( $n=1$  during placebo treatment), although none were assessed to be related to the trial medication. Glycaemic control was improved in all treatment arms assessed by HbA<sub>1c</sub> and blood glucose measurements, and baseline insulin doses were significantly reduced in both liraglutide-treated groups ( $p < 0.02$ ).

**Conclusion:** Liraglutide treatment appears to be applicable in patients with ESRD and T2D. Slower dose escalation and reduced treatment doses may be advisable.

### Influence of liraglutide treatment in obstructive sleep apnoea in obese type 2 diabetes patients

C. Abreu<sup>1</sup>, F. Gómez-Peralta<sup>1</sup>, J. Castro<sup>1</sup>, E. Alcarria<sup>1</sup>, M. Cruz-Bravo<sup>1</sup>, M. Llorente<sup>1</sup>, C. Albornos<sup>1</sup>, C. Moreno<sup>1</sup>, M. Cepeda<sup>2</sup>, F. Almodóvar<sup>3</sup>;

<sup>1</sup>Unidad de Endocrinología y Nutrición, Hospital General de Segovia,

<sup>2</sup>Servicio de Medicina Interna, Hospital General de Segovia,

<sup>3</sup>Unidad de Endocrinología y Nutrición, Hospital Universitario Fundación Alcorcón, Madrid, Spain.

**Background and aims:** Liraglutide, a long-acting human glucagon-like peptide-1 analogue, is a novel class of type 2 diabetes mellitus (T2DM) treatment that exerts its glucose-lowering effect through different mechanisms that lead to clinically significant reductions in HbA1c and fasting and postprandial glucose levels with moderate weight loss. Concerns about the health impact of obstructive sleep apnoea (OSA) among obese patients with T2DM have been increasing. We aimed to evaluate the impact of liraglutide in the OSA symptoms-somnolence in obese T2DM patients.

**Materials and methods:** This was a retrospective observational, unicentric study conducted in obese (BMI  $\geq 30$  kg/m<sup>2</sup>) T2DM subjects receiving treatment with liraglutide for at least 3 months before study inclusion. Following routine clinical practice, data of the HbA1c, anthropometric measures, blood pressure, and the Epworth Sleepiness Scale (ESS) were collected at the study initiation (V1) and month 3 (V2).

**Results:** A total of 109 subjects were evaluated (mean age, 59.7 $\pm$ 10.9 years; female, 51.4%). Significant differences between V1 and V2 were found in mean values of body weight (106.0 $\pm$ 16.8Kg vs 102.3 $\pm$ 15.8Kg;  $p < 0.001$ ), BMI (40.5 $\pm$ 6.4 kg/m<sup>2</sup> vs 39.0 $\pm$ 5.9 kg/m<sup>2</sup>;  $p < 0.001$ ), waist circumference (124.7 $\pm$ 13.5cm vs 121.4 $\pm$ 12.3cm;  $p < 0.001$ ), HbA1c (8.2  $\pm$  1.7% vs 7.4 $\pm$ 1.6%;  $p < 0.001$ ), glycemia (188.4 $\pm$ 48.7 mg/dL vs 164.6 $\pm$ 44.8 mg/dL;  $p < 0.001$ ), fast glycemia (185.6 $\pm$ 81.6 mg/dL vs 135.4 $\pm$ 30.6 mg/dL;  $p < 0.005$ ), total cholesterol (196.2 $\pm$ 52.7mg/dL vs 173.1 $\pm$ 30.2mg/dL;  $p < 0.05$ ) and ESS (5.7 $\pm$ 4.7 vs 4.2 $\pm$ 3.5;  $p < 0.005$ ). A significant correlation was observed between baseline ESS score and HDL-cholesterol ( $r = -0.248$ ;  $p < 0.05$ ), Tg/HDL ratio ( $r = +0.248$ ;  $p < 0.05$ ), body weight ( $r = -0.215$ ;  $p < 0.05$ ), and BMI ( $r = -0.225$ ;  $p < 0.05$ ).

**Conclusion:** Our findings show that treatment with liraglutide significantly reduced the ESS score in obese T2DM patients. Besides this, an improvement in glycemic control, cholesterol and body weight was also achieved.

### Time course and mechanisms of the antihypertensive and renal effects of liraglutide treatment

B. von Scholten<sup>1</sup>, M. Lajer<sup>1</sup>, J. Goetze<sup>2,3</sup>, F. Persson<sup>1</sup>, P. Rossing<sup>1,4</sup>;

<sup>1</sup>Steno Diabetes Center, Gentofte, <sup>2</sup>Rigshospitalet, Copenhagen,

<sup>3</sup>Aarhus University, <sup>4</sup>University of Copenhagen, Denmark.

**Background and aims:** Glucagon-like peptide-1 receptor agonist studies have revealed clinically significant reductions in systolic blood pressure (SBP). The aim was to investigate the time course of the anti-hypertensive effect of liraglutide treatment and potential mechanisms behind, in patients with type 2 diabetes.

**Materials and methods:** Open-label, single-centre trial; 31 patients with type 2 diabetes and hypertension completed the study. All patients were treated with liraglutide up-escalated to maximum dose of 1.8 mg/d for 7 weeks, followed by a 21-day washout period. The primary outcome was change in 24-hour blood pressure.

**Results:** 24-hour SBP increased by 10 mmHg on day 3 ( $p = 0.008$ ) and 7 mmHg on day 7 ( $p = 0.033$ , 0.6 mg/d). On day 29, (1.8 mg/d), 24-hour SBP was 7 mmHg lower vs. baseline ( $p = 0.106$ ). Following the treatment period (day 49) and after washout (day 70), 24-hour BP was equivalent to baseline. Secondly, extracellular volume (ECV) was reduced by 2.0 L (CI= 1.0-3.1 L,  $p = 0.0005$ ) and midregional-pro-atrial natriuretic peptide (MR-proANP) by 20% (CI= 12%-28%,  $p < 0.0001$ ). In addition, urinary albumin excretion declined 30% (CI=12%-44%,  $p = 0.003$ ), glomerular filtration rate (GFR) by 11 mL/min/1.73m<sup>2</sup> (CI=7.2-14.4 mL/min/1.73m<sup>2</sup>,  $p < 0.0001$ ), and fractional albumin excretion by 29% (CI=3%-48%,  $p = 0.032$ ).

**Conclusion:** Liraglutide treatment was associated with an initial increase in 24-hour SBP, followed by a 7 mmHg reduction after escalation to 1.8 mg/day. This effect subsided after 4 weeks of maximum dose. Reductions in ECV and MR-proANP may explain the antihypertensive potential. Liraglutide treatment was associated with reversible reductions in albuminuria and GFR, which has to be confirmed in randomised blinded trials.

### Continuous exenatide infusion improved perioperative glucose control and reduced glycaemic variability in cardiac surgery patients: the EXECUTIVE trial

M. Haluzik<sup>1</sup>, M. Lips<sup>2</sup>, J. Drapalova<sup>1</sup>, M. Mraz<sup>1</sup>, M. Dobias<sup>3</sup>, P. Kopecky<sup>2</sup>,

J. Lindner<sup>3</sup>, V. Burda<sup>4</sup>, D. Novak<sup>4</sup>, M. Diamant<sup>5</sup>, S. Svacina<sup>1</sup>;

<sup>1</sup>3rd Department of Medicine, Charles University, Prague, Czech Republic,

<sup>2</sup>Department of Anaesthesiology, Resuscitation and Intensive Medicine,

Charles University, Prague, Czech Republic, <sup>3</sup>2nd Surgical Dept. of

Cardiovascular Surgery, Charles University, Prague, Czech Republic,

<sup>4</sup>Department of Cybernetics, Czech Technical University, Prague, Czech

Republic, <sup>5</sup>Diabetes Centre, Vrije Universiteit University Medical Centre,

Amsterdam, Netherlands.

**Background and aims:** Reduction of operation-related hyperglycaemia has been shown to improve postoperative outcomes, though this effect is often blunted by increased number of hypoglycaemic episodes. To intensify perioperative glucose control while minimizing the risk of hypoglycaemia we performed a randomized control trial with the GLP-1 receptor agonist exenatide as add-on to standard perioperative insulin therapy in subjects undergoing elective cardiac surgery.

**Materials and methods:** Thirty eight subjects (63,2% diabetics) with decreased left ventricular systolic function (ejection fraction  $< 50\%$ ) scheduled for elective CABG (coronary artery by-pass grafting) were randomized to receive either exenatide or placebo in a continuous 72-hour i.v. infusion on top of standard perioperative insulin therapy. Parameters of glucose control and glycaemic variability together with indices of cardiac function assessed by transthoracic echocardiography, perioperative hemodynamic parameters, the need of antiarrhythmic treatment and inotropic drug dosage were collected as primary endpoints.

**Results:** Compared to placebo group subjects receiving exenatide showed improved perioperative glucose control (average glycaemia 6.1  $\pm$  2.5 vs. 6.8  $\pm$  2.8 mmol/l,  $p < 0.001$ ; time in target range of 4.5-6.5 mmol/l 55.0  $\pm$  3.4 vs. 38.6  $\pm$  3.3%,  $p = 0.001$ ; time above target range 39.7  $\pm$  3.3 vs. 53.5  $\pm$  3.6%,  $p < 0.01$ ) without an increased risk of hypoglycaemia (2 episodes of hypoglycaemia  $\leq 3.3$  mmol/l in exenatide vs. 4 episodes in placebo group). Exenatide infusion

also reduced glycaemic variability (SD - standard deviation:  $1.4 \pm 0.5$  vs.  $2.0 \pm 0.6$ ,  $p < 0.01$ ; MAGE - mean amplitude of glycaemic excursions:  $2.5 \pm 1.1$  vs.  $3.3 \pm 0.9$ ,  $p < 0.01$ ) and decreased the need of temporary pacing (16.7 vs. 47.4% of subjects,  $p < 0.05$ ), while no significant difference in perioperative hemodynamics, postoperative echocardiographic parameters and inotropic medication dosage was found between the groups.

**Conclusion:** Perioperative administration of i.v. exenatide in subjects undergoing elective CABG improved glucose control and decreased glycaemic variability without increasing the risk of hypoglycaemia. Except of decreased need of temporary pacing, exenatide did not significantly affect parameters of cardiac function.

**GLP-1 reduces the activation of PI3K and MAPK pathways and of oxidative stress induced by Na-arachidonate in platelets**

**C. Barale, L. Mattiello, F. Cavalot, A. Guerrasio, I. Russo;**  
Internal Medicine and Metabolic Disease Unit, Department of Clinical and Biological Sciences, San Luigi Gonzaga Hospital, University of Turin, Orbassano, Italy.

**Background and aims:** Glucagon-like peptide-1 (GLP-1), exerts not only metabolic but also cardiovascular effects: its influence on platelets, however, is largely unknown. We previously showed that GLP-1 increases platelet sensitivity to the anti-aggregating pathway nitric oxide/cGMP/cGMP-dependent protein kinase (PKG). The GLP-1 influence on pro-aggregating pathways has not been investigated so far. Aim of this study is to verify the GLP-1 ability to interplay with arachidonic acid, a precursor of platelet activators which increases reactive oxygen species (ROS) production: in particular, we aimed at investigating whether the native GLP-1 (7-36), the truncated GLP-1(9-36), and the GLP-1 analogue liraglutide influence the arachidonic acid-induced activation of the signalling pathways PI3-Kinase (PI3K) and MAP-Kinase (MAPK) and of oxidative stress in platelets, and whether these putative GLP-1 effects persist when PKG is inhibited.

**Materials and methods:** In washed platelets from 24 healthy subjects (M/F 13/11; age  $25.6 \pm 5.9$  years, body mass index  $22.5 \pm 2.4$  kg/m<sup>2</sup>) we measured the influence of a 15 min pre-incubation with 100nmol/l GLP-1(7-36), or GLP-1(9-36) or liraglutide on the effects of Na-arachidonate (NaA) (0.5 mmol/l) on: i) phosphorylation of Akt and Erk-1/2, molecules of the PI3K and MAPK pathways, respectively (Western Blot); ii) ROS production (DCF-DA assay). Experiments were repeated in the presence of the PKG inhibitor KT5823 (1 micromol/l), the Erk-1/2 inhibitor U0126 (40 micromol/l) and the GLP-1 receptor (GLP-1R) antagonist exendin (9-39) (100 nmol/l).

**Results:** GLP-1 (7-36), GLP-1 (9-36) and liraglutide, similarly reduced platelet signalling induced by NaA. In particular: i) the fold increase on basal values of pAkt with NaA alone, NaA+GLP-1 (7-36), NaA+GLP-1 (9-36) and NaA+liraglutide was  $11.2 \pm 2.1$ ,  $3.1 \pm 0.8$ ,  $2.8 \pm 1.1$ ,  $2.8 \pm 1.3$  respectively ( $p < 0.0001$  vs NaA alone for all), ii) the fold increase on basal values of pErk1/2 with NaA alone, NaA+GLP-1 (7-36), NaA+GLP-1 (9-36) and NaA+liraglutide was  $14.6 \pm 2.5$ ,  $3.9 \pm 1.0$ ,  $3.7 \pm 1.5$ ,  $4.0 \pm 1.9$  respectively ( $p < 0.0001$  vs NaA alone for all); iii) in the presence of the PKG inhibitor KT5823 the inhibition of pAkt and pErk-1/2 exerted by GLP-1 (7-36), GLP-1 (9-36) and liraglutide did not occur ( $p = ns$  vs NaA alone for all); iv) the fold increase on basal values of ROS with NaA alone, NaA+GLP-1 (7-36), NaA+GLP-1 (9-36) and NaA+liraglutide was  $8.2 \pm 1.1$ ,  $5.6 \pm 2.0$ ,  $5.5 \pm 1.1$ ,  $5.5 \pm 1.4$  respectively ( $p = 0.001-0.0005$  vs NaA alone); v) the Erk-1/2 inhibitor U0126 reduced the NaA-induced activation of ROS, its fold increase on basal values with NaA+U0126 being  $4.2 \pm 1.0$  ( $p < 0.0005$  vs NaA alone). Pre-incubation with the GLP-1R antagonist exendin (9-39) did not modify the effects of all the incretin preparations on the NaA-induced activation of PI3K and MAPK pathways.

**Conclusion:** In human platelets, GLP-1 (7-36), GLP-1 (9-36) and liraglutide, independently of GLP-1R, reduce the NaA-induced activation of PI3K and MAPK pathways and of oxidative stress. Because MAPK activation is involved in the NaA-induced increase of oxidative stress, the inhibiting effects of GLP-1 on MAPK activation can account for its ability to attenuate the NaA-induced increase of oxidative stress. Finally, the effects of GLP-1 on intraplatelet signalling do not occur when PKG is inhibited, further confirming the interplay of GLP-1 with PKG.

## 914

**Effect of dipeptidyl peptidase-4 inhibitor sitagliptin on CD4+ T lymphocytes and monocytes in patients with type 2 diabetes**A. Hattori<sup>1</sup>, H. Tokuyama<sup>1</sup>, F. Shimada<sup>2</sup>, M. Nieda<sup>3</sup>, Y. Maezawa<sup>1</sup>, K. Kobayashi<sup>1</sup>, H. Kawamura<sup>1</sup>, M. Takemoto<sup>1</sup>, K. Yokote<sup>1</sup>;<sup>1</sup>Clinical Cell Biology and Medicine, Chiba University Graduate School of Medicine, <sup>2</sup>Diabetes and Metabolism, National Hospital Organization Chiba Medical Center, <sup>3</sup>Japan Biotherapy Institute, Tokyo, Japan.

**Background and aims:** Dipeptidyl Peptidase-4 inhibitors (DPP-4i) are currently used widely because of their efficacy and relative low risk of side effects. However several adverse effects of DPP-4i have been reported, e.g. raising the risk of pancreatitis and autoimmune diseases. DPP-4 is identical to CD26, a molecule expressed on immune cells particularly activated helper T cell (CD4<sup>+</sup>T;Th), but the effect of DPP-4i on immune cells is still unclear. The aim of this study is to evaluate the effect of DPP-4i on human T lymphocytes, especially Th, and monocytes *in vivo* and *ex vivo*.

**Materials and methods:** Thirty-two Japanese patients with type 2 diabetes (19 male and 13 female, mean age 62.5 years, mean HbA1c 7.6%) taking Sitagliptin 50mg/day as the first or the additional medication were enrolled to the study. Blood sampling was performed before and 8 weeks after the treatment. Leukocyte counts were performed by automatic blood cell counter. Surface markers including CD26 and CD163 on lymphocytes and monocytes were measured by flow cytometer after purification of peripheral blood mononuclear cells. *Ex vivo* intracellular cytokine assay was performed to detect subsets of Th: Th0, Th1 and Th2. The concentration of soluble CD26 (=DPP-4), soluble CD163 (macrophage/monocyte activation marker), TNF- $\alpha$  (Th1 cytokine) and IL-4 (Th2 cytokine) in patients' serum were measured by ELISA. **Results:** Cell numbers (T cell numbers/ $\mu$ L) and percentages of circulating T lymphocytes were significantly decreased (1252 $\pm$ 77/ $\mu$ L vs 1131 $\pm$ 78/ $\mu$ L,  $p=0.02$  and 65.4 $\pm$ 8.9% vs 62.2 $\pm$ 11.3%,  $p=0.02$ ) after the administration of DPP4i, although those of total lymphocytes did not change. In the T lymphocyte subset, cell numbers and percentages of Th decreased significantly (853 $\pm$ 316/ $\mu$ L vs 764 $\pm$ 286/ $\mu$ L,  $P=0.01$  and 44.8 $\pm$ 8.3% vs 43.0 $\pm$ 9.5%,  $p=0.04$ ), but not Tc (CD8<sup>+</sup>T). *Ex vivo* assay showed the significant increase of Th1/2 ratio (8.7 $\pm$ 1.0 vs 10.7 $\pm$ 1.5,  $p=0.03$ ) but TNF- $\alpha$  and IL-4 concentrations did not change. The change of Th1/2 ratio in 8 weeks were more correlated to the change of Th2 ( $r=-0.90$ ) than a change of Th1 ( $r=0.58$ ). The number of CD26<sup>+</sup>Th cells and serum level of soluble CD26 did not show any significant change. The percentage of circulating CD163<sup>+</sup> monocytes (as it is called M2 phenotype monocyte) were significantly decreased (10.0 $\pm$ 2.3% vs 2.7 $\pm$ 0.5%,  $p=0.006$ ) though total monocyte number did not. The concentration of soluble CD163 was significantly decreased (623 $\pm$ 57ng/mL vs 584 $\pm$ 60ng/mL,  $p=0.008$ ).

**Conclusion:** These findings suggest that DPP-4i possibly effect the balance of circulating T lymphocyte subset, particularly Th, and monocyte, but not effect Th1 and Th2 cytokines. These observation may indicate the direct effect of DPP-4 (CD26) inhibition on the differentiation from Th0 to Th2 rather than to Th1. On the other hand the decrease of soluble CD163 possibly reflects the suppression of macrophage/monocyte activation that could lead to improvement of chronic inflammation. Further detailed study is needed to clarify the effect of DPP-4i to human T lymphocytes and monocytes.

**A dipeptidyl peptidase-4 inhibitor directly suppresses inflammation and foam cell formation in monocytes/macrophages beyond incretins**

K. Nohtomi, M. Terasaki, K. Kohashi, M. Hiromura, M. Nagashima, T. Hirano;

Showa University School, Department of Medicine, Tokyo, Japan.

**Background and aims:** We reported that incretins (Glucagon-like peptide (GLP)-1 and glucose-dependent insulinotropic polypeptide (GIP)) and a dipeptidyl peptidase-4 inhibitor (DPP-4i) confer an anti-atherosclerotic effect in apolipoprotein-E null mice. It remains unclear whether the anti-atherogenesis of DPP-4i is wholly dependent on incretins or partly initiated via direct mechanisms independent of incretins. In this study we sought to elucidate the direct action of DPP-4i on anti-atherogenesis by examining the *in vitro* effect of incretins and DPP-4i on the expression of inflammatory cytokines and foam cell formation in monocytes/macrophages.

**Materials and methods:** Mouse peritoneal macrophages were obtained from the ascites by injection of thioglycolate. Monocytes/macrophages were ob-

tained from human peripheral blood mononuclear cells through a CD14 column. Foam cell formation was determined by the incorporation of [<sup>3</sup>H]-oleate into cholesteryl-oleate stimulated by oxidized-LDL.

**Results:** Exendin (Ex)-4 (5nM) and GIP (1nM) elicited cyclic (c)AMP generation and suppressed the LPS-induced gene expression of inflammatory molecules such as Interleukin (IL)-1 $\beta$ , IL-6, TNF- $\alpha$ , and nuclear factor-kappa B by 10~50% in U937 human monocytes. This suppressive effect, however, was attenuated by an inhibitor of adenylate cyclase and mimicked by 8-bromo-cAMP or forskolin. Telenigleptin (1-10 nM) substantially suppressed the LPS-induced expression of inflammatory cytokines by 20~75% without affecting the cell viability or DNA synthesis. Similarly, treatments with antibody or small interfering RNA of CD26 suppressed the expression of inflammatory cytokines. Telenigleptin with DPP4-resistant incretins (Ex-4 and DAla(2)GIP) additively suppressed the expression of these cytokines. Ex-4, GIP, and telenigleptin all suppressed LPS-induced extracellular signal-regulated kinase (ERK) phosphorylation to the same extent. The suppression of p-ERK by incretins was cAMP-dependent, while the suppression by telenigleptin was not. Telenigleptin suppressed cell surface toll-like receptor (TLR)-4 and TLR-5-mediated cytokine production, but had no effect on the intracellular TLRs-induced cytokines. Ex-4 and GIP slightly suppressed foam cell formation in mouse peritoneal macrophages and human macrophages whereas telenigleptin did not. Foam cell formation was enhanced by 2-fold in peritoneal macrophages of diabetic mice (db/db) and in the macrophages of patients with poorly controlled type 2 diabetes. Ex-4, GIP, and telenigleptin suppressed foam cell formation in the macrophages of diabetic mice and patients by 25-50%. The gene expressions of acyl-CoA cholesterol acyltransferase (ACAT)-1 and CD36 were up-regulated in diabetes, and incretins and telenigleptin attenuated the upregulation. CD26 mRNA and transcripts coded by exons 3-13 of the GLP-1 receptor and exons 1-14 of the GIP receptor were detectable in the monocytes/macrophages of mouse and human.

**Conclusion:** The present *in vitro* study suggests that DPP-4i suppresses inflammation partly via ERK inactivation and foam cell formation by down-regulating CD36 and ACAT-1 in monocytes/macrophages. This suppressive effect appears to be independent of incretin's action via cAMP.

**Liraglutide associated reversal of obesity and age dependent cardiac fibrosis correlates with improved vascular reactivity and modulation of macrophage gene expression**A.E. Dear<sup>1</sup>, T. Gaspari<sup>2</sup>, I. Welungoda<sup>2</sup>, Y. Hu<sup>1</sup>, R.E. Widdop<sup>2</sup>, R.W. Simpson<sup>1</sup>;<sup>1</sup>Medicine, Monash University,<sup>2</sup>Pharmacology, Monash University, Melbourne, Australia.

**Background and aims:** Cardiac fibrosis observed in obesity and myocardial aging results from excessive deposition of extracellular matrix (ECM) components, contributes to a detrimental increase in myocardial stiffness and is a major factor in the development of cardiac hypertrophy and the transition to heart failure. Excessive deposition of cardiac ECM is characterised by increased macrophage infiltration, differentiation of fibroblasts to the secretory myofibroblast phenotype and enhanced deposition of type I and III collagens. Expression of the glucagon like peptide-1 receptor (GLP-1R) in cardiac cells together with cardioprotective effects of GLP-1 and GLP-1R agonists in *in vivo* studies suggests a possible role for GLP-1 and GLP-1R agonists in the modulation of cardiac fibrosis. Our current study aimed to determine the effect of the GLP-1R agonist liraglutide in obesity and age induced models of cardiac fibrosis and identify associated molecular mechanisms.

**Materials and methods:** *In vivo* experiments utilised 5 month old C57Bl/6J mice maintained on a high fat diet (HFD) for 16 weeks to evoke obesity induced hypertension and cardiac fibrosis. 20 month old C57Bl/6J mice maintained on a normal chow diet were utilised as a model of aged induced cardiac fibrosis. Treatment regimens for both obesity and age induced cardiac fibrosis consisted of liraglutide 300 $\mu$ g/kg s.c., twice daily for 4 weeks. *In vitro* studies utilised the murine macrophage cell line RAW264.7 stimulated with lipopolysaccharide (LPS) (100ng/ml) and treated with liraglutide (100nM), with or without the specific GLP-1R antagonist exendin-9 (100nM) for 48 hours.

**Results:** Treatment of 5 month old C57Bl/6J mice with liraglutide prevented HFD-induced increase in blood pressure, reduced fat mass and importantly protected against increased interstitial cardiac fibrosis over vehicle treated animals ( $n=4$ ,  $p<0.05$ ). Studies comparing young 5 month old with 20 month old aged C57Bl/6J mice maintained on a normal chow diet demonstrated

liraglutide treatment significantly inhibited age associated cardiac fibrosis (n=4-6, p<0.05) and was associated with a reduction in body weight and improved vascular reactivity. In vitro studies identified significant induction of the M2 anti-inflammatory gene IL-10 mRNA expression together with inhibition of the M1 pro-inflammatory gene MCP-1 mRNA expression in liraglutide treated RAW264.7 cells (n=3, p<0.05).

**Conclusion:** Taken together these observations identify a potential role for liraglutide in the prevention of obesity and age associated cardiac fibrosis and downstream effects of this condition including cardiac failure in a non-diabetic setting and posits components of a molecular mechanism responsible for these effects.

### The effect of liraglutide and ischaemic postconditioning on myocardial salvage after ischaemia-reperfusion injury in pigs

K. Ekström<sup>1</sup>, M. Dalsgaard<sup>1</sup>, K.K. Iversen<sup>1</sup>, U. Pedersen-Bjergaard<sup>1</sup>, N.G. Vejstrup<sup>2</sup>, S.S. Diemar<sup>1</sup>, M. Idorn<sup>3</sup>, B. Thorsteinsson<sup>1</sup>, T. Engstrøm<sup>2</sup>;

<sup>1</sup>Department of Cardiology, Nephrology and Endocrinology, Nordsjællands Hospital, <sup>2</sup>Department of Cardiology, Rigshospitalet, <sup>3</sup>Center for Cancer Immune Therapy, Department of Hematology, Herlev Hospital, Copenhagen, Denmark.

**Background and aims:** Acute ST-segment elevation myocardial infarction (STEMI) is routinely treated by acute primary percutaneous coronary intervention (pPCI) in Denmark. Despite timely reperfusion, this may itself damage the tissue (reperfusion injury). Conditioning with glucagon-like peptide-1 (GLP-1) analogues, used for treatment of type 2 diabetes, has been shown to reduce reperfusion injury. Gradual restoration of blood flow (ischemic postconditioning) provides protection of cardiac tissue following acute myocardial infarction (MI). It has not yet been tested if combined postconditioning treatment with a GLP-1 analogue and ischemic postconditioning offers additive protective effect on the myocardium. We here present preliminary results.

**Materials and methods:** 58 non-diabetic female Danish Landrace pigs (60±10kg) were randomly assigned to four groups. MI was induced by occlusion of the left anterior descending artery (LAD) for 45 minutes in all groups. Group 1 (n=14) was treated with i.v. liraglutide after 15 minutes of ischemia until reperfusion. Group 2 (n=17) received liraglutide treatment concomitant with ischemic postconditioning, performed after 45 minutes of ischemia. Group 3 (n=15) was treated with ischemic postconditioning, and group 4 (n=12) served as controls.

**Results:** No intergroup differences in relative infarct size were detected (overall mean 57 ± 3%; p=0.68). Overall mortality was 34% (CI: 25-41%) including 26% post-intervention, with no intergroup differences (p=0.99). Occurrence of VF was 59% (CI: 25-80%) including 39% post-intervention with no intergroup differences (p=0.65).

**Conclusion:** No cardioprotective effects of liraglutide, ischemic postconditioning or combined treatment were found. Thus, based on our preliminary data, we cannot support a class effect of GLP-1 analogues in cardioprotection. Neither an additive effect of additional treatment with ischemic postconditioning could be demonstrated.

### Effects of liraglutide in an adolescent prediabetic transgenic pig model

E. Streckel<sup>1</sup>, C. Braun-Reichhart<sup>1</sup>, N. Herbach<sup>2</sup>, M. Dahlhoff<sup>3</sup>, B. Kessler<sup>1</sup>, A. Blutke<sup>2</sup>, A. Bähr<sup>1</sup>, N.B. Michaelsen<sup>4</sup>, N. Übel<sup>5</sup>, M. Eddicks<sup>5</sup>, M. Ritzmann<sup>5</sup>, B. Goeke<sup>6</sup>, R. Wanke<sup>2</sup>, E. Wolf<sup>3</sup>, S. Renner<sup>1</sup>;

<sup>1</sup>Chair for Molecular Animal Breeding and Biotechnology, LMU Munich, <sup>2</sup>Institute of Veterinary Pathology, LMU Munich, <sup>3</sup>Chair for Molecular Animal Breeding and Biotechnology, Gene Center, LMU Munich, Germany, <sup>4</sup>Research Bioanalysis, Måløv, Denmark, <sup>5</sup>Clinic for Swine, LMU Munich, <sup>6</sup>Department of Internal Medicine II, University Hospital Grosshadern, Munich, Germany.

**Background and aims:** To evaluate the effect of the glucagon-like peptide-1 receptor agonist liraglutide in adolescent transgenic pigs expressing a dominant-negative glucose-dependent insulinotropic polypeptide receptor (GIPR<sup>dn</sup>), with special emphasis to body weight, food intake, glycemic con-

trol, alpha- and beta-cell mass as well as proliferation in the exocrine pancreas.

**Materials and methods:** GIPR<sup>dn</sup> transgenic pigs (Trial 1: 2 months, unchanged β-cell mass; Trial 2: 5 months, 35% reduced β-cell mass) were treated with 0.6 mg - 1.8 mg liraglutide or placebo subcutaneously once daily for 90 days. Glucose tolerance was evaluated in a mixed meal oral test. Finally animals were subjected to necropsy and alpha- and beta-cell mass as well as beta-cell and acinus-cell proliferation were determined by quantitative-stereological analyses.

**Results:** Liraglutide treatment led to marked and sustained reductions in body weight gain (30-40%) and food intake (20-50%) compared to placebo treatment, associated with reduced activation of the growth-related insulin signaling pathway in skeletal muscle. In the mixed meal test performed after the treatment period, liraglutide-treated animals exhibited only a moderate increase of blood glucose, probably due to the known effect of liraglutide on gastric emptying. Additionally, AUC insulin was significantly smaller in liraglutide- vs. placebo-treated animals. Further, liraglutide treatment reduced HOMA-IR and increased several insulin sensitivity indices. Absolute alpha- and beta-cell mass was reduced in liraglutide-treated pigs, but not when related to body weight. Beta-cell proliferation was reduced in liraglutide-treated animals while acinus-cell proliferation in the exocrine pancreas did not differ between the two treatment groups.

**Conclusion:** The GIPR<sup>dn</sup> transgenic pig model recapitulates principle clinical effects of liraglutide observed in type 2 diabetic humans. However, the reduction of body weight gain observed in adolescent pigs was much more dramatic than the weight reduction seen in adult patients; thus special care is warranted in prospective treatment trials involving adolescent patients. There was no evidence for an increasing effect of liraglutide on alpha- and beta-cell mass or a stimulating effect on beta-cell and acinus-cell proliferation.

### Exenatide stimulates leptin gene expression and attenuates lipid deposition in skeletal muscle

Z. Chen<sup>1</sup>, F. Xu<sup>1</sup>, H. Gu<sup>1</sup>, B. Lin<sup>1</sup>, K. Zeng<sup>1</sup>, H. Lu<sup>2</sup>, W. Shao<sup>2</sup>, H. Liang<sup>1</sup>, J. Yan<sup>1</sup>, I. George Fantus<sup>2</sup>, T. Jin<sup>2</sup>, J. Weng<sup>1</sup>;

<sup>1</sup>The Third Affiliated Hospital of Sun Yat-sen University, Guangzhou, China, <sup>2</sup>Banting and Best Diabetes Centre, Toronto, Canada.

**Background and aims:** GLP-1-based drugs, such as exenatide, exert their beneficial effects on both pancreatic β-cells and extra-pancreatic organs. Here, we aim to assess the stimulation of exenatide on leptin gene expression in adipocytes and determine the effects of exenatide on ectopic lipid deposition in the skeletal muscle in two obese mouse models.

**Materials and methods:** High fat diet (HFD) fed C57BL/6 mice and db/db mice were treated with exenatide for 4 or 8wks. After treatment, serum leptin level was measured by ELISA kit and lipid accumulation in skeletal muscle was detected by oil red o staining. Key proteins involved in muscle lipid oxidation were determined by Western blotting. Rat primary adipocytes and differentiated 3T3-L1 adipocytes were treated with exendin-4 in vitro. Meanwhile, rat primary adipocytes were transfected with Leptin-LUC fusion gene plasmid by electroporation and LUC reporter activity was measured followed by exendin-4 treatment.

**Results:** Exendin-4 increased leptin mRNA levels in both rat primary adipocytes and differentiated 3T3-L1 cells, and stimulated leptin gene promoter activity. This increase, however, was not observed in adipocytes from GLP-1R<sup>-/-</sup> mice. In HFD fed C57BL/6 mice, exenatide administration for four wks resulted in a transient increase of serum leptin levels. In db/db mice, exenatide treatment for 8 wks resulted in increased serum leptin level, associated with increased leptin mRNA expression in epididymal adipocytes and reduced serum triglyceride and free fatty acid contents. In addition, exenatide administration attenuated lipid accumulation in skeletal muscle of db/db mice, along with elevated JAK2 and phosphorylated STAT3 levels, as well as increased expression fatty acid transport protein 1 (FATP1), lipid oxidation related protein CPT1, and lipolysis related protein LPL and ATGL.

**Conclusion:** This study revealed that adipocytes are among the targets of the incretin hormone GLP-1 and the therapeutic agent exenatide. Our observations support the notion that leptin reduces intramyocellular lipid through activating the short-form leptin receptors.

**Effect of liraglutide on beta cell mass and function in alloxan diabetic mice**

K. Tamura, K. Minami, H. Takahashi, M. Kudo, S. Seino;  
Kobe University Graduate School of Medicine, Japan.

**Background and aims:** Although GLP-1 receptor agonists have been shown to have beneficial effects on both beta-cell mass and function, the mechanism of the effect of the drugs on beta-cells is still unclear. The objective of this study is to characterize the effect of liraglutide, a long-acting GLP-1 analog, on beta-cell mass and function in alloxan-induced diabetic mice.

**Materials and methods:** We crossbred Ins2-CreER knock-in mice with R26R-YFP mice to generate Ins2-CreER/R26R-YFP double knock-in mice, in which the pancreatic beta-cells can be labeled specifically and permanently upon injection of tamoxifen. These mice enabled us to discriminate beta-cell neogenesis from self-replication. Pancreatic beta-cells were labeled by 5 consecutive injections of tamoxifen (4 mg/head/injection) to male mice at 6 weeks of age. Ten days after the last injection, diabetes was induced by a single dose of alloxan (60 mg/kg, i.p.). On the following day, mice with blood glucose concentration above 300 mg/dl were used for the study. Liraglutide (200 µg/kg s.c.) or vehicle (saline) was administered once daily from the day following alloxan injection for 30 days. Food intake, body weight, blood glucose levels, serum insulin levels and serum glucagon levels were measured. Beta-cell mass was estimated by immunofluorescent staining of pancreas sections. Proliferation rate was evaluated by Ki67 immunostaining and apoptosis rate was evaluated by TUNEL-method. To investigate beta-cell function, oral glucose tolerance test was performed.

**Results:** About 80% of beta-cells were destroyed by alloxan injection, leading to hypoinsulinemia and hyperglycemia in the mice. Liraglutide treatment ameliorated hyperglycemia in alloxan-diabetic mice. We found that beta-cell mass in liraglutide-treated group was two-fold higher than that in vehicle group, which correlates with the increment of serum insulin levels. In liraglutide-treated group, proliferation rate was significantly higher and apoptosis rate was significantly lower than in vehicle-treated mice. To examine the effect of liraglutide on beta-cell neogenesis, we injected tamoxifen to the alloxan-treated Ins2-CreER/R26R-YFP mice. As a result, the percentage of YFP-labeled beta-cells was not changed significantly before and after liraglutide treatment, suggesting that the contribution of neogenesis is, if any, limited to the increment of beta cell mass by liraglutide treatment. Furthermore, oral glucose tolerance test showed that the insulin secretory response to glucose was recovered following 30 days liraglutide treatment, and that this effect was sustained two weeks after drug withdrawal.

**Conclusion:** Chronic treatment of alloxan-induced diabetic mice with liraglutide preserved beta-cell mass by increasing cell proliferation and decreasing cell death. In addition, liraglutide treatment achieved sustained improvement of insulin secretory function of pancreatic beta-cells.

## 921

**Peripheral glucagon-like peptide-1 receptor agonism decreases VLDL production and fasting dyslipidaemia in insulin resistance**

J. Taher, C. Baker, C. Cuizon, M. Naples, S. Farr, K. Adeli;  
The Hospital for Sick Children, Toronto, Canada.

**Background and aims:** Glucagon-like peptide-1 (GLP-1) is an incretin hormone that stimulates pancreatic insulin release to reduce plasma glucose levels and thus acts as an important drug target in the treatment of type 2 diabetes (T2D). While GLP-1 receptor (GLP-1R) agonism is known to enhance satiety and induce weight loss, our laboratory has also shown that GLP-1 regulates lipoprotein metabolism by decreasing intestinal chylomicron production and may also play a similar role in the liver. Hepatic lipids are packaged with apolipoprotein B-100 (apoB100) into VLDL and secreted into the plasma. Dysregulation of VLDL production results in the fasting dyslipidemia that is observed in patients with T2D. In a similar way to intestinal metabolism, we postulate that GLP-1R agonism regulates fasting dyslipidemia by decreasing VLDL production in insulin resistance. We further postulate that this occurs through either a peripheral or central pathway independent of changes in food consumption.

**Materials and methods:** Fructose-fed insulin resistant Syrian golden hamsters were given twice daily intraperitoneal (i.p) injections of the GLP-1R agonist exendin-4 (ex4; 20µg/kg) for 7 days and placed into metabolic cages. Alternatively, fructose-fed hamsters received an intracerebroventricular

(ICV) administration of ex4 (250ng) into the third ventricle of the brain for 4 days. Plasma was subsequently collected over a 6 hour time course following i.p poloxamer administration to prevent lipoprotein uptake. Livers were excised for PCR analysis.

**Results:** Peripheral ex4 prevented fructose-induced fasting hypertriglyceridemia (vehicle(veh)=3.4 fold triglyceride (TG)increase; ex4=1.4 fold TG increase) and hypercholesterolemia (veh=1.3 fold increase; ex4=0.8 fold decrease). Ex4 also decreased VLDL-triglyceride( 1.28mmol/L vs 0.55mmol/L; p<0.01), -cholesterol (0.37mmol/L vs 0.16mmol/L; p<0.05) and -apoB100 levels following poloxamer (veh=2.4 fold increase; ex4= 0.12 fold increase) indicating a decrease in VLDL production. Ex4 reduced food consumption by 4.3g/day (p<0.001) and body weight by 11g over 7 days(p<0.001) however pair-fed (PF) hamsters did not significantly differ in fasting lipid levels from vehicles fed ad libitum. Ex4 treated hamsters had decreased expression of hepatic mRNA markers for *de novo* lipogenesis including *srebp-1c* (1.96 fold decrease; p<0.001). Ex.4 significantly reduced respiratory exchange ratio (veh=0.89; PF=0.90; ex.4=0.80; p<0.001) and CO<sub>2</sub> production (veh=1355ml/kg/hr; PF=1344ml/kg/hr; ex.4=1200ml/kg/hr; p<0.05) indicating a switch from carbohydrate to lipid metabolism as the main source of energy utilization. When ex4 was administered by ICV, there was a similar decrease in body weight (10g; p<0.001) and food consumption (4g/day; p<0.05) however no changes in VLDL-TG, -cholesterol or apoB100 accumulation. This suggests that while the effects of ex4 on satiety may be regulated centrally, the effects on VLDL production may be regulated peripherally.

**Conclusion:** Our studies suggest that GLP-1R agonism reduces fasting dyslipidemia in insulin resistance by decreasing VLDL production through a peripheral pathway. Additional studies are in progress to examine the involvement of an afferent-efferent signalling pathway. Further experimental evidence to test this role can lead to identification of putative drug targets to fight the metabolic complications of the fasting dyslipidemia observed in T2D.

#### Near-normalisation of glycaemic control in patients with type 2 diabetes with a glucagon-like peptide-1 receptor agonist in combination with exercise

P.F. Mensberg<sup>1,2</sup>, S. Nyby<sup>1,2</sup>, P.G. Jørgensen<sup>3</sup>, H. Storgaard<sup>1</sup>, J. Sivertsen<sup>3</sup>, M.T. Jensen<sup>3</sup>, J.J. Holst<sup>4</sup>, B. Kiens<sup>2</sup>, E.A. Richter<sup>2</sup>, F.K. Knop<sup>1</sup>, T. Viltsbøll<sup>1</sup>; <sup>1</sup>Diabetes Research Center, Department of Medicine, Gentofte Hospital, Hellerup, <sup>2</sup>Department of Nutrition, Exercise and Sports, Section of Molecular Physiology, Copenhagen, <sup>3</sup>Department of Cardiology, Gentofte Hospital, Hellerup, <sup>4</sup>Department of Biomedical Sciences, NNF center for Basic Metabolic Research, Copenhagen, Denmark.

**Background and aims:** Exercise and glucagon-like peptide-1 receptor agonist (GLP-1RA) treatment, respectively, improve glycaemic control in patients with type 2 diabetes (T2D). We investigated the effects of exercise in combination with GLP-1RA treatment in patients with T2D.

**Materials and methods:** Thirty-three untrained obese patients with T2D were included in a randomised double-blinded placebo-controlled clinical trial (23 men, age: 56±10 years (mean±SD); weight 99±16 kg; BMI: 32±4 kg/m<sup>2</sup>; fasting plasma glucose (FPG): 10.1±2.8 mmol/l; HbA1c: 65±14 mmol/mol (8.1±1.3%)), treated with diet only (n=3) or metformin (n=30). Patients were randomised to liraglutide (titrated to 1.8 mg once-daily) and exercise or placebo and exercise during 16 weeks. Both groups had 3 60-minute supervised training sessions per week; 2 spinning sessions and 1 session with resistance training.

**Results:** HbA1c, FPG and weight reductions were greater with liraglutide and exercise vs. placebo and exercise (Table 1). Both groups exhibited similar reduction in body fat mass and increase in maximal oxygen uptake. The most common adverse event was transient nausea (liraglutide: 24%, placebo: 6%).

**Conclusion:** Exercise alone for 16 weeks has no or little effect on glycaemic control and body weight, but combined with GLP-1RA treatment it can near-normalise glycaemic control and cause robust weight loss in overweight, dysregulated patients with type 2 diabetes.

**Table 1.**

| Changes from baseline                            | Liraglutide + Exercise (n=17) | Placebo + Exercise (n=16) | P value (between groups) |
|--|-------------------------------|---------------------------|--------------------------|
| HbA <sub>1c</sub> (mmol/mol)                     | -22±14*                       | -3±10                     | <0.001                   |
| HbA <sub>1c</sub> (%)                            | -2.0±1.2*                     | -0.3±0.9                  | <0.001                   |
| Fasting plasma glucose (mmol/l)                  | -3.4±2.3*                     | -0.3±2.6                  | <0.001                   |

#### Transfer of liraglutide from blood to cerebrospinal fluid is limited and an unlikely contributor to body weight loss in patients with type 2 diabetes

M. Christensen<sup>1,2</sup>, A.H. Sparre-Ulrich<sup>1,3</sup>, B. Hartmann<sup>4</sup>, U. Grevstad<sup>5</sup>, M.M. Rosenkilde<sup>3</sup>, J.J. Holst<sup>4</sup>, T. Viltsbøll<sup>1</sup>, F.K. Knop<sup>1</sup>; <sup>1</sup>Diabetes Research Division, Department of Medicine, Gentofte Hospital, Hellerup, <sup>2</sup>Department of Clinical Pharmacology, Bispebjerg Hospital, <sup>3</sup>Department of Neuroscience and Pharmacology, Faculty of Health and Medical Sciences, University of Copenhagen, <sup>4</sup>NNF Center for Basic Metabolic Research, Department of Biomedical Sciences, Faculty of Health and Medical Sciences, University of Copenhagen, <sup>5</sup>Department of Anesthesiology, Gentofte Hospital, Hellerup, Denmark.

**Background and aims:** The mechanisms by which subcutaneously administered glucagon-like peptide-1 (GLP-1) receptor agonists confer weight loss in humans are incompletely understood. A centrally mediated effect by passage of the blood-brain barrier has been suggested from animal studies. There are no human data on blood-brain transfer of GLP-1 receptor agonists.

**Materials and methods:** We measured liraglutide in plasma and cerebrospinal fluid (CSF) obtained by lumbar puncture in 8 patients with type 2 diabetes (male: 4/8, age: 63±2 years [mean±SEM], BMI: 30±1 kg/m<sup>2</sup>, HbA1c 56±4 mmol/mol) treated with 1.8 mg liraglutide subcutaneously for at least 1 month and with weight loss 8.4±0.4 kg in response to treatment. Liraglutide was measured with a radioimmunoassay (antibody no. 98302) specific for the intact N-terminus of the GLP-1 moiety of liraglutide. For validation of the CSF-assay, we obtained control CSF from subjects (n=9) not treated with liraglutide.

**Results:** Plasma-liraglutide was in the nanomolar range (31±4.4 nmol/L). When applying the assay to the CSF control samples, we measured a picomolar baseline level of 17±1.2 pmol/L. Recovery of liraglutide added to CSF was 100 % and sensitivity < 2 pmol/L. The non-corrected CSF-liraglutide concentrations in the liraglutide-treated patients were 23±1.8 pmol/L (comparison to untreated controls, Mann-Whitney test: P0.6).

**Conclusion:** Blood-brain barrier transport of liraglutide appears very limited and CSF-liraglutide does not seem to correlate with the plasma liraglutide concentrations or with clinical weight loss. Therefore, our results do not support that blood-to-CSF transfer is a significant contributor to the anorectic effects of GLP-1 receptor agonists.

#### Exenatide promotes hyperbolic-like specular changes in insulin sensitivity and beta cell function in non-human primates

F. Casiraghi<sup>1</sup>, A. Caumo<sup>1,2</sup>, S. Benedini<sup>1,2</sup>, L. Luzi<sup>1,2</sup>, F. Folli<sup>3</sup>; <sup>1</sup>I.R.C.C.S Policlinico San Donato, Milan, <sup>2</sup>University of Milan, Italy, <sup>3</sup>UTHSCSA, San Antonio, USA.

**Background and aims:** The GLP-1 receptor agonist Exenatide (EXE) improves glycemic control in type 2 diabetes mellitus (T2DM) by enhancing glucose-dependent insulin secretion, suppressing inappropriate glucagon secretion, slowing gastric emptying, and regulating appetite. However, the effects of continuous chronic EXE infusion on insulin sensitivity and β-cell function are not completely understood. We investigated the effect of continuous EXE infusion on a well characterized non-human primate (baboon) model of insulin resistance and T2DM.

**Materials and methods:** We examined the effect of a continuous IV infusion (via tether system) of: i) EXE (0.014 ug/kg.h, n=10) or ii) saline (SAL, n=10) on insulin sensitivity and β-cell function in non-diabetic baboons (NDB). At baseline, baboons received a two-step Hyperglycemic Clamp (+125 and +225 mg/dl) followed by an IV Arginine bolus (0.15 g/kg) (HC+A), with a total duration of 210 minutes. Immediately after HC+A, baboons underwent a partial pancreatectomy (~30% total mass) and started EXE or SAL infusion for 13 weeks. At the end of treatment, EXE infusion was stopped for 72 hours before HC+A was repeated and remnant pancreas was collected after humane euthanasia, at necropsy. Insulin sensitivity was calculated by linear regression from the two-step dose-response relationship between the incremental (above baseline) glucose clearance and the incremental insulin concentration measured during the final 30 min of each step. Beta-cell function was calculated by linear regression from the two-step dose-response relationship between the incremental C-peptide concentration and the incremental glucose concentration measured during the final 30 min of each step.

**Results:** We found a significant increase in insulin sensitivity ( $6.6 \pm 3.4$  to  $11.2 \pm 5.5$   $10^4$  ml/kg per  $\mu\text{U/ml}$ ,  $p < 0.05$ ) and a significant decrease in beta cell function ( $4.6 \pm 1.9$  to  $3.1 \pm 1.7$   $10^2$  ng/ml per mg/dl,  $p < 0.05$ ) in the EXE group. No significant changes were found in the saline group. When plotted on the insulin sensitivity vs. beta-cell function diagram (Figure 1), the changes in insulin sensitivity and beta-cell function induced by EXE (Basal vs. End of Study [EOS]) were reminiscent of the hyperbolic-like changes induced by aerobic exercise.

**Conclusion:** This study shows a significant increase of insulin sensitivity coupled with a significant decrease in beta cell function, after chronic EXE infusion. These results are similar to what has been observed in diabetic patients performing aerobic physical activity. Since baboon is good model to study human metabolic diseases, we speculate that a similar pattern of increased insulin sensitivity and decreased beta function can be reasonably expected in humans treated with exenatide.

### Sitagliptin may improve insulin sensitivity through increases in serum osteocalcin and adiponectin concentrations in patients with type 2 diabetes

Y. Sakuma<sup>1</sup>, Y. Suzuki<sup>2</sup>, R. Iwai<sup>3</sup>, S. Fukushima<sup>4</sup>, J. Ogino<sup>4</sup>, S. Yoshida<sup>5</sup>, N. Hashimoto<sup>4</sup>;

<sup>1</sup>Clinical Research Support Center, Asahi General Hospital, Asahi Chiba, <sup>2</sup>Diabetes and Metabolic disease, Asahi General Hospital, Tokyo Women's Medical University, Asahi, Yachiyo, <sup>3</sup>Clinical Laboratory, Asahi General Hospital, <sup>4</sup>Diabetes, Endocrine and Metabolic disease, Tokyo Women's Medical University, Yachiyo, <sup>5</sup>Diabetes and Metabolic disease, Asahi General Hospital, Japan.

**Background and aims:** Recent reports have suggested that dipeptidyl peptidase (DPP)-4 inhibitors improve insulin sensitivity in addition to their glucose lowering effects in patients with type 2 diabetes. The underlying mechanisms are not well known. There is growing evidence that osteocalcin, an osteoblast-secreted protein, can enhance insulin sensitivity and secretion in animal models. We aimed to evaluate the relationship between circulating undercarboxylated osteocalcin (unOC) and insulin sensitivity, especially serum adiponectin concentration during sitagliptin add-on therapy in patients with type 2 diabetes.

**Materials and methods:** A total of 131 Japanese patients with type 2 diabetes were enrolled in the study with the informed consent: 73 males/58 females, age  $61 \pm 12$  years, estimated duration of the disease  $11 \pm 7$  years, body mass index  $25.8 \pm 4.7$   $\text{kg/m}^2$ , and HbA1c  $7.9 \pm 1.1$  %. They were treated with 50 to 100 mg of sitagliptin for 12 months in addition to the preceding anti-diabetic agents. We measured fasting glucose, fasting insulin, indexes of insulin sensitivity (HOMA-IR and quantitative insulin sensitivity check index or QUICKI) and secretion capacity (HOMA- $\beta$  and C-peptide index or CPI), and serum concentrations of unOC and adiponectin. Next we examined cross-sectional and longitudinal associations between serum unOC and adiponectin.

**Results:** Sitagliptin add-on therapy significantly improved parameters for glycaemic control (HbA1c:  $7.9 \pm 1.1$  vs.  $7.5 \pm 1.0$  %,  $p < 0.0001$ ) and insulin sensitivity (HOMA-IR:  $3.2 \pm 2.3$ , vs.  $2.7 \pm 1.8$ ,  $p < 0.0005$ , QUICKI:  $0.336 \pm 0.035$  vs.  $0.343 \pm 0.034$ ,  $p < 0.005$ ). Serum unOC and adiponectin levels were significantly increased (unOC:  $2.22 \pm 1.11$  vs.  $2.48 \pm 1.38$ ,  $p < 0.05$ , adiponectin:  $8.67 \pm 5.65$  vs.  $11.22 \pm 8.58$   $\mu\text{g/ml}$ ,  $p < 0.0001$ ). Increases in serum adiponectin were significantly associated with decreases in HOMA-IR ( $r = -0.228$ ,  $p < 0.05$ ) and increases in QUICKI ( $r = 0.222$ ,  $p < 0.05$ ). Serum unOC concentrations were positively correlated with adiponectin concentrations after 12-month treatment with sitagliptin ( $r = 0.333$ ,  $p < 0.001$ ) although both parameters showed no association at baseline ( $r = 0.103$ ,  $p = 0.2537$ ).

**Conclusion:** Sitagliptin improved insulin sensitivity associated with increases in concentrations of unOC and adiponectin, which suggests some potential roles of DPP-4 inhibitors through bone and fat tissues, described as endocrine organs important for the regulation of glucose homeostasis and energy expenditure.

### Effect of lixisenatide vs liraglutide on glycaemic control, gastric emptying and safety parameters in optimised insulin glargine type 2 diabetes mellitus $\pm$ metformin

J.J. Meier<sup>1</sup>, J. Rosenstock<sup>2</sup>, A. Hincelin-Mèry<sup>3</sup>, C. Roy-Duval<sup>3</sup>, A. Delfolie<sup>3</sup>, H.-V. Coester<sup>4</sup>, T. Forst<sup>5</sup>, C. Kapitza<sup>4</sup>;

<sup>1</sup>St Josef Hospital, Ruhr-University Bochum, Germany,

<sup>2</sup>Dallas Diabetes and Endocrine Center, USA, <sup>3</sup>Sanofi R&D, Paris, France,

<sup>4</sup>Profil Institute, Neuss, <sup>5</sup>Profil Institute, Mainz, Germany.

**Background and aims:** The meal test-related pharmacodynamics and safety of lixisenatide 20  $\mu\text{g}$  and liraglutide 1.2 and 1.8 mg once daily (QD) were compared in this 8-week, randomized, open-label, 3-arm parallel mechanistic trial in patients with type 2 diabetes mellitus (T2DM)  $\pm$  metformin after optimal insulin glargine titration.

**Materials and methods:** The primary endpoint was change from baseline in incremental area under the glucose curve for 4 hours after a standardized solid breakfast (AUC post-prandial plasma glucose [PPG]<sub>00:30-04:30 h</sub>).

**Results:** Lixisenatide reduced PPG AUC<sub>00:30-04:30 h</sub> (least squares [LS] mean  $\pm$  standard error) by  $-240.2 \pm 20.0$  h.mg/dL, which was significantly more than liraglutide 1.2 and 1.8 mg ( $-131.8 \pm 20.2$  and  $-157.1 \pm 21.0$  h.mg/dL, respectively;  $p < 0.0001$ ; Table). Lixisenatide delayed gastric emptying more than liraglutide 1.2 and 1.8 mg ( $p < 0.0001$ ; Table) as measured by a <sup>13</sup>C octanoic acid breath test. A<sub>1C</sub> decreased significantly from baseline in all groups, with similar reductions with lixisenatide and liraglutide 1.2 mg and small but significantly greater reductions with liraglutide 1.8 mg (by  $-0.16\%$ ). Mean ambulatory monitored 24-h increase in heart rate was greater with liraglutide 1.2 and 1.8 mg (by 6 beats/min) vs lixisenatide ( $p < 0.0001$ ). Symptomatic hypoglycaemia was slightly more frequent with lixisenatide and liraglutide had more gastrointestinal adverse events reported. There were greater increases in amylase and lipase levels with liraglutide vs lixisenatide (Table) and 1 patient in the liraglutide 1.8 mg group developed asymptomatic oedematous pancreatitis documented by MRI and lipase elevations.

**Conclusion:** Lixisenatide and liraglutide + insulin glargine improved glycaemic control in T2DM ± metformin, albeit with differing gastric emptying mechanisms of action and safety/tolerability profiles.

### The influence of DPP-4 inhibitors on fat metabolism in type 2 diabetes patients

A.S. Ametov, D.G. Gusenbekova;  
Department Endocrinology and Dietology RMAPO, Ministry of Health,  
Moscow, Russian Federation.

**Background and aims:** To evaluate the effect of sitagliptin in combination with metformin on glucose toxicity and lipotoxicity in patients with type 2 diabetes and obesity.

**Materials and methods:** The study involved 82 patients (55 women, 27 men, mean age 56,1 ± 5,47 years) with obesity, lipid metabolism disorders, who have not reached target levels HbA1s (average HbA1c 8,3 ± 1,6%) after metformin and diet therapy. The first group of patients (42 patients) received co-formulated drug, consisting of sitagliptin 100mg and metformin 2g once a day; the second comparison group (40 patients) received metformin 1.5-2.0 g/day. Dynamics of fasting glycemia, postprandial glycemia, glycated hemoglobin, weight, BMI, WC, WHR, lipid profile (total cholesterol, triglycerides, LDL, HDL, apoB protein), insulin, proinsulin, leptin, adiponectin, insulin resistance using the index HOMA IR and functional activity of β-cells (by HOMA-β index) was evaluated at baseline and at 6 months of therapy. In addition, MRI was performed to assess visceral fat in all the patients.

**Results:** At 6 months patients in both groups demonstrated significant positive changes in the levels of fasting glucose, postprandial glycemia and glycosylated hemoglobin. In group I, HbA1 decreased from 8,3 ± 1,6% to 6,6 ± 1,24% (p < 0,01), in group II there was a decrease from 8,35 ± 1,75% to 7,62

± 1,39% (p < 0,01). FPG and late products of glycosylation levels in group I reduced on average by 2.67 and 3.3 mmol/L, correspondingly, in group II by 2.1 and 1.8 mmol/l. No significant differences in the dynamics of total cholesterol, HDL between the groups were found. LDL in group I lowered by 0.7 mmol/l, in group II by 0.3 mmol/l (p < 0,05); in group I, TG decreased by 1.33 mmol/l. in group II by 0, 63 mmol/l (p < 0,05); in group I IRI reduction was 3.45 mcU/ml. in group II 1.63 mcU/ml (p = 0.05). Proinsulin level dropped down in group I by 2,93 ± 3,02, in group II by 1,26 ± 1,1, C-peptide level increased by 1,4 ± 1,6 ng/ml, in group II 0.16 ± 0,1 ng/ml, HOMA β grew up in group I by 23.4 standard units, in group II by 4.8 standard units (p < 0,005). The ratio of proinsulin/insulin dropped down in group I by 0, 19 ± 0,7, in group II by 0,02 ± 0,2. There were no significant differences between the groups in the dynamics of HOMA IR and both groups demonstrated positive dynamics. Adiponectin levels were different between the groups, there was an increase by 1.9 ng/ml in group I, in group II by 0.49 ng/ml. (p < 0,01). Leptin lowered by 7.37 ng/ml in group I, in group II by 1.21 ng/ml (p < 0,01). Also groups showed dramatic difference in anthropometric parameters dynamics (p < 0,001). Average weight loss was 4, 9 ± 3, 2 kg in group I, in group II 2,0 ± 0,94 kg correspondingly. BMI in group I decreased by 1,8 ± 1,3, in group II by 0,68 ± 0,3. WC shortened by 6,5 ± 4,7 sm in group I, in group II by 2,42 ± 1,02 sm. WHR in group I decreased from 0,95 ± 0,06 sm to 0,91 ± 0,05 sm, in group II from 0,94 ± 0,03 sm to 0,93 ± 0,03 sm, respectively. Also MRI showed a significant reduction of visceral fat area by 20,6 ± 13,5 sm<sup>2</sup> (7.5%) in group I, compared to group II with 5,7 ± 3,75 sm<sup>2</sup> reduction (1.76%). P < 0,01, while in the dynamics of the area of the subcutaneous fat there is no reliable dynamics between groups. Episodes of hypoglycemia have not been registered in any of the groups during the treatment.

**Conclusion:** The administration of sitagliptin and metformin decreased glucose toxicity and lipotoxicity that generally led to the improvement of glycaemic control.

## 928

### Feed-back suppression of meal-induced GLP-1 secretion: a randomised, prospective comparison of the DPP-4 inhibitors sitagliptin and vildagliptin

O. Baranov<sup>1</sup>, C.F. Deacon<sup>2</sup>, J.J. Holst<sup>2</sup>, U. Buss<sup>1</sup>, M.A. Nauck<sup>1</sup>;

<sup>1</sup>Diabetes Centre, Bad Lauterberg im Harz, Germany,

<sup>2</sup>Department of Biomedical Sciences, University of Copenhagen, Denmark.

**Background and aims:** DPP-4 inhibitors inhibit/delay proteolytic degradation of intact incretin hormones (GIP, GLP-1) and thereby stimulate insulin and suppress glucagon secretion. Higher intact GLP-1 increments with DPP-4 inhibitors lead to feedback inhibition of (total) GLP-1 (L-cell-) secretion. In this respect, the present study wanted to compare the effects of vildagliptin and sitagliptin.

**Materials and methods:** 24 patients with type 2 diabetes (12 without diabetes medication, 12 on metformin monotherapy), including 10 women/14 men, age 63 ± 3 years, BMI 30 ± 4 kg/m<sup>2</sup>, diabetes duration 5 ± 5 years, HbA1c 6.6 ± 0.7 % participated, in randomized order, in treatment periods lasting 7-9 days on either vildagliptin (50 mg b.i.d. = 100 mg/d), sitagliptin (100 mg q.d. in those on diet, 50 mg b.i.d. in those on metformin treatment = 100 mg/d) or placebo (b.i.d.). On the last day of the treatment period, participants underwent a mixed meal stimulation test after an overnight fast. Capillary blood was taken for glucose measurements, venous blood samples were taken for the determination of serum insulin and C-peptide, and plasma GLP-1 and GIP (both intact and total concentrations), and glucagon. Statistics: ANCOVA for repeated measures. **Results:** Both DPP-4-inhibitors significantly reduced the post-prandial increments in plasma glucose. Intact GLP-1 and GIP concentrations were roughly doubled by both DPP-4 inhibitors. Total GLP-1 secretion reduced by 56 % with vildagliptin and by 33% with sitagliptin treatment (significant if compared to placebo, not between vildagliptin and sitagliptin). Glucagon was suppressed slightly more markedly with vildagliptin. Parameters of glycaemic control and insulin secretion did not differ much between vildagliptin and sitagliptin treatment.

**Conclusion:** Vildagliptin and sitagliptin affect the concentrations of incretin hormones, glucose concentrations, insulin and glucagon secretion as expected, including a feedback inhibition of L-cell secretion induced by DPP-4 inhibition, most likely mediated by elevated „intact“ GLP-1 concentrations. In this respect, and regarding more clinical parameters (glycaemic control, insulin secretion, glucagon suppression) at most minor differences were described between vildagliptin and sitagliptin treatment, which most likely are without clinical significance.

**Effects of standard dose of vildagliptin vs sitagliptin on blood glucose fluctuations evaluated by long-term self-monitoring blood glucose (SMBG)**

K. Kimachi, H. Miyoshi, N. Aikawa, H. Nomoto, H. Kameda, K. Cho, T. Kondo, T. Atsumi;

Department of Medicine II (Immunology and Metabolism), Hokkaido University School of Medicine, Sapporo, Japan.

**Background and aims:** No previous studies have compared the DPP-4 inhibitors, vildagliptin and sitagliptin, in terms of fluctuations of daily blood glucose profile by using long-term SMBG. The aim of this study was to evaluate the effects of switching from sitagliptin to vildagliptin, or from vildagliptin to sitagliptin on 12-week glucose fluctuations using SMBG in Japanese patients with type 2 diabetes.

**Materials and methods:** We conducted a multicenter, prospective, open-label controlled trial with blinded endpoint analysis. Thirty-two patients with type 2 diabetes mellitus had been treated by vildagliptin or sitagliptin in each standard use (vildagliptin 50mg twice daily or sitagliptin 50mg once daily), and were allocated to two groups who received vildagliptin during 12 weeks then switched to sitagliptin during 12 weeks, or vice versa. SMBG systems were distributed to all patients at the beginning and measurements of seven-point SMBG (daily profile of blood glucose level of before and 2 hours after each meal, and at bedtime) during the trial were used to determine: 1) the mean amplitude of glycemic excursions (MAGE), 2) M-value, 3) mean ( $\pm$  standard deviation) blood glucose level, and 4) fasting and postprandial blood glucose level. Plasma glycosylated hemoglobin (HbA1c), glycoalbumin (GA), 1,5-anhydroglucitol (1,5AG), immunoreactive insulin (IRI), Proinsulin/IRI ratio, C-peptide immunoreactivity (CPR) and glucagon levels were measured.

**Results:** The MAGE was significantly lower in patients taking vildagliptin than sitagliptin ( $61.9 \pm 27.3$  vs.  $72.9 \pm 38.4$  mg/dL;  $p=0.04$ ). In patients taking vildagliptin, the mean blood glucose level was significantly lower ( $151.0 \pm 31.6$  vs.  $157.5 \pm 29.2$  mg/dL;  $p=0.02$ ), M-value was significantly lower ( $11.7 \pm 2.4$  vs.  $14.5 \pm 2.5$ ;  $p=0.01$ ) and the blood glucose level after supper was significantly lower ( $172.2 \pm 40.8$  vs.  $190.6 \pm 42.2$  mg/dL;  $p=0.04$ ). 1,5-anhydroglucitol (1,5AG) was significantly higher ( $1.40 \pm 2.67$  vs.  $-0.90 \pm 1.59$ ;  $p=0.003$ ), and proinsulin/IRI ratio was significantly lower ( $-0.039 \pm 0.13$  vs.  $0.51 \pm 0.11$ ;  $p=0.01$ ). There were no significant differences in plasma HbA1c, GA, fasting CPR, or glucagon levels between patients taking vildagliptin and sitagliptin.

**Conclusion:** Vildagliptin was superior to reduce the fluctuations of daily blood glucose profile compared with sitagliptin in Japanese patients with type 2 diabetes.

**Factors associated with progression of type 2 diabetes and impact of treatment with saxagliptin in the SAVOR-TIMI 53 trial**

G. Leibowitz<sup>1</sup>, O. Mosenzon<sup>1</sup>, D.L. Bhatt<sup>2</sup>, B. Hirshberg<sup>3</sup>, C. Wei<sup>3</sup>, A. Cahn<sup>1</sup>, G. Jermendy<sup>4</sup>, W.H.H. Sheu<sup>5</sup>, J. Lopez-Sendon<sup>6</sup>, A. Avogaro<sup>7</sup>, B.M. Scirica<sup>2</sup>, I. Raz<sup>1</sup>;

<sup>1</sup>The Diabetes Unit, Hadassah Hebrew University - Medical Center, Jerusalem, Israel, <sup>2</sup>Brigham and Women's Hospital, Harvard Medical School, Boston, <sup>3</sup>AstraZeneca, Wilmington, USA, <sup>4</sup>Bajcsy-Zsilinszky Hospital, Budapest, Hungary, <sup>5</sup>Department of Internal Medicine, Division of Endocrinology and Metabolism, Taichung Veterans General Hospital, Taiwan, <sup>6</sup>Cardiology Department, Hospital Universitario La Paz, Madrid, Spain, <sup>7</sup>Dept. of Medicine, University of Padova, Italy.

**Background and aims:** In type 2 diabetes (T2D), glycemic control often deteriorates over time, requiring intensification of treatment. We aimed to identify factors associated with progression of diabetes and studied the impact of saxagliptin, a DPP-4 inhibitor, on diabetes progression. In addition, we evaluated the effect of saxagliptin on beta cell function as reflected by a decline in HOMA2- $\beta$ .

**Materials and methods:** We studied the association of clinical and biochemical parameters with diabetes progression in the SAVOR-TIMI 53 study, a randomized clinical trial of 16,492 patients with T2D treated with saxagliptin vs. placebo added to current anti-diabetic medications for a median of 2.1 years. Diabetes progression was defined by 1) HbA1C increase  $\geq 0.5\%$ , 2) initiation of new anti-diabetic medications, 3) increase in oral medication dose or 4)

$\geq 25\%$  increase in insulin dose for  $\geq 3$  months. HOMA2- $\beta$  was measured at baseline and at year 2 in 4134 patients (25.1% of trial).

**Results:** Progression of diabetes during the study occurred in 54.7% of all subjects. Compared with placebo, treatment with saxagliptin decreased the risk of diabetes progression (OR 0.60; 95% CI 0.57-0.65;  $p<0.001$ ). The occurrence of an HbA1C increase of  $\geq 0.5\%$ , initiation of insulin, and the increase in dose for an oral hypoglycemic medication or insulin was decreased by 30%, 30% and 19% respectively in patients treated with saxagliptin compared with placebo. At 2 years, HOMA2- $\beta$  was decreased by 7.6% with placebo, compared with 2.7% with saxagliptin ( $p=0.0004$ ). A multivariate analysis that included baseline demographics, biochemical parameters, and medical treatments showed that older age, lower HDL, lower baseline HOMA2- $\beta$ , and baseline sulfonyleurea use were significantly associated with diabetes progression.

**Conclusion:** Saxagliptin decreased the progression of diabetes via improved glycemic indices and fewer concomitant anti-hyperglycemic agents compared with placebo, which may be related to reduced natural decline in  $\beta$ -cell function.

## PS 074 The potential future of insulin therapy

931

### IDegAsp provides superior FPG control and reduced hypoglycaemia vs BAsp 30 in insulin-naïve adults with type 2 diabetes: a randomised phase 3 trial

E. Franek<sup>1</sup>, M. Haluzik<sup>2</sup>, S. Canecki Varžić<sup>3</sup>, M. Sargin<sup>4</sup>, S. Macura<sup>5</sup>, J. Zacho<sup>5</sup>, J. Christiansen<sup>6</sup>;

<sup>1</sup>Central Clinical Hospital MSWiA, Warsaw, Poland, <sup>2</sup>General University Hospital and <sup>1</sup> Faculty of Medicine, Praha, Czech Republic, <sup>3</sup>Clinical Hospital Center Osijek, Croatia, <sup>4</sup>Kartal Training and Research Hospital, Istanbul, Turkey, <sup>5</sup>Novo Nordisk A/S, Copenhagen, Denmark, <sup>6</sup>Aarhus University Hospital, Denmark.

**Background and aims:** Insulin degludec/insulin aspart (IDegAsp) is a 70%/30% combination of insulin degludec (IDeg) and insulin aspart (IAsp), providing both a basal insulin with an ultra-long duration of action and a rapid-acting bolus insulin in a single injection. The aim of this trial was to compare the efficacy and safety of IDegAsp and biphasic insulin aspart 30 (BAsp 30), each administered twice daily (BID) ± metformin in insulin-naïve adults with type 2 diabetes (T2DM).

**Materials and methods:** This was a 26-week randomised, open-label, multinational, treat-to-target trial. Subjects (mean: age 58.9 years, duration of diabetes 9.5 years, HbA<sub>1c</sub> 8.4%, FPG 10.2 mmol/L, BMI 31.2 kg/m<sup>2</sup>) were randomised 1:1 to IDegAsp BID (n=197) or BAsp 30 BID (n=197). Insulin was administered before breakfast and the main evening meal and titrated to a pre-breakfast and pre-main evening meal self-measured plasma glucose (SMPG) target of ≤5 mmol/L. Patient characteristics were similar in both treatment arms.

**Results:** IDegAsp was non-inferior to BAsp 30 based on mean change in HbA<sub>1c</sub> from baseline (primary endpoint; estimated treatment difference [ETD] +0.02% [95% CI -0.12; 0.17]), end of treatment mean HbA<sub>1c</sub> was 49.0 (6.6) and 48.0 (6.5) (mmol/mol [%]), respectively. IDegAsp was superior to BAsp 30 in lowering FPG (ETD -1.0 mmol/L [95% CI -1.42; -0.59]; p<0.001). Mean daily insulin dose after 26 weeks was similar in both treatment arms. IDegAsp was associated with significantly lower rates of confirmed (plasma glucose (PG) <3.1 mmol/L or severe [requiring assistance]) and nocturnal confirmed (between 00.01-05.59 h) hypoglycaemia vs BAsp 30 (Figure). Rates of severe hypoglycaemia were low in both treatment arms. Both treatments were well tolerated and rates of adverse events were similar.

**Conclusion:** IDegAsp BID in insulin-naïve adults with T2DM effectively improves HbA<sub>1c</sub> (non-inferior to BAsp 30) and is superior to BAsp 30 in lowering FPG. The significantly lower rates of confirmed and nocturnal confirmed hypoglycaemia for IDegAsp vs BAsp 30 are consistent with previous findings, reflecting the more prolonged and stable glucose-lowering effect of the IDeg (basal) component in IDegAsp compared to the protaminated portion of IAsp in BAsp 30.

### Pharmacokinetic (PK) and pharmacodynamic (PD) properties of BioChaperone Combo (BC Combo), the first fixed combination of glargine and lispro, in type 1 diabetes (T1DM)

U. Hoevelmann<sup>1</sup>, B. Alluis<sup>2</sup>, G. Meiffren<sup>2</sup>, A. Ranson<sup>2</sup>, O. Soula<sup>2</sup>, G. Soula<sup>2</sup>, R. Soula<sup>2</sup>, B. Kronshage<sup>1</sup>, L. Nosek<sup>1</sup>, S. Famulla<sup>1</sup>, T. Heise<sup>1</sup>;

<sup>1</sup>Profil, Neuss, Germany, <sup>2</sup>Adocia, Lyon, France.

**Background and aims:** BC Combo is a novel insulin formulation in a clear solution combining the two already licensed insulin analogues glargine and lispro (75/25) at neutral-pH using the BioChaperone technology.

**Materials and methods:** We investigated the pharmacodynamic and pharmacokinetic properties in patients with T1DM (21 randomised (mean±SD age: 42.3±13.0 years; HbA1c: 7.8±0.6%), 19 completers) receiving a single dose of 0.8 U/kg (s.c.) of BC Combo or Humalog Mix25 (MIX) under automated glucose clamp conditions (ClampArt®, target blood glucose (BG) 100 mg/dL, duration 30 h post-dosing) in this double-blind, 2 way-crossover study.

**Results:** As visible from the mean glucose infusion rate (GIR) curves (Figure), BC Combo showed a faster onset of action (25±11 vs. 40±13 min, p=0.0017), an earlier T<sub>max</sub> (2.8±0.8 vs. 3.4±0.8 h, p=0.0145) and an improved glucose-lowering effect in the first two hours post-dosing (AUC<sub>GIR 0-2h</sub> 504±210 vs. 325±183 mg/kg, p=0.0012), compared with MIX, likewise evidenced by a greater early appearance (AUC<sub>INS 0-1h</sub> 86±39 vs. 34±19 h\*mU/L, p<0.0001). Minimal duration of action was achieved before 30 hours by less subjects on BC Combo than on MIX (2 vs 14, p=0.0002) indicating a longer duration of action (defined as the time after dosing at which the BG increases to > 118 mg/dL, Figure) for BC Combo (29.8±0.7 vs. 25.5±4.3 h). This also resulted in lower mean BG values in the last hour of the clamp (104.5±8.8 and 137.8±35.7, p=0.0008). In addition, BC Combo showed a more pronounced late metabolic effect (AUC<sub>GIR 12-30h</sub> 1480±900 vs. 961±553 mg/kg, p=0.0257) which was in line with a higher late exposure (AUC<sub>INS 12-30h</sub> 563±409 vs. 286±233 h\*mU/L, p<0.0001) and a longer half-life (17.6±8.7 vs. 7.7±3.0 h, p<0.0001) supporting the use of BC Combo as a once daily injection. No

safety issues were identified. Both formulations were well tolerated and no injection site reactions occurred.

**Conclusion:** The PK and PD results of BC Combo showed a stronger prandial effect with a faster onset and also a longer basal action for BC Combo indicating the potential of an improved metabolic control vs. MIX when used as once daily treatment.

Figure: Pharmacodynamic (GIR, upper panel) and blood glucose (BG, lower panel) profiles (5 min mean values, respectively) of BioChaperone Combo and Humalog Mix25

**Long-acting basal insulin (HM12470) offers once-weekly dosing potential with a favorable PK, PD and mitogenic profile**

I. Choi<sup>1</sup>, S. Hwang<sup>1</sup>, J. Kim<sup>1</sup>, S. Jung<sup>1</sup>, D. Kim<sup>1</sup>, Y.-M. Lee<sup>1</sup>, Y. Kim<sup>1</sup>, M. Trautmann<sup>2</sup>, M. Hompesch<sup>2</sup>, J. Son<sup>1</sup>, S. Kwon<sup>1</sup>;  
<sup>1</sup>Hanmi Pharmaceutical Co., Ltd., Gyeonggi-do, Republic of Korea,  
<sup>2</sup>Profil Institute, Chula Vista, USA.

**Background and aims:** The novel long-acting basal insulin (HM12470) has been developed for once-weekly injection by conjugating an insulin analog with the constant region of a human immunoglobulin fragment via non-peptidyl linker. This study investigated the *in vitro* properties, pharmacokinetics and pharmacodynamics of HM12470 in normal and diabetic animal models to evaluate the once-weekly dosing potential and the mitogenic potency.

**Materials and methods:** Pharmacokinetics of HM12470 was evaluated after subcutaneously administration to mice, rats, dogs, pigs, and monkeys. Based on these preclinical PK data, human plasma profile of HM12470 was predicted for once-weekly dosing by the Wajima  $C_{ss}$ -MRT method. Blood glucose lowering was monitored in *db/db* mice after HM12470 was subcutaneously injected. *In vitro* analysis, the lipogenic potency in fully differentiated 3T3-L1 adipocyte cells, and cell proliferative potency in MCF-7 and SaOs-2 cells were evaluated.

**Results:** In a pharmacokinetic study, subcutaneously injected HM12470 exhibited a half life of ~ 43 hr in normal rats, while insulin degludec showed 2.9 hr of half-life. The extended half-life was also confirmed in other species such as mice, dogs, pigs, and monkeys. The improved pharmacokinetic profile had contributed to prolonged glucose lowering efficacy in *db/db* mice. Based on the results from three different species (mice, rats, and dogs), human phar-

macokinetics was predicted that half-life time of HM12470 was expected to be ~132 hr and the peak-to-trough ratio was to be 1.6 on once weekly dosing. *In vitro* mitogenic potency of HM12470 was assessed by using cell proliferation in MCF-7 and SaOs-2 cells. Compared to its lipogenic efficacy assessed in fully differentiated 3T3-L1 adipocyte cells, the mitogenic to lipogenic potency ratio was significantly lower than that of human insulin.

**Conclusion:** HM12470 has a prolonged pharmacokinetic and pharmacodynamic profile in animal studies, and the predicted half-life and peak-to-trough ratio of HM12470 in human are promising once-weekly dosing potential with flat exposure profile. Moreover, HM12470 is expected to have low mitogenic potency based on *in vitro* results.

## 934

**The ultra-rapid biochaperone insulin lispro shows a faster onset of action and stronger early metabolic effect than insulin lispro alone**

G. Andersen<sup>1</sup>, B. Alluis<sup>2</sup>, G. Meiffren<sup>2</sup>, A. Ranson<sup>2</sup>, O. Soula<sup>2</sup>, G. Soula<sup>2</sup>, R. Soula<sup>2</sup>, A. Fischer<sup>1</sup>, L. Nosek<sup>1</sup>, F. Schliess<sup>1</sup>, T. Heise<sup>1</sup>;  
<sup>1</sup>Profil Institut für Stoffwechselforschung GmbH, Neuss, Germany,  
<sup>2</sup>Adocia, Lyon, France.

**Background and aims:** We investigated the pharmacodynamic characteristics of BioChaperone insulin lispro (BC LIS), a novel insulin lispro formulation with BioChaperone aimed at accelerating the absorption from the subcutaneous tissue.

**Materials and methods:** In this double-blind, crossover study people with type 1 diabetes received 0.2 U/kg of BC LIS or insulin lispro (LIS) alone under automated glycaemic clamp conditions (ClampArt<sup>®</sup>, target blood glucose 100 mg/dL, clamp duration 6h post-dosing).

**Results:** Thirty-seven patients were enrolled and 36 completed this study (age 42.7±13.4 years (mean±SD), BMI 24.8±1.7 kg/m<sup>2</sup>, HbA1c 7.6±0.6%). Mean glucose infusion rates (GIR) are given in the figure. Compared with LIS, BC LIS showed ultra-rapid properties with a faster onset of action (23.1±7.0 vs. 34.4±15.3 min, p<0.0001), an earlier maximum effect ( $T_{GIR\ max}$  99±42 vs. 133±45 min, p=0.0002) and a stronger early metabolic effect in the first hour ( $AUC_{GIR\ 0-1h}$  218±88 vs. 129±63 mg/kg, p<0.0001) and first 2 hours ( $AUC_{GIR\ 0-2h}$  627±235 vs. 525±214 mg/kg, p=0.0041). Total ( $AUC_{GIR\ 0-6h}$  1409±494 vs. 1434±506 mg/kg, p=0.72) and maximum metabolic effect ( $GIR_{max}$  7.85±2.87 vs. 7.96±2.81 mg/kg/min, p=0.76) were comparable. Both insulin formulations were well tolerated.

**Conclusion:** BC LIS has the characteristics of an ultra-fast acting insulin with a faster onset of action, an earlier maximum action and stronger metabolic effect in the first 2 hours than insulin lispro alone. BC LIS therefore has the potential to provide excellent postprandial glycaemic control.

**Comparison of duration of action of 2 insulin glargine products, LY2963016 and insulin glargine, in subjects with type 1 diabetes mellitus**  
H. Linnebjerg<sup>1</sup>, T. Heise<sup>2</sup>, X. Zhang<sup>1</sup>, M.E. Seger<sup>1</sup>, D. Coutant<sup>1</sup>, L. Chua<sup>3</sup>, E. Lam<sup>3</sup>;

<sup>1</sup>Eli Lilly and Company, Indianapolis, USA, <sup>2</sup>Profil, Neuss, Germany,

<sup>3</sup>Lilly-NUS Centre for Clinical Pharmacology, Singapore.

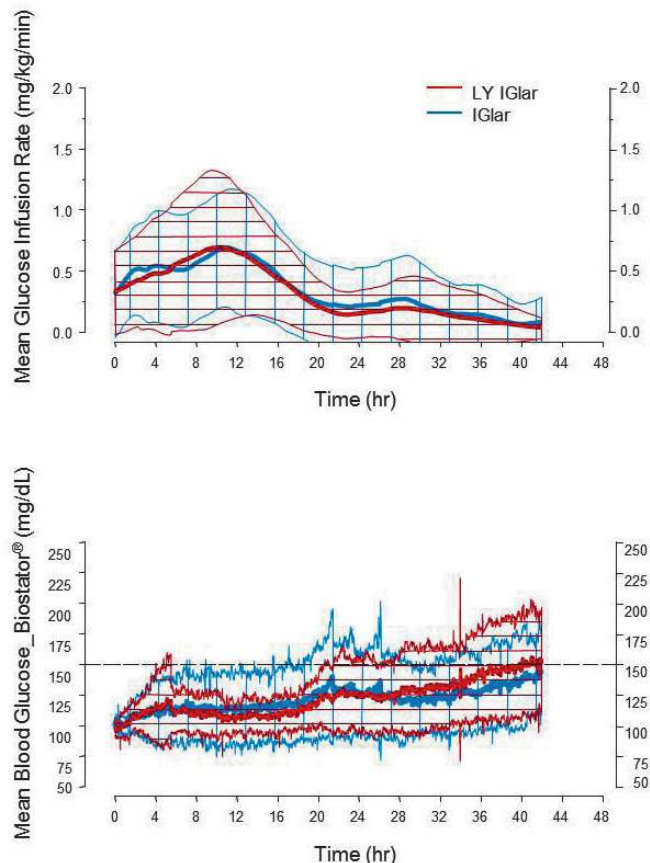

**Background and aims:** LY2963016 (LY IGLar) and insulin glargine (Sanofi-Aventis; IGLar) are both insulin glargine products, with identical amino acid sequences. Even with identical amino acid sequences, proteinbased therapeutics manufactured by distinct processes must be shown to be similar. This study compared the duration of action of LY IGLar and IGLar.

**Materials and methods:** This was a Phase I, randomised, doubleblind, 2period, crossover, glucose clamp study. Fasted male subjects with type 1 diabetes mellitus received a single subcutaneous dose of 0.3 U/kg LY IGLar and IGLar on 1 occasion each. A minimum 7day washout separated doses. Pharmacodynamic effects were assessed with a euglycaemic clamp (Biostator®, glucose target level 100 mg/dL [5.6 mmol/L]) lasting up to 42 hours postdose. Duration of action was defined as the time post dosing at which the subject's blood glucose level was consistently >150 mg/dL (8.3 mmol/L) without any glucose infusion.

**Results:** Twenty male subjects aged 2354 years with type 1 diabetes mellitus participated in this study. Based on timetoevent (survival) analysis, median duration of action was estimated to be 37.1 and 40.0 hours for LY IGLar and IGLar, respectively, while mean duration of action (standard error) was 23.8 (3.8) and 25.5 (3.9) hours for LY IGLar and IGLar, respectively. In 14 of the 40 clamps (7 LY IGLar, 7 IGLar), subjects' duration of action exceeded the 42hour clamp period. The mean profiles of the pharmacodynamic variables (glucose infusion rate and blood glucose) were similar between treatments over the 42hour clamps (see figure below). LY IGLar was well tolerated, with similar adverse event profiles observed following LY IGLar and IGLar dosing. No safety concerns from clinical laboratory, vital signs or ECG data were noted.

**Conclusion:** Similar pharmacodynamic effects and duration of action were demonstrated for LY IGLar and IGLar in this 42hour clamp study in subjects with type 1 diabetes mellitus.

**Figure: Mean (and 90% confidence interval) glucose infusion rate-time profiles (upper) and corresponding Biostator® glucose levels (lower) following a single subcutaneous administration of 0.3 U/kg LY IGLar (LY2963016) or IGLar (insulin glargine)**

## 936

**Higher early insulin exposure and greater early glucose-lowering effect with faster-acting insulin aspart in patients with type 1 diabetes mellitus**

H. Haahr<sup>1</sup>, U. Hövelmann<sup>2</sup>, L. Brøndsted<sup>1</sup>, C.L. Adrian<sup>1</sup>, L. Nosek<sup>2</sup>, T. Heise<sup>2</sup>;

<sup>1</sup>Novo Nordisk A/S, Søborg, Denmark, <sup>2</sup>Profil, Neuss, Germany.

**Background and aims:** Faster-acting insulin aspart (faster aspart) is insulin aspart (IAsp) in a new formulation containing two new excipients (nicotinamide and arginine), which result in a faster initial absorption after s. c. injection.

**Materials and methods:** In total, 52 patients with type 1 diabetes mellitus (mean ± standard deviation age: 40.3 ± 12.0 years; haemoglobin A<sub>1c</sub>: 7.3 ± 0.7%) were randomised to a single dose (0.2 U/kg s. c.) of faster aspart or IAsp under glucose clamp conditions (Biostator; blood glucose target 100 mg/dl; clamp duration 12 hours post-dose) in a crossover design.

**Results:** Compared with IAsp, faster aspart had a faster onset of appearance, i.e., time from trial drug administration until the first time serum insulin aspart concentrations reached the lower limit of quantification (mean difference [95% confidence interval (CI)]: -6.33 minutes [-7.30; -5.36]), earlier time to 50% C<sub>max</sub> (median difference [95% CI]: -11.0 minutes [-13.5; -9.0]), earlier t<sub>max</sub> (median difference [95% CI]: -7.5 minutes [-17.5; 0.0]), and greater early exposure up to 2 hours post-dose (e.g., 4.5-fold more insulin aspart in the circulation in the first 15 minutes post-dose); total exposure was similar (Table). Faster aspart had an earlier and higher glucose-lowering effect (indicated by higher glucose infusion rates, GIR) in the first 2 hours post-injection versus IAsp (Table) and an earlier time to 50% GIR<sub>max</sub> (mean difference [95% CI]: -7.81 minutes [-13.19; -2.44]). The maximum GIR and total glucose-lowering effect (Table) were similar between faster aspart and IAsp. No safety or tolerability issues were identified; in particular, no injection site reactions occurred.

**Conclusion:** Faster onset and higher early exposure with faster-acting insulin aspart led to a greater early glucose-lowering effect, indicating that faster aspart has the potential to improve postprandial glucose versus IAsp.

**Table:** PK and PD results for faster-acting insulin aspart versus insulin aspart.

| PK endpoints                            | Insulin exposure <sup>†</sup><br>Ratio [95% CI] | PD endpoints                              | Ratio [95% CI]    |
|---|---|---|-------------------|
| AUC <sub>0–15 minutes</sub>             | 4.53 [3.62; 5.66]                               | N/A                                       | N/A               |
| AUC <sub>0–30 minutes</sub>             | 2.05 [1.76; 2.38]                               | AUC <sub>GIR,0–30 minutes</sub>           | 1.48 [1.13; 2.02] |
| AUC <sub>0–1 hour</sub>                 | 1.28 [1.15; 1.43]                               | AUC <sub>GIR,0–1 hour</sub>               | 1.31 [1.18; 1.46] |
| AUC <sub>0–1.5 hours</sub> <sup>§</sup> | 1.11 [1.01; 1.22]                               | AUC <sub>GIR,0–1.5 hours</sub>            | 1.17 [1.05; 1.30] |
| AUC <sub>0–2 hours</sub>                | 1.04 [0.95; 1.14]                               | AUC <sub>GIR,0–2 hours</sub> <sup>‡</sup> | 1.10 [1.00; 1.22] |
| C <sub>max</sub>                        | 0.98 [0.90; 1.07]                               | GIR <sub>max</sub>                        | 1.02 [0.93; 1.12] |

## 937

### Biphasic pharmacokinetic and pharmacodynamic profiles associated with concentrated insulin BIOD-531 show rapid onset and basal duration of action

L. Morrow<sup>1</sup>, M. Hompesch<sup>1</sup>, L. Canney<sup>2</sup>, P. Pichotta<sup>2</sup>, A. Krasner<sup>2</sup>, E. De Souza<sup>2</sup>;

<sup>1</sup>Profil Institute for Clinical Research, Chula Vista,

<sup>2</sup>Biodel Inc., Danbury, USA.

**Background and aims:** Formulations of human insulin and insulin analogs containing citrate and EDTA have been shown to be more rapidly absorbed than commercially available insulin products. The aim of this study was to compare the pharmacokinetic (PK) and pharmacodynamic (PD) profiles of BIOD-531, a concentrated (400 U/ml or U-400) formulation of recombinant human insulin containing EDTA, citrate and MgSO<sub>4</sub>, to products marketed as combined prandial/basal insulins.

**Materials and methods:** A single-center, randomized, double-blind four-period crossover study employing 24-hour euglycemic clamps, evaluating the PK and PD profiles of BIOD-531 at two doses (1 U/kg and 0.5 U/kg) vs. Humulin® R U-500 (1 U/kg, U-500R) and Humalog® Mix75/25™ (0.5 U/kg, HU 75/25) in obese non-diabetic subjects.

**Results:** Thirteen subjects (age 39.8 ± 13.5 yrs; weight 99.5 ± 12.6 kg) were randomized. BIOD-531 was associated with an increased rate of absorption vs. U-500R as measured by multiple PK parameters including a 92% shorter time to early ½ T<sub>max</sub> (11.0 ± 1.9 min) vs. U-500R (135.3 ± 34.9 min), a 43% shorter time to T<sub>max</sub> (223.8 ± 62.3 min) vs. U-500R (393.3 ± 58.3 min) and a 765% increase in early insulin exposure as measured by AUC<sub>ins0–30min</sub> (2966 ± 383 mU\*min/L) vs. U-500R (343 ± 74 mU\*min/L). BIOD-531 was associated with a more rapid glucose lowering effect as measured by multiple PD parameters including a 66% faster time to onset of action (7.2 ± 4.1 min) vs. U-500R (21.4 ± 6.7 min) and 169% increase in AUC<sub>GIR0–60min</sub> (108.5 ± 22.0 mg/kg vs. U-500R (40.4 ± 10.0 mg/kg). These differences were all statistically significant. BIOD-531 was associated with an increased rate of absorption vs. HU 75/25 as measured by multiple PK parameters including a 66% shorter time to early ½ T<sub>max</sub> (16.4 ± 4.9 min) vs. HU 75/25 (47.9 ± 2.6 min), an 18% shorter time to T<sub>max</sub> (131.3 ± 43.4 min) vs. HU 75/25 (160.0 ± 11.9 min) and a 917% increase in early insulin exposure as measured by AUC<sub>ins0–30min</sub> (1200 ± 141 min) vs. HU 75/25 (118 ± 22 mU\*min/L). BIOD-531 was associated with a more rapid glucose lowering effect as measured by multiple PD parameters including a 59% faster time to onset of action (14.6 ± 6.0 min) vs. HU 75/25 (35.9 ± 7.9 min) and 375% increase in AUC<sub>GIR0–60min</sub> (68.9 ± 13.4 mg/kg) vs. HU 75/25 (14.5 ± 4.7 mg/kg). With the exception of T<sub>max</sub>, these differences were all statistically significant. The duration of action of BIOD-531 is approximately 18 hours, shorter than that of either comparator. All study drugs were well tolerated.

**Conclusion:** BIOD-531 is associated with more rapid onset of action than either marketed prandial/basal insulin product suggesting that it may provide improved mealtime glucose control with low injection volumes. Furthermore, the duration of action of BIOD-531 is consistent with a basal insulin.

### Pharmacokinetics and elimination of basal insulin peglispro (BIL) versus PEG-only in rats following a single IV or SC dose

M. Knadler, J.A. Martin, B.B. Ellis, P.L. Brown-Augsburger, A.T. Murphy, V.J. Wroblewski;

Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, USA.

**Background and aims:** BIL (LY2605541) is a novel, 20-kDa PEGylated insulin lispro that has a large hydrodynamic size. It has a prolonged duration of action which is related to a delay in insulin absorption and a reduction in clearance. The aim of this study was to examine the pharmacokinetics and elimination of BIL compared with 20-kDa PEG only in rats.

**Materials and methods:** Male Sprague Dawley rats were given a 0.5-mg/kg IV or 2-mg/kg SC dose of BIL with <sup>14</sup>C-labeled 20-kDa PEG portions of BIL or <sup>125</sup>I-labeled lispro portions of BIL. PEG only (<sup>14</sup>C-20-kDa PEG) was dosed at 10 mg/kg IV or SC. Blood for serum, urine, and feces were collected up to 336 h postdose. Samples were analyzed for <sup>14</sup>C using liquid scintillation counting, for <sup>125</sup>I using gamma counting, for BIL using ELISA, and for PEG-related products using liquid chromatography/mass spectrometry (MS) or size-exclusion chromatography.

**Results:** AUCs for BIL were 41% and 16% of circulating <sup>14</sup>C after IV and SC dosing, respectively. AUCs for BIL were 63% and 31% of circulating <sup>125</sup>I for IV and SC dosing, respectively. After SC dosing, t<sub>1/2</sub> of <sup>14</sup>C was 4.4-fold longer than that of <sup>125</sup>I. After IV dosing, BIL Cl was 2.4-fold faster than that of <sup>14</sup>C radioequivalents and 1.6-fold faster than that of <sup>125</sup>I radioequivalents indicating catabolism of BIL into products with longer half-lives. The t<sub>1/2</sub> and Cl of <sup>14</sup>C after PEG-only dosing were similar to those after BIL dosing. SC bioavailability of radiolabeled BIL was 23%–29%; absorption was ≥75%. The bioavailability of 20-kDa PEG-only was 78%. Excretion of radioactivity after IV or SC dosing of <sup>14</sup>C-BIL was generally similar. In the BIL study, <sup>14</sup>C was eliminated in urine and feces (urine:feces ratio, 0.9 for IV and 1.35 for SC). In the PEG-only study, most of the <sup>14</sup>C was recovered in urine after IV or SC administration. In the BIL study, ≥86% of <sup>125</sup>I was eliminated in urine mainly as small peptides, amino acids or free <sup>125</sup>I. After SC <sup>14</sup>C-BIL dosing, a mean ±SD of 2.5% ± 0.66% of the dose was excreted intact in urine. Based on qualitative MS analyses, the main PEG-related product found in serum and urine after BIL dosing was 20-kDa PEG with lysine attached. After PEG-only dosing, the main urinary product appeared to be intact PEG based on size-exclusion chromatography.

**Conclusion:** These data suggest that elimination of BIL is via catabolism to smaller peptides and/or amino acids and PEG with lysine attached. BIL is cleared faster than the products from catabolism. After BIL dosing, the PEG portion is eliminated via biliary and renal routes; after PEG alone, most of the <sup>14</sup>C dose is eliminated renally. The PEG in BIL would only partially depend on renal function for elimination, unlike PEG-only. The protein attached to PEG may direct the elimination of PEG.

### Pump use is less frequent in minority youth: transatlantic analysis in three large registries representing Austria, Germany, England, Wales and the United States

B. Rami-Merhar<sup>1</sup>, D. Maahs<sup>2</sup>, J. Warner<sup>3</sup>, S. Hofer<sup>4</sup>, W. Tamborlane<sup>5</sup>, J. Hermann<sup>6</sup>, A. Icks<sup>7</sup>, D. Schatz<sup>8</sup>, N. Foster<sup>9</sup>, R.W. Holl<sup>6</sup>;

<sup>1</sup>Medical University of Vienna, Austria, <sup>2</sup>University of Colorado, Denver, USA, <sup>3</sup>on behalf of the National Paediatric Diabetes Audit and the Royal College of Paediatrics and Child Health, Cardiff, UK, <sup>4</sup>Medical University of Innsbruck, Austria, <sup>5</sup>Yale School of Medicine, New Haven, USA, <sup>6</sup>University of Ulm, <sup>7</sup>Department of Public Health, Heinrich Heine University Düsseldorf, Germany, <sup>8</sup>University of Florida College of Medicine, Gainesville, <sup>9</sup>JAEB Center, Tampa, USA.

**Background and aims:** Use of insulin pumps has recently increased among children and adolescents with type-1 diabetes in many parts of the world. Patient and family preferences, beliefs and policies of healthcare professionals, expectations on metabolic goals, but also financial aspects / reimbursement by health insurance interact on the decision for or against CSII in individual patients. Each of these components depends on society and may be different for minority youth. Ideally, important treatment choices should be independent from the socio-economic background of a patient. The aim of this study was to evaluate this claim based on data from 3 large, multicenter registries.

**Materials and methods:** In total, 54,767 children and adolescents (<18 years) with T1D from the United States (T1D Exchange registry, n=13,966), England and Wales (National Paediatric Diabetes Audit, n=14,539) and Austria / Germany (DPV registry, n=26,262) with documented insulin therapy were available for analysis. Minority status was defined by ethnicity for UK and US, and by country of birth for Austria/Germany. Using a multivariable logistic regression model, the frequency of CSII was adjusted for differences in age, gender and diabetes duration among the 3 registries (SAS 9.4).

**Results:** Pump use differed among the 3 registries: 47.0 % in the US, 40.1 % in Austria/Germany and 13.9 % in the UK (p<0.001). After demographic adjustment, respective figures were 45.7 %, 40.5 % and 11.7 %. Despite different definitions, the percentage of minority youth was rather similar: 22.2 % in the US, 20.0 % in Austria/Germany and 23.8 % in the UK. In the whole cohort, 22.4 % of minority children, compared to 34.7 % of non-minority children, used insulin pumps (OR 0.543 [0.517, 0.570], p<0.001). This difference was detected in all 3 registries: US: 29.3 % versus 50.6 % on CSII, OR 0.403 [0.369 - 0.441]; Austria/Germany: 30.9 % versus 41.9 %, OR 0.621 [0.580 - 0.664] and UK: 8.1 versus 14.8 % on CSII, OR 0.507 [0.446-0.577].

**Conclusion:** Even after taking differences among age, gender and duration of diabetes among the registries into account, the use of CSII in children and adolescents differs markedly between the US, central Europe and the UK, 3 wealthy regions of the world. However, in all 3 registries, minority youth are significantly less likely to be treated with CSII. The reasons for this are likely to be complex, including health beliefs/acceptance of technology, patient selection by treatment facilities, including potential language barriers relevant for (technical) patient education, which is more demanding for CSII therapy. In addition, financial aspects, such as differences in availability of health insurance or reimbursement of CSII therapy, may play a role. In order to provide access to modern diabetes therapy irrespective of social background, more research into barriers to CSII use for minority youth in different societies is required.

### Cardiovascular outcomes and their relationship to risk factors and baseline disease over 4 years when starting insulin in type 2 diabetes: the CREDIT study

W. Scherbaum<sup>1</sup>, N. Freemantle<sup>2</sup>, F. Calvi-Gries<sup>3</sup>, N. Danchin<sup>4</sup>, M. Vincent<sup>5</sup>, P. Home<sup>6</sup>;

<sup>1</sup>Heinrich-Heine-University, University Hospital Düsseldorf, Germany, <sup>2</sup>University College London, UK, <sup>3</sup>AtlanStat, Rezé, France, <sup>4</sup>Université Paris 5, <sup>5</sup>Sanofi, Paris, France, <sup>6</sup>Newcastle University, Newcastle upon Tyne, UK.

**Background and aims:** To evaluate the relationship between risk factors/disease at baseline and adverse cardiovascular (CV) outcomes over 4 years from starting insulin therapy in people with type 2 diabetes (T2DM) in routine clinical practice in Europe, Canada, and Japan.

**Materials and methods:** CREDIT (Cardiovascular Risk Evaluation in people with Type 2 Diabetes on Insulin Therapy) was a noninterventional study of people with type 2 diabetes beginning insulin therapy in Europe, North America, and Asia. Data from people with T2DM starting any insulin were collected in 12 countries over 4 years ( $\pm$  6 months). Candidate explanatory variable for MACE+ (defined in Table) were age, sex, BMI, previous diagnosis of high blood pressure (BP), family history of premature CV disease, level of physical activity, smoking status, macrovascular disease, microvascular disease, HbA<sub>1c</sub> when starting insulin, and number of noninsulin antidiabetic treatments, first insulin regimen, time from diagnosis of T2DM, insulin dose (U/kg), systolic BP, diastolic BP, heart rate, antihypertensive treatment, antiplatelet/anticoagulant treatment, and statin/fibrate treatment. These variables were conditioned for multivariable survival analyses using a stepwise reduction process with forced inclusion of HbA<sub>1c</sub>. This enabled the estimate of the relationship between the variables and time to a composite of blindly adjudicated CV events.

**Results:** When starting insulin, participant characteristics (51% male) included median age of 61 years, 9.3 % HbA<sub>1c</sub> (78 mmol/mol), and 9.0 years' duration of diabetes. Survival models were based on 286 events in 2974 people. First insulin regimen and starting HbA<sub>1c</sub> were not predictive factors. The final multivariable Cox model included, as independent factors for MACE+, male gender, longer duration of diabetes, prior or current macrovascular disease, use of antihypertensive or of antiplatelet/anticoagulant medications, and lack of physical activity (Table).

**Conclusion:** Strong relationships were found between baseline factors and CV outcomes in people with T2DM starting insulin, after accounting for a number of explanatory characteristics. Evidence of CV disease at start of therapy (identified as prior macrovascular disease or use of antihypertensive/antiplatelet/anticoagulation therapy) was strongly predictive of a MACE+ event. Being physically active or being female was shown to have a strong protective effect for MACE+.

| Factor                                     | Modelled outcome  |          |
|--|-------------------|----------|
|  | MACE+             |          |
|  | HR (95% CI)       | P Value  |
| $\geq 1$ prior macrovascular disease (Y/N) | 2.88 (2.21, 3.77) | < 0.0001 |
| Gender (Female vs male)                    | 0.60 (0.47, 0.77) | < 0.0001 |
| Physical activity (yes vs no)              | 0.73 (0.58, 0.93) | 0.0101   |
| Duration of diabetes (years)               | 1.02 (1.00, 1.03) | 0.0105   |
| $\geq 1$ Blood pressure-lowering drug      | 1.65 (1.14, 2.39) | 0.0076   |

**Background and aims:** The aim of the present study was to assess the efficacy of telephone support on insulin treatment adherence in insulin naive type 2 diabetic patients using different insulin treatment regimens (basal, basal-bolus and premix) in third care medical centers in Turkey

**Materials and methods:** In this 12 week-open label randomized multicenter study A total of 1456 insulin naive type2 diabetic patients (mean age 56±12yrs, diabetes duration 6,0±6 yrs, 49.1% female) were recruited in 14 third care endocrine centers from different city's in Turkey. Patients randomized to telephonic intervention (TI) (50.3%) and control group (C) (%49.7). Primary outcome was medication adherence.

**Results:** At the end of the 12th week 83.2 % of TI group and %70.3 of the Control group were adherent to treatment (p<0,0001). According to insulin treatment regimens adherence rates were %76.9,%78.6,%74,1 for Basal-Bolus (BB), Premix and Basal regimens respectively and insulin regimens were not different in TI group. While patients on premixed insulin regimen were more compliant to insulin treatment compared to other regimens in control group (p<0.001). Non adherent subjects had shorter duration of diabetes and higher HbA1c levels compared to adherent subjects in the whole study group (p<0.01). Multivariate analysis indicate that illiterates, unwillingness to therapy are the independent risk factors for decreased adherence to insulin therapy. Noncompliance rates for daily insulin injections were 27%,15%,15.8% for basal-bolus ,premixed and basal insulin regimens respectively and was higher in basal bolus group compare to other insulin regimens (p<0.0001). Reported dropout causes of insulin therapy were depend on patients (56.8%) ,doctors (24.8%) and adverse effects of insulin (4.8%). Frequency of hypoglycemia (minor and major) were 30.5%, 34%, 11.2% for Basal-Bolus, Premixed and Basal regimens respectively (p<0.0001).

**Conclusion:** Telephonic intervention increases adherence and compliance to insulin treatment in insulin naive type 2 diabetic patients. Telephone communication between diabetes management team and diabetic patients could be considered as a part of routine follow up procedure in diabetes treatment

## 942

**Trajectories of HbA1c after initiation of insulin therapy in type 2 diabetes mellitus patients**

R. Mast<sup>1</sup>, I. Walraven<sup>1</sup>, T. Hoekstra<sup>1</sup>, D. Jansen<sup>1</sup>, A.A.W. van der Heijden<sup>1</sup>, P.J.M. Elders<sup>1</sup>, R.J. Heine<sup>2</sup>, J.M. Dekker<sup>1</sup>, J.G. Hugtenburg<sup>1</sup>, G. Nijpels<sup>1</sup>;

<sup>1</sup>EMGO Institute for Health and Care Research, VU University Medical Center, Amsterdam, Netherlands, <sup>2</sup>Eli Lilly and Company, Indianapolis, USA.

**Background and aims:** ADA/EASD guidelines for the management of type 2 diabetes mellitus (T2DM) recommend HbA1c levels of  $\leq 53$  mmol/mol. About 25% of all T2DM patients initiate insulin to reach this target. However, trajectories of the HbA1c levels after initiation of insulin have never been described and not much is known about characteristics associated with reaching and sustaining the HbA1c target. The aim of the current study was to identify subgroups of T2DM patients with distinct HbA1c trajectories after the start of insulin treatment and factors associated with reaching and sustaining the target HbA1c level ( $\leq 53$  mmol/mol).

**Materials and methods:** 798 T2DM patients from the Diabetes Care System (DCS) cohort of 9849 T2DM patients were included. Inclusion criteria: aged  $\geq 40$  year, initiated insulin during follow up after reaching a HbA1c level of  $\geq 53$  mmol/mol, with a follow up  $\geq 2$  years. Latent Class Growth Modelling (LCGM) was used to identify trajectories of HbA1c after the initiation of insulin. Cox regression analyses were used to determine which characteristics were associated with reaching and sustaining target HbA1c  $\leq 53$  mmol/mol.

**Results:** Four classes of HbA1c development were identified (figure 1). In the first class (3.8%) an gradual increase in HbA1c over time was seen, the second class (3.3%) showed a decrease in HbA1c during follow-up. The third class (5.1%) showed a good response to insulin treatment. The fourth class (87.8%) consisted of T2DM patients with stable HbA1c levels around 58 mmol/mol. During a mean follow-up of 4.5 years (SD 3.0), 174 patients (21.8%) reached and sustained the HbA1c target of  $\leq 53$  mmol/mol. Higher HbA1c levels at time of insulin initiation (HR 0.80 (95% CI 0.68 to 0.92)) and advanced age at baseline (HR 1.03 (95% CI 1.02 to 1.05)) were associated with reaching and sustaining the HbA1c target of  $\leq 53$  mmol/mol.

**Conclusion:** Less than a quarter of the patients achieved and sustained HbA1c levels  $\leq 53$  mmol/mol after insulin initiation. Low HbA1c level at the start of insulin, and higher age were associated with reaching the HbA1c target. Initiating insulin earlier, i.e. at lower HbA1c levels in T2DM patients, may improve the likelihood of achieving and sustaining glycemic control.

Figure 1 Trajectories of HbA1c over ten years in four classes of T2DM patients after initiation of insulin.

**Four-year analysis of insulin dose and hypoglycaemia in the real-world treatment of type 2 diabetes: results from the CREDIT study**

M. Pfohl<sup>1</sup>, N. Freemantle<sup>2</sup>, F. Calvi-Gries<sup>3</sup>, M.-P. Dain<sup>4</sup>, M. Vincent<sup>4</sup>, P. Home<sup>5</sup>;

<sup>1</sup>Evangelisches Bethesda-Krankenhaus zu Duisburg GmbH, Germany, <sup>2</sup>University College London, UK, <sup>3</sup>AtlanStat, Rezé, <sup>4</sup>Sanofi, Paris, France, <sup>5</sup>Newcastle University, Newcastle upon Tyne, UK.

**Background and aims:** CREDIT (Cardiovascular Risk Evaluation in People with Type 2 Diabetes on Insulin Therapy) was a noninterventional study of people starting insulin therapy in routine clinical practice in Europe, N. America, and Asia and followed for 4 years (n=2272 with 4-yr data).

**Materials and methods:** Baseline data were collected retrospectively to avoid influence on choice of insulin; data were extracted from regular clinical records. For this analysis, records of symptomatic and severe hypoglycaemia were extracted for the 6 months prior to the 1, 2, 3, and 4-year follow-up intervals.

**Results:** Total daily insulin dose increased 25.6% from year 1 to year 4 for all insulin regimens as taken at times of follow-up (Table). Overall, the percentage of patients reporting symptomatic hypoglycaemia was 18.5% at year 1 and 16.6% at year 4; event rates were between 0.8 and 1.5 per person across years and insulin regimens. Prevalence of severe hypoglycaemia was  $< 3.5\%$  for all insulins and years (except mealtime insulin alone at year 4); event rates ranged from 0.0 to 0.2 per person.

**Conclusion:** These CREDIT study results show that regardless of insulin regimen utilised (whether maintained from start or changed), total daily insulin dose increases over time, while symptomatic and severe hypoglycaemia were

relatively unchanged. Increased hypoglycaemia on insulin does not appear to be a necessary consequence of increased need for exogenous insulin with time in routine care.

**Insulin treatment across Europe: results from the GUIDANCE study**  
R.C. Vos, G.E.H. Rutten, GUIDANCE;  
Julius Center for Health Science and Primary Care, University Medical Center Utrecht, Netherlands.

**Background and aims:** Given the increasing prevalence of type 2 diabetes (T2DM), insulin treatment will be needed for a growing number of patients. Traditionally the conversion to insulin therapy has been managed in the secondary care setting, but more and more primary care physicians are involved in insulin therapy. We compared insulin treated patients across eight European countries, stratified to treatment setting.

**Materials and methods:** Data were available from the medical records of 1960 insulin treated T2DM patients of eight European countries, from mainly primary care (Belgium, France, Germany, Sweden, the Netherlands) and mainly secondary care (Italy, Ireland, the United Kingdom) countries. Patients from 'mainly primary care' and 'mainly secondary care' countries were compared for patient variables: age, sex, duration of diabetes, HbA1c, BMI, micro- and macro vascular complications, type of insulin treatment; and service variables: access of a nurse or a dietician, physician's number of T2DM patients treated, and physician's feelings about the diabetes guidelines. MLwiN for binomial multilevel analysis was used to analyse the relation of the patient and service variables with insulin treated patients from mainly primary and secondary care countries.

**Results:** Type of insulin treatment differed across European countries; insulin treated patients from mainly secondary care countries used more often short acting analogues (OR 2.54, 95%CI 1.89-3.43) and less often either NPH (OR 0.45, 95%CI 0.28-0.73), long acting analogues (OR 0.50, 95%CI 0.36-0.68) or short acting human insulin (OR 0.59, 95%CI 0.37-0.92) compared to those in mainly primary care countries. Further, insulin treated patients from the mainly secondary care countries showed higher HbA1c levels (OR 1.49, 95%CI 1.34-1.66) and had more often access to a dietician (OR 2.54, 95%CI 1.89-3.43), but were less likely to have macro vascular complications (OR 0.65, 95%CI 0.49-0.86). No clinical relevant differences were found for the other variables.

**Conclusion:** The results of this large European cross-sectional study show that T2DM patients on insulin and mostly treated in a primary care setting in five European countries did not differ from the same category of patients mainly treated in outpatient clinics or hospitals in three other countries, with the exception of type of insulin, HbA1c and the presence of macro vascular

complications. The decision to treat a T2DM patient in primary or secondary care is likely not based on clinical arguments.

**Metabolic control in type 2 diabetic patients with conventional or intensified insulin therapy: a retrospective single centre survey over a period of 22 years**

G. Kramer, N. Kuniss, C. Kloos, N. Mueller, A. Saemann, G. Wolf, U.A. Mueller;  
Dept. Internal Medicine III, University Hospital Jena, Germany.

**Background and aims:** The 2012 EASD/ADA position statement on management of hyperglycaemia in type 2 diabetes recommends mealtime insulin, consisting of one to three injections, when basal insulin has been titrated to an acceptable fasting glucose but HbA1c remains above target. The progression from basal insulin to a twice daily pre-mixed insulin (CT) is regarded as a "less studied alternative". Multiple insulin injection therapy (MIT) is regarded to be more easily adaptable to the patients needs. Therefore it is supposed that MIT is associated with better metabolic control and less hypoglycaemia compared to CT in patients with diabetes type 2 (DM2).

**Materials and methods:** HbA1c, insulin dose, body weight and incidence of non severe and severe hypoglycaemia were analysed in respect to the strategy of insulin therapy applied (MIT or CT). 20943 visits of 1447 insulin treated people with DM2 in a university outpatient department for endocrinology and metabolic diseases from a period of 22 years (9.1.1990 to 20.9.2012) were included. Data were drawn from the electronic patient record EMIL©. Because the strategy of insulin therapy changed over the long period, we compared visits with CT and visits with MIT. All visits with one or two insulin injections were classified as CT, visits with more than two injections as MIT. Visits with basal insulin only were not included. Non severe hypoglycaemia was defined as a condition with typical symptoms (e.g., sweating, feeling shaky, impaired concentration) which disappeared quickly after carbohydrate ingestion or a plasma glucose < 2.7 mmol/l with or without typical symptoms. Severe hypoglycaemia was defined as necessity of intravenous glucose injection. All patients participated in a structured education programme at least once. The normal range and mean value of HbA1c changed from 1999 to 2012, therefore we adjusted HbA1c according to the mean normal value of healthy people to the DCC trial (5.05 %).

**Results:** MIT was used in 13901 (66.4 %) of all 20943 visits. Compared to CT these patients were younger (62.0 ± 10.1 vs. 68.7 ± 9.9 years; p < 0.0001), time since diabetes diagnosis was longer (16.5 ± 8.7 vs. 15.8 ± 8.1 years; p < 0.0001), had higher BMI (32.8 ± 6.1 vs. 30.9 ± 5.3 kg/m<sup>2</sup>; p < 0.0001), a higher daily insulin dose (76.4 ± 52.0 vs. 46.5 ± 26.9 IU/day; p < 0.0001), and lower HbA1c (7.7 ± 1.4 vs. 7.9 ± 1.4 %; p < 0.0001). In MIT more non severe hypoglycaemic incidences per week (0.3 ± 0.7 vs. 0.2 ± 0.8; p = 0.01) occurred, episodes of severe hypoglycaemia/last 12 months were rare and comparable (0.02/Patient/year) with both insulin therapy strategies. Multiple, linear regression analysis showed that the only parameter associated with HbA1c was the insulin dose (β = 0.222, p < 0.001). Higher HbA1c is weakly associated with higher daily insulin dose, but not age (β = -0.019, p = 0.471), time since diabetes diagnosis (β = 0.060, p = 0.023) as well as incidence of non severe hypoglycaemia/week (β = 0.006, p = 0.797).

**Conclusion:** MIT and CT insulin therapy result in comparable metabolic control with HbA1c below 8 %. MIT is associated with higher BMI and

higher incidence of non severe hypoglycemia. People with DM2 should be actively involved in the decision which insulin therapy to choose considering the life style and convenience. Therapy strategies can be swapped if necessary.

### Less nocturnal hypoglycaemia and weight gain with new insulin glargine 300 U/ml vs 100 U/ml: 1-year results in people with type 2 diabetes using basal insulin and OADs (EDITION 2)

H. Yki-Järvinen<sup>1</sup>, R.M. Bergenstal<sup>2</sup>, G.B. Bolli<sup>3</sup>, M. Ziemien<sup>4</sup>, M. Wardecki<sup>5</sup>, I. Muehlen-Bartmer<sup>4</sup>, M. Marocchia<sup>6</sup>, M.C. Riddle<sup>7</sup>;

<sup>1</sup>University of Helsinki, Finland, <sup>2</sup>International Diabetes Center at Park

Nicollet, Minneapolis, USA, <sup>3</sup>University of Perugia, Italy,

<sup>4</sup>Sanofi-Aventis Deutschland GmbH, Frankfurt am Main, Germany,

<sup>5</sup>Sanofi, Warsaw, Poland, <sup>6</sup>Umanis, Levallois-Perret, France,

<sup>7</sup>Oregon Health & Science University, Portland, USA.

**Background and aims:** EDITION 2 investigated glycaemic control and hypoglycaemia using new insulin glargine 300 U/ml (Gla-300) versus glargine 100 U/ml (Gla-100) in people with type 2 diabetes mellitus on basal insulin plus OAD(s).

**Materials and methods:** In EDITION 2, 811 adults with type 2 diabetes mellitus and inadequate control of HbA<sub>1c</sub> were randomised to receive either Gla-300 or Gla-100 for 6 months. In this 6-month open-label extension, participants continued to receive Gla-300 or Gla-100 once daily plus OADs; 315 (78%) participants in the Gla-300 group and 314 (77%) participants in the Gla-100 group completed 12 months of treatment.

**Results:** Improved control of HbA<sub>1c</sub> was maintained at 12 months with each regimen. Over 12 months, per participant-year event rates of confirmed ( $\leq 3.9$  mmol/l [ $\leq 70$  mg/dl]) or severe nocturnal hypoglycaemia were 37% lower with Gla-300 than Gla-100 (1.74 vs 2.77, RR: 0.63 [95% CI: 0.42 to 0.96]). Fewer participants experienced  $\geq 1$  confirmed ( $\leq 3.9$  mmol/l [ $\leq 70$  mg/dl]) or severe nocturnal hypoglycaemic event with Gla-300 than Gla-100 (RR: 0.84 [95% CI: 0.71 to 0.99]). Severe hypoglycaemia at any time of day was infrequent, experienced by 7 participants in the Gla-300 group and 6 participants in the Gla-100 group. Body weight increase was observed in both groups, and was significantly less with Gla-300 than Gla-100 (LS mean [95% CI]: 0.42 [0.04 to 0.80] versus 1.14 [0.76 to 1.52] kg,  $p=0.0091$ ). No between-treatment differences in adverse events were seen.

**Conclusion:** Over 12 months of treatment, people with type 2 diabetes mellitus using Gla-300 and OADs had comparable glycaemic control, and experienced fewer nocturnal hypoglycaemic events and less weight gain compared with those using Gla-100.

Table – Glycaemic control and hypoglycaemia over 12 months in the EDITION 2 study

### New insulin glargine 300 U/ml: glycaemic control and hypoglycaemia in insulin-naïve people with type 2 diabetes mellitus (EDITION 3)

G.B. Bolli<sup>1</sup>, M.C. Riddle<sup>2</sup>, R.M. Bergenstal<sup>3</sup>, M. Ziemien<sup>4</sup>, K. Sestakauskas<sup>5</sup>, H. Goyeau<sup>6</sup>, P.D. Home<sup>7</sup>;

<sup>1</sup>University of Perugia, Italy, <sup>2</sup>Oregon Health & Science University, Portland, USA, <sup>3</sup>International Diabetes Center at Park Nicollet, Minneapolis, USA,

<sup>4</sup>Sanofi-Aventis Deutschland GmbH, Frankfurt am Main, Germany,

<sup>5</sup>Sanofi, Chilly Mazarin, <sup>6</sup>EXPERIS IT, Nanterre, France,

<sup>7</sup>Newcastle University, Newcastle upon Tyne, UK.

**Background and aims:** EDITION 3 studied the efficacy and safety of new insulin glargine 300 U/ml (Gla-300) vs glargine 100 U/ml (Gla-100) in people with type 2 diabetes mellitus uncontrolled on non-insulin therapy.

**Materials and methods:** In this 6-month, multicentre, open-label study, participants were randomised to once-daily Gla-300 or Gla-100 in the evening while stopping sulfonylureas. Insulin was titrated seeking FPG 4.4–5.6 mmol/l. The primary endpoint was HbA<sub>1c</sub> change to month 6. The main secondary endpoint was percentage of participants with  $\geq 1$  confirmed ( $\leq 3.9$  mmol/l [ $\leq 70$  mg/dl]) or severe nocturnal (00:00–05:59 h) hypoglycaemic event from week 9 to month 6.

**Results:** In total, 878 participants were randomised (baseline characteristics: BMI 33.0 kg/m<sup>2</sup>; diabetes duration 9.8 years; HbA<sub>1c</sub> 8.5 % [70 mmol/mol]). HbA<sub>1c</sub> decreased similarly with both treatments. LS mean changes (SE) were -1.42 [0.05] % (-15.5 [0.5] mmol/mol) with Gla-300 and -1.46 (0.05) % (-16.0 [0.5] mmol/mol) with Gla-100, and LS mean difference (95% CI) was 0.04 (-0.09 to 0.17) % (0.4 [-1.0 to 1.9] mmol/mol). The relative risk of experiencing  $\geq 1$  confirmed ( $\leq 3.9$  mmol/l [ $\leq 70$  mg/dl]) or severe nocturnal hypoglycaemic event with Gla-300 vs Gla-100 was 0.76 (95% CI: 0.59 to 0.99) for the 6-month treatment period, 0.74 (0.48 to 1.13) for baseline to week 8, and 0.89 (0.66 to 1.20) ( $p=0.45$ ) for week 9 to month 6. Using a stricter threshold of  $< 3.0$  mmol/l ( $< 54$  mg/dl), relative risks of experiencing  $\geq 1$  confirmed or severe nocturnal hypoglycaemia were 0.59 (0.33 to 1.06) for the entire 6-month treatment period, 0.73 (0.30 to 1.79) for the first 8 weeks of treatment, and 0.61 (0.31 to 1.21) for week 9 to month 6. Rates (per participant-year) of confirmed ( $\leq 3.9$  mmol/l) or severe events at any time of day (24 h) were lower with Gla-300 (rate ratio 0.75 [0.57 to 0.99]) over 6 months. Severe hypoglycaemia was infrequent (0.9% of participants experienced  $\geq 1$  event in both groups). Mean weight change was +0.4 (SD 3.8) kg with Gla-300 and +0.7 (3.8) kg with Gla-100. No differences in adverse events were seen.

**Conclusion:** In insulin-naïve people with type 2 diabetes mellitus, new insulin glargine 300 U/ml provides comparable effective glycaemic control, with less hypoglycaemia, compared with glargine 100 U/ml.

**Table: Hypoglycaemia in the EDITION 3 study: 6-month study period (safety population)**

### Similar efficacy and safety with LY2963016 insulin glargine compared with insulin glargine in patients with type 2 diabetes mellitus: the ELEMENT 2 study

P. Hollander<sup>1</sup>, J. Rosenstock<sup>2</sup>, A. Bhargava<sup>3</sup>, L.L. Ilag<sup>4</sup>, R.K. Pollom<sup>4</sup>, W.J. Huster<sup>1</sup>, M.J. Prince<sup>2</sup>;

<sup>1</sup>Baylor Endocrine Center, Dallas, <sup>2</sup>Dallas Diabetes and Endocrine Center,

<sup>3</sup>Iowa Diabetes and Endocrinology Research Center, Des Moines,

<sup>4</sup>Eli Lilly and Company, Indianapolis, USA.

**Background and aims:** LY2963016 (LY IGLar) and insulin glargine (Sanofi-Aventis; IGLar) are both insulin glargine products, with identical amino acid sequences. Even with identical primary structure, protein-based therapeutics manufactured by distinct processes must be shown to be clinically similar.

**Materials and methods:** This was a 24-week, Phase 3, randomized, double-blind, parallel study to compare the efficacy and safety of LY IGLar and IGLar. The primary objective was to test the non-inferiority (0.3% margin) of LY IGLar to IGLar as measured by change in HbA<sub>1c</sub> from baseline to 24 weeks in patients with T2DM on  $\geq$ 2 oral antihyperglycaemic medications (OAMs). Testing for non-inferiority of IGLar to LY IGLar was also performed and pre-specified as a complementary hypothesis, which if met along with the primary aim, would demonstrate equivalent efficacy between LY IGLar and IGLar. Patients were insulin-naïve (HbA<sub>1c</sub>  $\geq$ 7.0% to  $\leq$ 11.0%) or previously on IGLar (HbA<sub>1c</sub>  $\leq$ 11.0%). Insulin-naïve patients started on 10 U/day while those previously on IGLar started at an equivalent dose to their prestudy IGLar dose. Both groups followed a patient-driven titration algorithm until fasting blood glucose reached  $\leq$ 5.6 mmol/L. For blinding purposes, patients randomized to treatment were provided syringes and insulin vials contained in a partial cover that concealed distinguishing differences in vial appearance.

**Results:** Both treatment groups had within-group similarly significant ( $p < .001$ ) decreases in mean HbA<sub>1c</sub> values ( $\sim -1.3\%$  [Endpoint: LY IGLar, 7.04%; IGLar, 6.99%]). Change in HbA<sub>1c</sub> from baseline with LY IGLar was non-inferior to IGLar (Table). Noninferiority of IGLar to LY IGLar was also demonstrated; thus, criteria for equivalence in clinical efficacy between LY IGLar and IGLar were met. There were no treatment differences in secondary efficacy or safety outcomes, including hypoglycaemia and treatment-emergent antibody response, in the total population and in the insulin-naïve/prestudy IGLar subgroups. The treatment groups had similar mean (SD) overall nocturnal hypoglycaemia rate (events/patient/year) (LY IGLar: 7.46 (11.73),

IGlar: 8.08 (14.62),  $p = .686$ ) and only 2 patients per group experienced severe hypoglycaemia. Adverse event frequencies (LY IGLar, 52%; IGLar, 48%;  $p = .31$ ) were similar. No treatment differences were observed in mean (SD) weight change (kg) at endpoint, LY IGLar: 2.09 (3.80), IGLar: 2.33 (3.39),  $p = .334$ .

**Conclusion:** LY IGLar compared with IGLar in combination with OAMs provided equivalent efficacy and similar safety profiles in patients with T2DM.

### Insulin glargine 300 U/ml vs 100 U/ml: glucose profiles of morning vs evening injections in adults with type 1 diabetes mellitus measured with continuous glucose monitoring (CGM)

R.M. Bergenstal<sup>1</sup>, T.S. Bailey<sup>2</sup>, D. Rodbard<sup>3</sup>, M. Ziemann<sup>4</sup>, H. Guo<sup>5</sup>, I. Muehlen-Bartmer<sup>4</sup>, A.J. Ahmann<sup>6</sup>;

<sup>1</sup>International Diabetes Center at Park Nicollet, Minneapolis,

<sup>2</sup>AMCR Institute, Escondido, Biomedical Informatics Consultants, Potomac,

<sup>3</sup>Sanofi-Aventis Deutschland GmbH, Frankfurt am Main, Germany,

<sup>5</sup>BDM Consulting Inc., Somerset,

<sup>6</sup>Oregon Health and Science University, Portland, USA.

**Background and aims:** Previous euglycaemic clamp studies in type 1 diabetes (T1DM) showed that insulin glargine 300 U/ml (Gla-300) provides evenly distributed 24-h coverage due to low fluctuation and high reproducibility in insulin glargine exposure. The primary objective of this exploratory study in T1DM was to compare the percentage of time in the glycaemic range of 4.4–7.8 mmol/l, utilising CGM during Gla-300 vs insulin glargine 100 U/ml (Gla-100) treatment. HbA<sub>1c</sub>, mean glucose level, glucose variability and incidence of hypoglycaemia were evaluated.

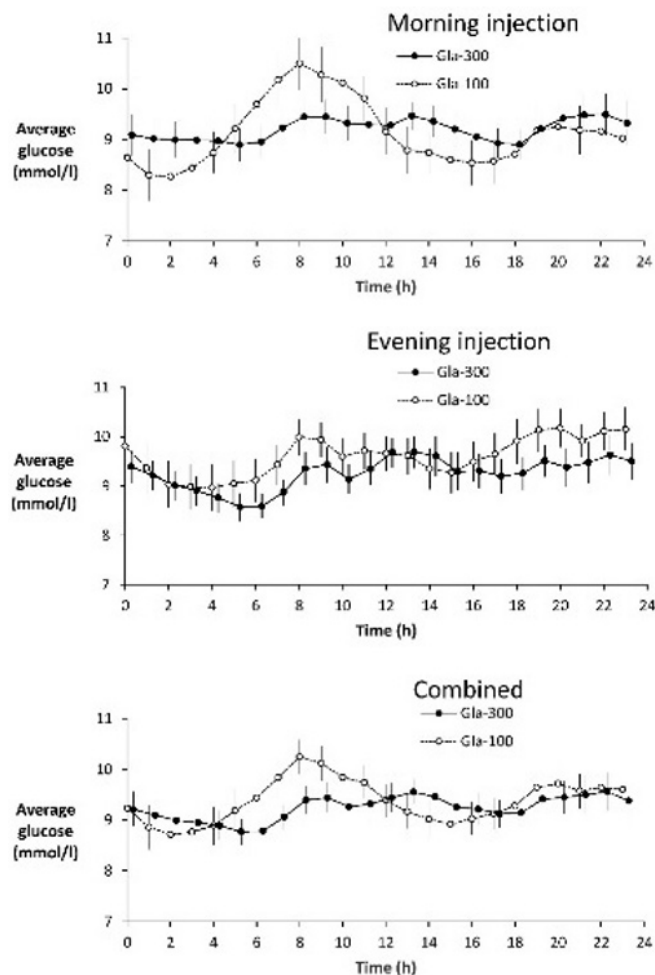

**Materials and methods:** In this multicentre, 16-week, open-label phase 2 study, 59 adults with T1DM (mean age 44.2 y; DM duration 22.1 y; baseline HbA<sub>1c</sub> 7.46 %) were randomised (1:1) to Gla-300 or Gla-100 once daily, with crossover between morning and evening injections. CGM data were evaluated during the last 2 weeks of each 8-week study period.

**Results:** HbA<sub>1c</sub> was similar for Gla-300 and Gla-100 (7.02 % vs 7.17 %) at week 16, and mean glucose (CGM sensor glucose [SG] from week 15–16) was similar for Gla-300 vs Gla-100 (9.2 mmol/l vs 9.4 mmol/l). The percentage of time SG was within the target range 4.4–7.8 mmol/l with Gla-300 and Gla-100 was 32% vs 31% (LS mean, difference [95% CI] 0.75 [-3.61 to 5.12] %, NS). Hypoglycaemia was lower for subjects receiving Gla-300 vs Gla-100 using SG thresholds of 3.9, 3.3, 2.8, and 2.2 mmol/l. Hyperglycaemia above thresholds of 10.0, 13.9, and 22.2 mmol/l was also lower. Frequency (%) of SG values 13.9 mmol/l for people on Gla-300 vs Gla-100 was mean (SD) 4.7 (3.3) vs 5.4 (4.3) and 12.7 (8.0) vs 16.4 (10.5), respectively. Mean 24-h glucose profiles, averaging SG during the last 2 weeks of each treatment period for all subjects on Gla-300 or Gla-100, showed less excursion on Gla-300 (Figure). When morning and evening injection periods were combined, all metrics for within-subject glycaemic variability were consistently lower with Gla-300: total standard deviation was lower by 7.4%, within day variability was lower by 5.4%, variability between daily means was lower by 14.3% and variability between days for the same time of day was lower by 7.2%.

**Conclusion:** In 59 adults with T1DM, Gla-300 injected either in the morning or the evening provided similar overall glucose control and percentage time

in target SG range (4.4–7.8 mmol/l) vs Gla-100, with less hypoglycaemia, a mean glucose profile for all subjects with less glucose excursion, and lower within- and between-day glucose variability.

### Getting the time right: is there any relationship between insulin administration-to-meal ingestion time interval and blood glucose control in type 2 diabetes?

U. Bujacz-Jedrzejczak, J. Loba, L. Czupryniak;  
Medical University of Lodz, Poland.

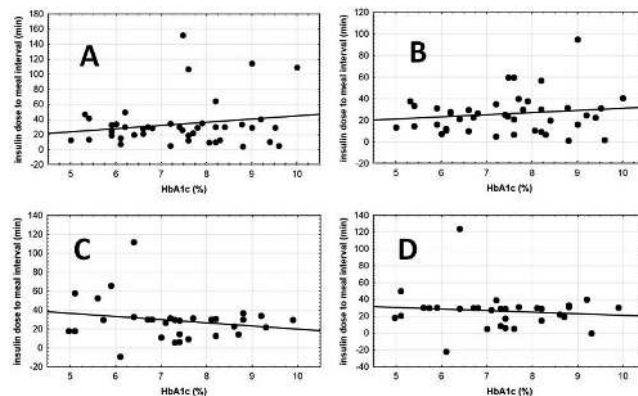

**Background and aims:** Patients treated with short-acting or premixed analog insulins are advised to take them immediately before a meal while those treated with classic human insulin are instructed to take insulin 20–30 minutes prior to a meal. The patients find the latter piece of advice difficult to comply with, and whether the compliance with recommended insulin dose-to-meal time interval (I-to-M, in minutes) has any relevance to metabolic control is unknown. We conducted a prospective observational study aiming at assessing the relationship between glucose control and mean duration of I-to-M.

**Materials and methods:** The study group consisted of 90 type 2 diabetes patients (mean age  $64 \pm 12$  years, duration of diabetes  $9.4 \pm 4.7$  years, HbA1c  $7.5 \pm 1.5\%$ , BMI  $30.8 \pm 4.4$  kg/m<sup>2</sup>), treated with insulin twice daily (before breakfast and evening meal), who were asked to record the actual hours of insulin injections and meal initiation for 30 consecutive days for I-to-M to be calculated. HbA1c was measured within 10 days after recordings were completed.

**Results:** There was no correlation between HbA1c and mean I-to-M in the whole study group. However, in the patients treated with analog insulins ( $n=51$ ) there was a trend to positive correlation between HbA1c and mean I-to-M, while in those treated with human insulins ( $n=39$ ) the trend was opposite (Fig. 1).

**Conclusion:** We conclude that compliance with the recommended pre-meal insulin dose timing might have some, albeit minor, impact on overall glucose control in type 2 diabetes.

Figure 1. Relationship between HbA1c and mean insulin dose to meal time interval in type 2 diabetes patients taking analog insulin in the morning (A) and evening (B) or taking human insulin in the morning (C) and evening (D).

### The impact of pure protein load on glucose levels in type 1 diabetes patients treated with insulin pumps

T. Klupa<sup>1,2</sup>, T. Benbenek-Klupa<sup>3</sup>, B. Matejko<sup>1</sup>, S. Mrozińska<sup>1</sup>, M. Małecki<sup>1,2</sup>;  
<sup>1</sup>Department of Metabolic Diseases, Jagiellonian University, <sup>2</sup>University Hospital, Krakow, Poland, <sup>3</sup>DiabMed Enterprise, Kraków, Poland.

**Background and aims:** It is well recognized that the mealtime insulin requirement in type 1 diabetes (T1DM) patients is driven mostly by carbohydrate content and controlling it may improve glucose levels. However, it is uncertain whether the calculation of other food components may optimize glycemic control. The aim of this study was to estimate the impact of pure protein load on glucose levels in T1DM patients treated with personal insulin pumps.

**Materials and methods:** We examined 10 T1DM patients (6 females, 4 males, mean age - 32.3 years, mean T1DM duration - 11.7 years, mean HbA1c - 6.85%) treated with insulin pump (Medtronic Paradigm 722 or Veo) equipped with a continuous glucose monitoring system (CGMS) option. In phase I of the study, baseline insulin infusion was optimized to minimize differences in fasting glucose levels to less than 30 mg/dL between any two time points between 9 am and 3 pm. The procedure of optimization was based on a retrospective analysis of CGMS records and included increasing or decreasing the rate of basal insulin infusion two hours before the observed rise or fall in glucose level. Then, the new settings of the basal infusion rate were rechecked with CGMS to meet the study criteria. In phase II, the patients were exposed to single, pure protein load (Protifar, Nutricia) at the dose of 0.3 g/kg (0.34 mL of Protifar/kg dissolved in 200 mL of water) of body weight administered at 9 a.m. Such a dose of protein is an equivalent of the usual protein portion in a medium-size meal, based on the dietary recommendations for patients with diabetes (15–20% of energy). The rate of basal insulin infusion during protein load was the same as defined initially in phase I, no modifications or extra insulin boluses were permitted. CGMS record was performed in both phases, during which the patients avoided physical activity. Glucose patterns were defined during 6 hours of phase I (fasting) and phase II (protein load).

**Results:** Mean baseline glucose level was 119.8 and 117.6 mg/dL for Phase I and Phase II, respectively ( $p=0.68$ ). Mean maximal glucose level was 146.4 and 145.2 mg/dL for Phase I and Phase II, respectively ( $p=0.85$ ). Mean maximal glucose level increment was similar for the entire 6-hour lasting fasting and protein load test (26.6 mg/dL vs. 27.6 mg/dL, respectively,  $p=0.78$ ). There was no difference between the change in baseline vs. 6th hour glucose levels for the fasting state vs. protein load test (12.5 mg/dL and 19 mg/dL, respectively,  $p=0.04$ ). The glucose variability assessed by CGMS-based standard deviation of mean glucose levels was 36.4 and 37.9 mg/dL for Phase I and Phase II, respectively ( $p=0.01$ ).

**Conclusion:** The administration of a pure protein load does not seem to have a clinically significant impact on glucose levels in T1DM patients treated with insulin pumps. Thus, we do not recommend protein content counting for glycemic control in this group of patients.

## 952

### Effects of insulin degludec and insulin glargine on day-to-day fasting blood glucose variability in patients with type 1 diabetes

T. Nakamura<sup>1</sup>, K. Sakaguchi<sup>1</sup>, A. So<sup>1</sup>, S. Nakajima<sup>2</sup>, M. Takabe<sup>2</sup>, H. Komada<sup>1</sup>, Y. Okuno<sup>1</sup>, Y. Hirota<sup>1</sup>, T. Nakamura<sup>3</sup>, K. Iida<sup>2</sup>, M. Kajikawa<sup>2</sup>, M. Nagata<sup>2</sup>, W. Ogawa<sup>1</sup>, S. Seino<sup>3</sup>;

<sup>1</sup>Diabetes, Metabolism and Endocrinology, Kobe University Graduate School of Medicine, <sup>2</sup>Best Basal Insulin Study Group, Kobe,

<sup>3</sup>Molecular and Metabolic Medicine, Kobe University Graduate School of Medicine, Japan.

**Background and aims:** Insulin degludec (IDeg), a novel ultra-long acting insulin analogue, has been suggested to have a longer and flatter glucose-lowering effect than insulin glargine (IGlar). It is thus possible that IDeg yields lower glycemic variability, in particular at fasting state. We have compared the effects of IDeg and IGlar on day-to-day variability of fasting blood glucose (FBG) in type 1 diabetes subjects treated with basal-bolus insulin injections.

**Materials and methods:** This open-label, multicenter, randomized crossover trial investigated the effects of 4-week basal-bolus insulin treatment with either IDeg or IGlar as a basal insulin. Patients who were found to satisfy the inclusion criteria were randomly allocated IGlar (first period) / IDeg (second period) or IDeg (first period) / IGlar (second period) groups. The last week of each treatment period was the data-collecting phase during which the patients were directed to examine blood glucose level 7 times per day. The level of glycoalbumin was measured at the end of each treatment period. The primary end point was the standard deviation (SD) and the coefficient of variation (CV) of FBG during the last week of the treatment period. Secondary end points included the level of glycoalbumin, the dose of daily insulin, the intra-day variability of blood glucose level, and the frequency of severe hypoglycemia. Data are shown as means  $\pm$  SD, and were statistically analyzed with the paired t-test.

**Results:** Thirty-six randomized subjects (17 in the IDeg/IGlar and 19 in the IGlar/IDeg groups) were recruited, and the data of 32 subjects who completed the trial were analyzed (age:  $57.4 \pm 13.9$  years, BMI:  $22.6 \pm 3.2$  kg/m<sup>2</sup>, HbA1c:  $7.4 \pm 0.8$  %). The mean ( $139.5 \pm 31.8$  vs.  $154.2 \pm 37.2$  mg/dL,  $P = 0.03$ ) and the SD ( $46.9 \pm 17.5$  vs.  $57.5 \pm 24.6$  mg/dL,  $P = 0.02$ ) of FBG were smaller during the IDeg treatment period than those during the IGlar treatment period whereas the CV was not different between the two periods (IDeg  $34.3 \pm 13.3$  vs. IGlar  $37.1 \pm 13.0$  mg/dL,  $P = 0.29$ ). The level of glycoalbumin was similar in the two treatment periods (IDeg  $21.5 \pm 3.0$  vs. IGlar  $21.8 \pm 3.6$  mg/dL,  $P = 0.39$ ). The daily dose of basal insulin in the IDeg period was slightly but significantly smaller than that in the IGlar period (IDeg  $11.0 \pm 5.2$  vs. IGlar  $11.8 \pm 5.6$  units/day,  $P < 0.01$ ). The SD of the 7 measurements of blood glucose was similar in the two treatment periods (IDeg  $56.4 \pm 15.3$  vs. IGlar  $61.0 \pm 16.9$  mg/dL,  $P = 0.19$ ). No severe hypoglycemia was observed during the trial period.

**Conclusion:** In patients with type 1 diabetes, IDeg yielded lower FBG levels with lower day-to-day variability of FBG as compared to IGlar. IDeg is thus a useful option for the supplementation of basal insulin in type 1 diabetes.

## 953

### Low within- and between-day variability in exposure to new insulin glargine 300 U/ml

R.H. Becker<sup>1</sup>, I. Nowotny<sup>1</sup>, L. Teichert<sup>1</sup>, K. Bergmann<sup>1</sup>, C. Kapitza<sup>2</sup>;

<sup>1</sup>Sanofi-Aventis Deutschland GmbH, Frankfurt am Main, Germany,

<sup>2</sup>Profil, Neuss, Germany.

**Background and aims:** Low fluctuation and high reproducibility in exposure are needed for effective and safe basal insulin use.

**Materials and methods:** Fifty people with type 1 diabetes mellitus underwent two 24-h euglycaemic clamps in steady state conditions after 6 QD administrations of  $0.4$  U.kg<sup>-1</sup> in a double-blind, randomised, two-way crossover study demonstrating equivalence in bioavailability of new insulin glargine 300

U.ml<sup>-1</sup> (Gla-300) formulations (R, standard cartridge; T, vial formulation). Serum insulin (INS) concentration was analysed by radioimmunoassay.

**Results:** The INS-AUC point estimate of T/R was 1.00 (90% CI: 0.95 to 1.06). Due to low fluctuation in INS-concentration over time (Table), median cumulative exposure (INS-AUC<sub>i</sub>/INS-AUC<sub>24</sub>) developed linearly over 24 h, and excursion (BDE =  $[C_{\max} - C_{\min}]/2$ ) from the average concentration within 24 h ( $C_{\text{AVG}} = \text{INS-AUC}_{24}/24$ ) was only  $3.3$   $\mu\text{U.ml}^{-1}$ . Within-day variability (fluctuation; peak-to-trough ratio [PTR] =  $C_{\max}/C_{\min}$ ) was  $<2$ . SWING ( $[C_{\max} - C_{\min}]/C_{\min} = \text{PTR}-1$ ) and peak-to-trough fluctuation (PTF =  $[C_{\max} - C_{\min}]/C_{\text{AVG}}$ ) were  $<1$ . Between-day variability (reproducibility; within-subject coefficient of variation for exposure, CV% [INS-AUC]), was 17.4% (90% CI: 14.9 to 21.1), at a between-subject CV% (INS-AUC) of 34.8% (90% CI: 28.8 to 43.4).

**Conclusion:** Gla-300 appears suitable for safe, effective basal insulin use, providing evenly distributed 24-h coverage at a clinically relevant dose of  $0.4$  U.kg<sup>-1</sup> due to low fluctuation and high reproducibility in insulin glargine exposure.

### Simulating the glycaemic impact of meal insulin dose determinations using continuous glucose monitoring vs self-monitored blood glucose

D. Price<sup>1</sup>, S. Nandagopalan<sup>2</sup>;

<sup>1</sup>Dexcom, Carlsbad, <sup>2</sup>San Jose, USA.

**Background and aims:** Current continuous glucose monitoring (CGM) systems are labeled as adjunctive to self-monitored blood glucose (SMBG). The user guides provide instructions that diabetes management decisions should be based on blood glucose values. However, there are many anecdotes and emerging data that some CGM users make their dosing decisions based on the CGM data. This Monte Carlo simulation compares the impact of determining a pre-meal insulin dose using CGM and SMBG glucose on the frequency of post-meal hypoglycemia ( $<70$  mg/dL, 3.8 mmol/L) and hyperglycemia ( $>180$  mg/dL, 10.0 mmol/L).

**Materials and methods:** The dose is calculated from pre-meal glucose and estimated carbohydrate (CHO) count and targets a post-meal glucose of 100 mg/dL (5.6 mmol/L), allowing CGM users an adjustment based on the direction and rate of glucose change (ROC). The study quantifies the impact of this adjustment at different magnitudes of CHO counting errors and assumes correct dosing parameters. The evaluation is based on simulated patient data across ranges of pre-meal glucose (50 to 400 mg/dL, 2.8 to 28 mmol/L), ROC ( $-4$  to  $4$  mg/dL/minute,  $-0.2$  to  $0.2$  mmol/L/minute) and CHO (30 to 100 grams). The dose and post-meal glucose are calculated using a simplified but realistic model and allows comparison of hypoglycemia and hyperglycemia frequencies for the two monitoring methods. The model considers the differences in device accuracy and precision. However, it does not consider the impact of outlier glucose values (from either SMBG or CGM) or include the use of CGM alerts.

**Results:** Both methods perform similarly when ROC is close to 0. With CGM, the frequency of hypoglycemia and hyperglycemia changes little across the ROC range. At negative values of ROC, SMBG results in a higher frequency of hyperglycemia and a lower frequency of hypoglycemia, compared to CGM. The opposite is true at positive ROC. As CHO error increases, so does the frequency of hyperglycemia and hypoglycemia, and the differences between dosing decisions using CGM and SMBG are minimized.

**Conclusion:** Similar to carbohydrate counting errors, the direction and ROC at the time of the insulin dose can have major impacts on subsequent rates of hypoglycemia and hyperglycemia. Accordingly, in order to optimize glycemic control, the direction and ROC should be considered when determining a meal insulin dose. This model suggests that using CGM data to determine a dose has glycemic advantages relative to using a static SMBG measurement.

**Least glucose variability is observed with the combination of a GLP-1 agonist and basal insulin among four commonly used insulin regimens in type 2 diabetes (VARIATION study)**

H.S. Bajaj<sup>1</sup>, R. Aronson<sup>2</sup>, C. Ye<sup>3</sup>, K. Venn<sup>3</sup>, A.L. Patrick<sup>2</sup>; <sup>1</sup>LMC Diabetes & Endocrinology, Brampton, <sup>2</sup>LMC Diabetes & Endocrinology, Toronto, <sup>3</sup>McMaster University, Hamilton, Canada.

**Background and aims:** The majority of insulin management trials to date have focused on HbA1c as the primary measure of glycemic control. Limited data pertaining to glucose variability with various insulin regimen exists in the literature. This cohort study compares glucose variability in patients with well-controlled type 2 diabetes (DM) among four commonly-used insulin regimen (A= basal insulin + oral drugs, B= basal insulin + GLP-1 agonist, C= pre-mix insulin and D= basal-bolus insulin).

**Materials and methods:** Eighty patients were recruited from five of our diabetes clinics in Ontario, Canada between November 2013 and March 2014. Study inclusion criteria were 1. type 2 DM; 2. age between 18 to 80 years; 3. BMI ≤ 45 kg/m<sup>2</sup>; 4. stable insulin regimen for a minimum of 6 months; 5. clinically stable HbA1c value of ≤7.5% within 3 months before study enrolment. Participants were instructed to follow usual diet and exercise regimen during the 6-day, masked Continuous Glucose Monitoring (CGM) period. Daily glucose standard deviation (SD) was chosen as the primary outcome for the study. Six patients were excluded from analysis (three for clinical instability; three for missed medication doses during 6-day CGM period).

**Results:** Key baseline clinical characteristics as well as CGM results are presented in Table 1. Each of the four study cohorts had an average HbA1c of 7.0%. Statistically significant differences were observed on inter-cohort comparisons on Analysis of Covariance (ANCOVA) modeling - with the lowest SD observed in cohort B compared to cohorts C and D (1.8 mmol/L vs. 2.1 and 2.2 mmol/L; p=0.05 and 0.01, respectively). SD of cohort B was also numerically less compared to that for cohort A (2.0 mmol/L), however this did not reach statistical significance (p=0.15). Self-reported hypoglycemia episodes during the 6-day study period were highest among cohort D compared to the other three cohorts (p=0.01 vs. cohorts A & B; p=0.03 vs. cohort C). No other statistically significant differences were observed on inter-cohort comparisons for CGM measurements (frequency, duration and degree of hypoglycemia or hyperglycemia).

**Conclusion:** Among patients with Type 2 DM who have well-controlled HbA1c on insulin, least glucose variability is observed in the combination regimen using basal insulin with a GLP-1 agonist. This reduced glucose variability with GLP-1 agonists suggests their complementary glycemic action with basal insulin and is explained by known mechanisms of action for this incretin-based injectable medication class - with multi-pronged effects on both alpha and beta cells in the pancreas as well as appetite suppression.

**Sodium glucose co-transporter-2 (SGLT2) inhibitor empagliflozin (EMPA) in type 1 diabetes (T1D): impact on diurnal glycaemic patterns**

B.A. Perkins<sup>1</sup>, D.Z. Cherney<sup>2</sup>, H. Partridge<sup>1</sup>, N. Soleymanlou<sup>3</sup>, H. Tschirhart<sup>1</sup>, B. Zinman<sup>1</sup>, R. Mazze<sup>4</sup>, N. Fagan<sup>5</sup>, S. Kaspers<sup>6</sup>, H.J. Woerle<sup>6</sup>, U.C. Broedl<sup>6</sup>, O. Johansen<sup>7</sup>;

<sup>1</sup>Department of Medicine, Division of Endocrinology, University of Toronto, <sup>2</sup>Department of Medicine, Division of Nephrology, Toronto General Hospital, University of Toronto, <sup>3</sup>Boehringer Ingelheim Canada Ltd./Ltée, Burlington, Canada, <sup>4</sup>International Diabetes Center, Park Nicollet Institute, Minneapolis, <sup>5</sup>Boehringer Ingelheim Pharmaceuticals, Inc., Ridgefield, USA, <sup>6</sup>Boehringer Ingelheim, Ingelheim, Germany, <sup>7</sup>Boehringer Ingelheim Norway KS, Asker, Norway.

**Background and aims:** We recently reported improved glycemic control, decreased hypoglycemia incidence, and reduced insulin dose in T1D patients treated with open-label EMPA. To further characterize the effects, we analysed glucose patterns by continuous glucose monitoring (CGM).

**Materials and methods:** In this 8-week single-arm open-label pilot study of EMPA (NCT01392560), we compared ambulatory glucose profiles (AGP) during 2-week intervals in a placebo run-in, end-of-treatment, and post-treatment period. Glucose exposure was measured by total area under the curve (AUC<sub>TOTAL</sub> in mg/dL-h), AUC<sub>NIGHT</sub> (23:00 to 6:59h) and AUC<sub>DAY</sub> (7:00 to 22:59h). Glucose Variability was represented by inter-quartile range and Glucose Stability by the average hourly absolute change (in mg/dL/hr) of all CGM readings in the 2-week periods.

**Results:** 40 patients aged 24±5 years, and A1c 8.0±0.9% completed the trial. 39 patients had data available for the analysis of the CGM endpoints. Though A1c decreased (8.0±0.9% to 7.6±0.9%, p<0.0001), AUC<sub>TOTAL</sub> decreased non-significantly from 153.7±25.4 to 149.0±30.2 mg/dL-h (p=0.31) and increased post-treatment (164.1±29.5 mg/dL-h, p=0.02 vs. baseline). The trend of decrease in AUC<sub>NIGHT</sub> (152.0±36.6 to 141.9±34.4 mg/dL-h, p=0.13) exceeded AUC<sub>DAY</sub> (154.5±24.5 to 152.6±30.4 mg/dL-h, p=0.65). Glucose Variability showed a decreasing trend (from 83.1±18.9 to 75.6±28.6 mg/dL, p=0.06) more than Glucose Stability (from 10.8±3.6 to 10.3±4.5 mg/dL/h, p=0.51), and subsequently levels increased relative to pre-treatment levels (89.3±19.3, p=0.04 and 11.8±3.7, p=0.08) when EMPA was discontinued. The on-treatment changes occurred despite basal insulin reduction (25.7±10.6 to 19.5±7.9U, p<0.0001) without significant bolus reduction (29.0±15.8 to 27.0±14.2U, p=0.19).

**Conclusion:** The improved A1c observed with EMPA was associated with a pattern of improved night-time glycaemia more prominent than daytime.

### A single dose pharmacokinetic study of basal insulin peglispro in subjects with hepatic impairment

S.L. Choi<sup>1</sup>, C. Lohin<sup>2</sup>, P. Garhyan<sup>3</sup>, M.P. Knadler<sup>3</sup>, E. Lam<sup>1</sup>, V. Sinha<sup>4</sup>, N. Porksen<sup>3</sup>, H. Linnebjerg<sup>3</sup>;

<sup>1</sup>Eli Lilly-NUS Centre for Clinical Pharmacology, Singapore,

<sup>2</sup>Clinical Pharmacology, Eli Lilly and Company, Indianapolis,

<sup>3</sup>US Endocrinology/Diabetes Care, Eli Lilly and Company, Indianapolis,

<sup>4</sup>Office of Clinical Pharmacology, Center for Drug Evaluation and Research, Silver Spring, USA.

**Background and aims:** Basal insulin peglispro (BIL; LY2605541) is being developed for the treatment of type 1 and type 2 diabetes mellitus (T2DM) as a once daily subcutaneous (SC) administration. BIL is a novel, PEGylated insulin lispro that has a large hydrodynamic size. It has prolonged duration of action which is related to a delay in insulin absorption and a reduction in clearance. The patient population may include those with hepatic impairment, so the pharmacokinetics (PK) of BIL was assessed in subjects with varying degrees of hepatic impairment compared to healthy subjects with normal hepatic function.

**Materials and methods:** In this parallel-group, open-label study, 35 subjects received a single SC dose of 0.33 U/kg (0.075 mg/kg) BIL and blood samples for PK were taken up to 9 days postdose. BIL PK was determined using a specific, validated enzyme-linked immunosorbent assay method. PK parameters were calculated using noncompartmental analyses. The effect in subjects with hepatic impairment was compared to subjects with normal hepatic function using the ratio of least squares (LS) geometric means of primary PK parameters: area under the concentration time curve from zero to infinity ( $AUC(0-\infty)$ ) and maximum observed drug concentration ( $C_{max}$ ).  $AUC(0-\infty)$  and  $C_{max}$  were log transformed and analyzed using an Analysis of Variance model with group as a factor.

**Results:** In total, 35 subjects were assessed (12 with normal hepatic function; 8 mild, 8 moderate, 7 severe hepatic impairment, based on the Child-Pugh criteria). Subjects were nondiabetic, apart from one subject with T2DM (moderate hepatic impairment). Subjects were male (57%) and female (43%), 41–69 years old, with mean body mass index (SD) 27.7 kg/m<sup>2</sup> (4.52 kg/m<sup>2</sup>). Healthy subjects were matched to hepatically impaired subjects for age ( $\pm 10$  years), weight ( $\pm 10$  kg), and gender. Ratios of the LS geometric means and 90% confidence intervals (CIs) for  $AUC(0-\infty)$  for mild, moderate, and severe hepatically impaired subjects to the healthy subjects were 0.789 (0.556, 1.12), 0.744 (0.525, 1.06), and 0.782 (0.543, 1.12), respectively. Ratios (90% CIs) for  $C_{max}$  were 0.728 (0.398, 1.33), 0.905 (0.495, 1.65), and 0.840 (0.448, 1.58), respectively. Median time of  $C_{max}$  and mean half-life were similar between the hepatically impaired subjects and healthy subjects. Healthy subjects reported 7 treatment emergent adverse events (TEAEs) (5 of 12 subjects; 41.7%) and hepatically impaired subjects reported 7 TEAEs (1 TEAE reported by 1 of 8 [12.5%] mild; 3 TEAEs reported by 2 of 8 [25.0%] moderate, and 3 TEAEs reported by 2 of 7 [28.6%] severe). The majority of TEAEs were mild in severity. TEAEs experienced by >1 subject included hypoglycemia, nausea, fatigue, and headache.

**Conclusion:** Single doses of BIL were well tolerated by hepatically impaired and healthy subjects in this study. A substantial overlap of  $AUC(0-\infty)$  and  $C_{max}$  was observed across all groups. Although the mean  $AUC(0-\infty)$  and  $C_{max}$  were lower in hepatically impaired subjects, the ratios between hepatically impaired and healthy subjects were not statistically different. Based on data from this study, requirement for dose adjustment of BIL in subjects with hepatic impairment would not be anticipated.

### Conventional insulin therapy (CT) vs multiple insulin injection (MIT) in type 2 diabetes: analysis of a quality assurance project (DPV)

C.S. Kloos<sup>1</sup>, G. Kramer<sup>1</sup>, U.A. Müller<sup>1</sup>, R. Schiel<sup>2</sup>, S. Hofer<sup>3</sup>, S. Merger<sup>4</sup>, W. Kerner<sup>5</sup>, R.W. Holl<sup>6</sup>;

<sup>1</sup>Internal Medicine, Klinikum für Innere Medizin III, Jena,

<sup>2</sup>Medigreif Inselklinik Heringsdorf, Germany, <sup>3</sup>Medical University of Innsbruck, Austria, <sup>4</sup>Pediatric Department, University Ulm,

<sup>5</sup>Karlsburg Hospital, <sup>6</sup>Institute for Epidemiology and Medical Biometry, Ulm, Germany.

**Background and aims:** People with type 2 diabetes and insulin therapy receive predominantly an intensive form of insulin treatment with multiple insulin injections (MIT). Evidence from randomized studies for the superiority of MIT over CT in type 2 diabetes is lacking, but MIT produced increased weight gain, higher costs of therapy and more hypoglycaemic episodes. This survey provides data from a project of quality assurance in Germany and Austria (DPV) with documentation of insulin treatment in type 2 diabetes.

**Materials and methods:** Patients older than 18 years with type 2 diabetes and insulin treatment were extracted from the DPV database. CT was defined as 2 insulin injection time-points per day, MIT as more than 2 insulin injection time-points per day. Patients with less than 2 daily insulin injection time-points and patients with LADA (positive  $\beta$ -cell antibodies) were excluded from the analysis. Patients with insulin therapy and Metformin as concomitant therapy were included, but not evaluated separately.

**Results:** A total of 88 519 (CT 23 118 (26%); MIT 65 401 (74%)) patients were analysed. Patients with CT (44% male) compared to patients with MIT (53% male) were older (74.6 (10.2) vs. 66.7(12.0) years), had comparable time from diabetes diagnosis (13.0 (9.5) vs. 13.4 (9.8) years), lower BMI (29.1 (5.7) vs. 31.7 (6.7)kg/m<sup>2</sup>), lower daily insulin dose (39.2 (20.2) vs. 65.3 (41.1) IE/day) and better HbA<sub>1c</sub> (7.81 (1.9) vs. 8.14 (2.0)%;  $p < 0.001$ ; normal mean 5.05%). Hypoglycaemic events (per patient/year) with need for help was comparable in both groups (1.02 (1.07) vs. 1.06 (1.24)), hypoglycaemia with coma was associated more often with CT (0.051 (0.43) vs. 0.038 (0.38)).

**Conclusion:** In a non randomized, multicentric, observational survey with data derived from clinical routine care, glycaemic control of people with CT was comparable to people with MIT. Patients with MIT were predominantly male, younger, had higher BMI and needed more insulin. Hypoglycaemic episodes had a similar incidence compared to other studies in patients with insulin-treated type 2 diabetes.

### Preserved pharmacokinetic properties and distinct glycaemic effects of insulin degludec and liraglutide in IDegLira, a fixed ratio combination product

C. Kapitza<sup>1</sup>, B.W. Bode<sup>2</sup>, S.H. Ingwersen<sup>3</sup>, L.V. Jacobsen<sup>3</sup>, P. Poulsen<sup>3</sup>;

<sup>1</sup>Profil Institut fuer Stoffwechselforschung GmbH, Neuss, Germany,

<sup>2</sup>Atlanta Diabetes Associates, USA, <sup>3</sup>Novo Nordisk A/S, Søborg, Denmark.

**Background and aims:** Insulin degludec/liraglutide (IDegLira) is a novel fixed ratio combination of insulin degludec (IDeg), a basal insulin with an ultra-long duration of action, and liraglutide (Lira), a once-daily glucagon-like peptide-1 analogue. The pharmacokinetics (PK) and pharmacodynamics of IDegLira were compared with those of the mono-components in healthy volunteers and in subjects with type 2 diabetes.

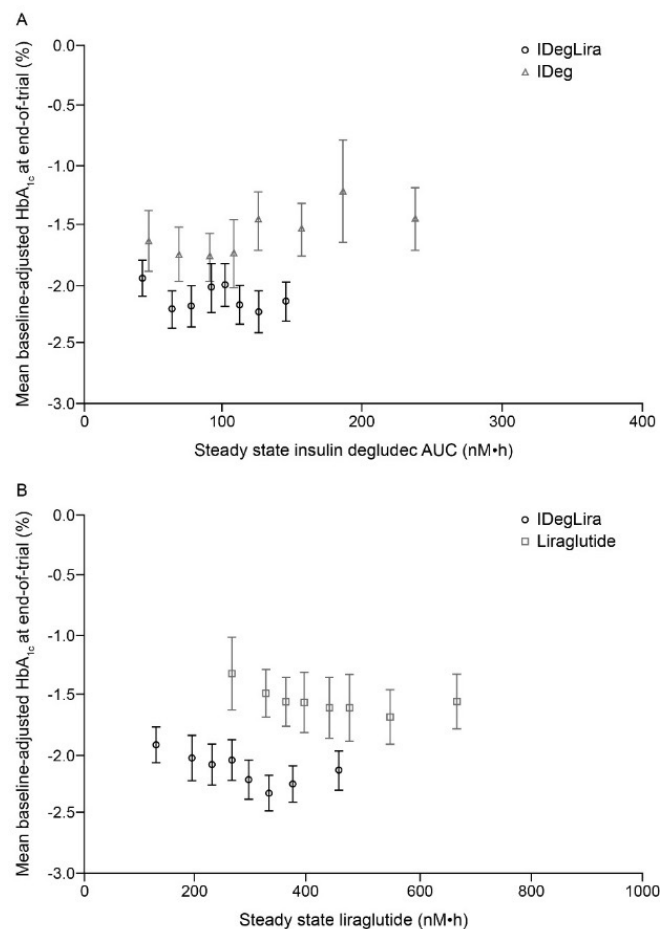

**Materials and methods:** The relative bioavailability of IDegLira and its mono-components were compared in a single-dose, randomised, double-blind, double-dummy four-period crossover clinical pharmacology study in 24 healthy volunteers. Dose proportionality and covariate effects on exposure were evaluated in a population PK analysis of data from a randomised treatment-to-target phase 3 study (n=1549) in subjects with type 2 diabetes. The exposure-response relationship for change from baseline in HbA<sub>1c</sub> of IDegLira relative to mono-components was also assessed using phase 3 data.

**Results:** The overall PK properties of IDeg and Lira were preserved for IDegLira compared with IDeg or Lira when dosed separately. The IDeg exposure (area under the curve) was equivalent when dosed as IDegLira or IDeg alone. Lira AUC was lower when dosed as IDegLira but met the criterion for bioequivalence (90% CI within 0.8–1.25). Population PK analysis revealed no relevant deviations from dose proportionality for the components of IDegLira, and covariate effects on exposure (such as body weight) were consistent with previous results for IDeg and Lira. Glycaemic response to IDegLira was larger than that of IDeg or Lira alone, reflecting distinct glucose-lowering

effects of its mono-components throughout the dose/exposure range (see Figure).

**Conclusion:** The PK properties of IDeg and Lira are preserved in the IDegLira co-formulation; both mono-components contribute to glycaemic control across the recommended dose range.

Change in  $HbA_{1c}$  from baseline to Week 26 (A) IDegLira and IDeg versus exposure of IDeg and (B) IDegLira and Lira versus exposure of Lira

IDegLira, IDeg and Lira are represented by circles, triangles and squares, respectively.  $HbA_{1c}$  is expressed as baseline-adjusted mean change with 95% CI. Exposure is depicted as percentiles of AUC at steady state.

### Aspart pharmacokinetics in children with type 1 diabetes during closed loop insulin delivery: comparison between diluted (U20) and standard (U100) insulin strengths

Y. Ruan<sup>1</sup>, D. Elleri<sup>1</sup>, M. Tauschmann<sup>1</sup>, J.M. Allen<sup>1</sup>, M.E. Wilinska<sup>1</sup>, D.B. Dunger<sup>2</sup>, R. Hovorka<sup>1</sup>

<sup>1</sup>Wellcome Trust-MRC Institute of Metabolic Science, University of Cambridge, <sup>2</sup>Department of Paediatrics, University of Cambridge, UK.

**Background and aims:** To compare pharmacokinetics of two different concentrations of insulin aspart in children aged 3 to 6 years with type 1 diabetes (T1D) during closed loop insulin delivery.

**Materials and methods:** Young children with T1D underwent an open-label, randomized, two-period crossover study involving two occasions in a clinical research facility, 2 to 6 weeks apart, from 17:00 day 1 to 8:00 day 2 with an evening meal consumed at 17:00. In random order, diluted (1:5 dilution with normal saline, 20 IU/ml) or standard strength (100 IU/ml) insulin aspart was administered via an insulin pump as a meal bolus and then overnight during closed loop advised by a model predictive algorithm. Plasma insulin was measured every 30 to 60 min. A compartment model adopting Bayesian parameter estimation was used to measure time-to-peak of insulin concentra-

tion ( $t_{max}$ ), insulin metabolic clearance rate ( $MCR_I$ ), and background insulin concentration ( $ins_c$ ).

**Results:** Eleven children [6 male; age 5.07(range 3.75-6.96yrs); A1C 60(14) mmol/mol; BMI sds 1.0(0.8); duration of diabetes 2.2(1.0)yrs; mean (SD); total daily dose 12.9(10.6,16.5)IU; fasting C-peptide 5(5,17.1)pmol/l; median(IQR)] participated in the study. Pharmacokinetic parameters (Table) were not different between the two aspart concentrations but  $t_{max}$  showed less inter-subject variability following administration of diluted aspart (SD 8.7 vs. 14.4min; diluted vs. standard strength;  $P=0.047$ ).  $ins_c$  but not the other parameters was positively correlated with total daily insulin dose (Spearman's  $r_s = 0.7$ ;  $P=0.014$ ) but not with fasting C-peptide ( $r_s = -0.19$ ;  $P=0.39$ ) suggesting that it does not reflect residual insulin secretion.

**Conclusion:** Diluting insulin aspart does not change its pharmacokinetics, but may result in less variable absorption and could be used in young people with T1D undergoing closed loop insulin therapy.

**Table. Comparison of parameter estimates following administration of standard strength (100IU/ml) and diluted (20IU/ml) insulin aspart**

| Model parameter                       | Standard (n=11) | Diluted (n=11)  | P value           |
|---------------------------------------|-----------------|-----------------|-------------------|
| $t_{max}$ (min)                       | 59.2 (14.4)     | 61.6 (8.7)      | 0.59 <sup>a</sup> |
| $MCR_I$ ( $10^{-2} \times l/kg/min$ ) | 1.98 (0.99)     | 1.89 (0.82)     | 0.47 <sup>a</sup> |
| $ins_c$ (mU/l)                        | 5.6 (0.2, 12.0) | 3.9 (0.5, 10.9) | 0.66 <sup>b</sup> |

### New insulin glargine 300 U/ml: efficacy and safety of flexible vs fixed dosing intervals in people with type 2 diabetes mellitus

N. Jeandier<sup>1</sup>, M.C. Riddle<sup>2</sup>, G.B. Bolli<sup>3</sup>, P.D. Home<sup>4</sup>, R.M. Bergenstal<sup>5</sup>, M. Ziemer<sup>6</sup>, I. Muehlen-Bartmer<sup>6</sup>, M. Wardęcki<sup>7</sup>, L. Vinet<sup>8</sup>, H. Yki-Järvinen<sup>9</sup>

<sup>1</sup>University of Strasbourg, France, <sup>2</sup>Oregon Health & Science University, Portland, USA, <sup>3</sup>University of Perugia, Italy, <sup>4</sup>Newcastle University, Newcastle Upon Tyne, UK, <sup>5</sup>International Diabetes Center at Park Nicollet, Minneapolis, USA, <sup>6</sup>Sanofi-Aventis Deutschland GmbH, Frankfurt am Main, Germany, <sup>7</sup>Sanofi, Warsaw, Poland, <sup>8</sup>EXPERIS IT, Nanterre, France, <sup>9</sup>University of Helsinki, Finland.

**Background and aims:** The smoother, more prolonged PK and PD profiles of new insulin glargine (300 U/ml; Gla-300) vs glargine 100 U/ml (Gla-100), with glycaemic control extending beyond 24 h, provide a rationale for flexible timing of daily injections depending on individual lifestyle. These 3-month sub-studies, of Gla-300 injected each evening, compared the efficacy and safety of using a fixed 24-h dosing interval with a flexible dosing regimen allowing between-injection intervals of  $24 \pm 3$  h on at least 2 days each week.

**Materials and methods:** The background multicentre, 6-month, open-label studies compared Gla-300 vs Gla-100 in people with type 2 diabetes mellitus using basal + meal-time insulin (EDITION 1) or basal insulin + OADs (EDITION 2). Participants (EDITION 1,  $N=109$ ; EDITION 2,  $N=89$ ) using Gla-300 were randomised at month 6 to continue the fixed regimen or move to flexible intervals. Efficacy and safety were evaluated 3 months later (month 9).

**Results:** The frequency of maintaining a  $24 \pm 1$  h interval between injections was ~88% with the fixed regimen and ~60% with the flexible regimen.  $HbA_{1c}$  change (primary endpoint) was comparable in fixed vs flexible regimens (Table). Percentages of participants with  $\geq 1$  hypoglycaemia at any time of day (24 h), or  $\geq 1$  nocturnal (00:00-05:59 h) hypoglycaemia, were also comparable. Severe hypoglycaemia was experienced by only 1 participant, in the EDITION 1 sub-study. There were no differences in adverse events.

**Conclusion:** Occasional flexibility in timing of daily Gla-300 injections by  $\pm$  3 h resulted in similar efficacy and safety compared with advising injections at a fixed time each day.

**Table: Outcomes of flexible and fixed dose intervals in the two sub-studies**

### Unmet needs in HbA<sub>1c</sub> goal achievement (< 7.0%) by patients with type 2 diabetes mellitus treated with basal insulin: pooled randomised controlled trial data and real-world clinical practice data

P. Chava<sup>1</sup>, L. Blonde<sup>1</sup>, S. Brunton<sup>2</sup>, R. Zhou<sup>3</sup>, J. Meyers<sup>4</sup>, K. Davis<sup>4</sup>, M. Dalal<sup>5</sup>, A. DiGenio<sup>6</sup>;

<sup>1</sup>Ochsner Medical Center, New Orleans,

<sup>2</sup>University of North Carolina, Chapel Hill, <sup>3</sup>Medpace Inc., Cincinnati,

<sup>4</sup>RTI Health Solutions, Research Triangle Park, <sup>5</sup>Sanofi US, Inc., Bridgewater,

<sup>6</sup>Isis Pharmaceuticals, Inc., Carlsbad, USA.

**Background and aims:** Despite the efficacy of basal insulin therapy in patients with type 2 diabetes mellitus (T2DM), many patients do not reach glycaemic goals. Here we use both randomized clinical trial (RCT) data and “real-world” data from a retrospective study of electronic medical records (EMR) to assess the characteristics of T2DM patients who do not achieve target glycaemic control while on basal insulin (HbA<sub>1c</sub>  $\geq$  7.0%) in order to better understand the clinical characteristics of these patients.

**Materials and methods:** Patients with T2DM aged  $\geq$  18 years treated with basal insulin, but with HbA<sub>1c</sub>  $\geq$  7.0% were identified by analysing results from 11 RCTs at 6 months after the index date, defined as date of first prescription for basal insulin, and results from the GE Centricity EMR database at 6-months and at 12-months follow-up after the index date. Patients were stratified based on fasting plasma glucose (FPG) levels (< 130 or  $\geq$  130 mg/dL). Information on patient demographic and clinical characteristics were available from both sources of data.

**Results:** The table shows that in the RCTs around 52% achieved HbA<sub>1c</sub> < 7.0% (recommended by the ADA for most diabetic patients). HbA<sub>1c</sub> < 7.0% was achieved by fewer patients (~27%) in the EMR database at both 6 and 12 months. Among those with HbA<sub>1c</sub>  $\geq$  7.0%, 54.9% of RCT patients and 17.6% and 27.7% of EMR patients at 6 and 12 months, respectively, had FPG < 130 mg/dL. About half of the RCT patients not achieving goal had a FPG  $\geq$  130 mg/dL. This suggested that these patients needed further basal insulin titration, whereas patients at goal likely required postprandial glucose control. In the EMR cohort, > 70% of patients were likely to need additional basal insulin titration.

**Conclusion:** Failure to adequately titrate basal insulin is an unmet need in many T2DM patients, which is evident even in RCTs. When basal insulin is adequately titrated and FPG is controlled, additional postprandial treatment may be needed. Another important unmet need is understanding the causes of failure to achieve control of FPG with basal insulin.

### New insulin glargine 300 U/ml: glycaemic control and hypoglycaemia in a meta-analysis of phase 3a EDITION clinical trials in people with type 2 diabetes mellitus

R.A. Ritzel<sup>1</sup>, R. Rousel<sup>2</sup>, G.B. Bolli<sup>3</sup>, L. Vinet<sup>4</sup>, H. Yki-Järvinen<sup>5</sup>;

<sup>1</sup>Klinikum Schwabing, Städtisches Klinikum München GmbH, Germany,

<sup>2</sup>Assistance Publique Hôpitaux de Paris, Bichat Hospital, France,

<sup>3</sup>University of Perugia, Italy, <sup>4</sup>EXPERIS IT, Nanterre, France,

<sup>5</sup>University of Helsinki, Finland.

**Background and aims:** The EDITION 1, 2 and 3 studies compared the efficacy and safety of new insulin glargine 300 U/ml (Gla-300) with insulin glargine 100 U/ml (Gla-100) in people with type 2 diabetes mellitus on basal and mealtime insulin, basal insulin and OADs, and no prior insulin, respectively. A meta-analysis of these studies was conducted to study efficacy and safety.

**Materials and methods:** Meta-analysis of these three studies enabled glycaemic control and hypoglycaemia to be examined over 6 months in a large, heterogeneous type 2 diabetes mellitus population (Gla-300, N=1247; Gla-100, N=1249).

**Results:** Mean change in HbA<sub>1c</sub> was comparable for Gla-300 and Gla-100 (LS mean change [SE]: -1.02 [0.03] % for both groups). Gla-300 was associated with reduced risk of experiencing hypoglycaemia compared with Gla-100 (nocturnal and at any time of day; Table). Nocturnal hypoglycaemic event rates were consistently lower with Gla-300 than Gla-100. Severe hypoglycaemia was rare in both treatment groups (2.3% with Gla-300 vs 2.6% with Gla-100). Weight gain with Gla-300 and Gla-100 was slight (LS mean change [SE]: 0.49 [0.10] kg and 0.75 [0.10] kg, respectively), with a trend for less weight gain with Gla-300 (LS mean difference: -0.26 [95% CI: -0.52 to 0.01] kg, p=0.058).

**Conclusion:** Gla-300 provides comparable glycaemic control to Gla-100 in type 2 diabetes mellitus, with consistently less hypoglycaemia at any time of the day and less nocturnal hypoglycaemia.

**Table – Glycaemic control and hypoglycaemic events over 6 months in a meta-analysis of the EDITION 1, 2 and 3 studies**

### Long-term efficacy and safety of insulin degludec in combination with bolus insulin aspart in children and adolescents with type 1 diabetes

N. Thalange<sup>1</sup>, L.C. Deeb<sup>2</sup>, V. Iotova<sup>3</sup>, T. Kawamura<sup>4</sup>, G.J. Klingensmith<sup>5</sup>, A. Philotheou<sup>6</sup>, J. Silverstein<sup>7</sup>, S. Tumini<sup>8</sup>, A. Ocampo Francisco<sup>9</sup>, O. Kindurtye<sup>10</sup>, T. Danne<sup>11</sup>;

<sup>1</sup>Norfolk & Norwich University Hospital, Norwich, UK, <sup>2</sup>Larry Deeb PA, Tallahassee, USA, <sup>3</sup>University Hospital Sveta Marina, Varna, Bulgaria, <sup>4</sup>Osaka City University, Japan, <sup>5</sup>Barbara Davis Center for Childhood Diabetes, Aurora, USA, <sup>6</sup>UCT Private Academic Hospital, Cape Town, South Africa, <sup>7</sup>University of Florida, Gainesville, USA, <sup>8</sup>Ospedale „SS. Annunziata“, Chieti, Italy, <sup>9</sup>Novo Nordisk A/S, Søborg, <sup>10</sup>Novo Nordisk A/S, Bagsvaerd, Denmark, <sup>11</sup>Children's Hospital auf der Bult, Hannover, Germany.

**Background and aims:** This 1:1 randomised controlled, open-label, treat-to-target trial investigated the efficacy and safety of insulin degludec (IDeg) and insulin detemir (IDet), both in combination with bolus insulin aspart (IAsp) in children and adolescents with type 1 diabetes for 26 weeks (n=174 IDeg; 176 IDet) followed by a 26-week extension (n=152 IDeg; 128 IDet).

**Materials and methods:** The trial included 85 children aged 1–5 years (IDeg: 43), 138 children 6–11 years (IDeg: 70) and 127 adolescents 12–17 years (IDeg: 61). Randomised subjects [baseline mean (SD) diabetes duration 4.0 (3.5) years, HbA<sub>1c</sub> 8.1 (1.1)%, fasting plasma glucose (FPG) 8.7 (5.1) mmol/L], received IDeg once daily + IAsp or IDet once/twice daily + IAsp.

**Results:** Non-inferiority of IDeg vs. IDet at 26 weeks was confirmed for HbA<sub>1c</sub> (primary endpoint): estimated treatment difference (ETD) 0.15% [-0.03; 0.32]<sub>95% CI</sub> (non-inferiority margin: 0.4%, p<0.05). At 52 weeks, HbA<sub>1c</sub> was 7.9% with IDeg and 7.8% with IDet (NS), change in mean FPG was -1.29

mmol/L with IDeg vs. +1.10 mmol/L with IDet (ETD -1.62 mmol/L [-2.84; -0.41], p<0.05) and mean basal insulin dose was 0.38 U/kg (IDeg) vs. 0.55 U/kg (IDet). Rates of confirmed hypoglycaemia (i.e., severe [altered mental status, cannot assist in own care, semiconscious/unconscious, or in coma ± convulsions] and/or plasma glucose (PG) <3.1 mmol/L) were similar for IDeg and IDet at 52 weeks (57.7 vs. 54.1 events/exposure year, estimated rate ratio (ERR): 1.11 [0.89; 1.38], NS), as were rates of nocturnal (11 pm - 7 am) hypoglycaemia; (6.0 vs. 7.6 events/exposure year, ERR 0.99 [0.72; 1.34], NS). Incidence and rates of severe hypoglycaemia tended to be higher with IDeg than IDet: 17.8% vs. 13.7%; 0.51 vs. 0.33 events/exposure year (ERR 1.30 [0.64; 2.64], NS). Rates of severe hypoglycaemia, including only episodes of semiconscious/unconsciousness and coma ± convulsions, were 0.09 and 0.14 for IDeg and IDet, respectively (ERR 0.62 [0.24; 1.60] NS, *post-hoc* analysis). The rate of hyperglycaemic episodes with ketosis (self-measured PG >14.0 mmol/L with blood ketones >1.5 mmol/L) was significantly lower for IDeg vs. IDet (0.7 vs. 1.1 events/exposure year, treatment ratio 0.41 [0.22; 0.78], p<0.05). Weight SD scores increased with IDeg and remained unchanged with IDet (change: 0.11 vs. -0.06, ETD: 0.17 [0.10; 0.25], p<0.05). Adverse event profiles were similar for IDeg and IDet.

**Conclusion:** IDeg+IAsp effectively improved long-term glycaemic control at lower dose, achieving significantly greater reduction in FPG versus IDet+IAsp with similar rates of overall and nocturnal hypoglycaemia and significantly lower rates of hyperglycaemia with ketosis. Rates of severe hypoglycaemia tended to be higher with IDeg than IDet. Less weight gain was observed with IDet. No safety issues were identified with IDeg or IDet.

### Injection depth does not affect the pharmacokinetics or pharmacodynamics of insulin lispro in healthy obese or normal weight subjects

K. Ye<sup>1</sup>, A. de la Peña<sup>2</sup>, E. Catton<sup>2</sup>, D.A. Ignaut<sup>2</sup>;<sup>1</sup>Lilly-NUS Centre for Clinical Pharmacology, Singapore,<sup>2</sup>Eli Lilly and Company, Indianapolis, USA.

**Background and aims:** An 8-mm needle length is commonly used worldwide, and recent recommendations suggest that using shorter, 4-, 5-, or 6-mm needles may be optimal for most patients to avoid intramuscular injection and still maintain adequate glucose control. The goal of this analysis was to compare the pharmacokinetics (PK) and pharmacodynamics (PD) of insulin lispro after administration at a 5-mm injection depth or an 8-mm injection depth in 2 separate populations: normal weight (Study 1) or obese (Study 2). **Materials and methods:** In both open-label, randomized, 2-period crossover euglycemic clamp studies, subjects received single doses of insulin lispro (0.25 U/kg) on 2 different occasions; PK and PD measures were collected under euglycemic conditions for up to approximately 6 hours post-dose.

**Results:** In Study 1, 16 healthy normal weight subjects (13 male; age 31±9 years; BMI=23±2 kg/m<sup>2</sup>) were dosed at a 5-mm and an 8-mm injection depth on 2 separate occasions. In Study 2, 16 healthy obese subjects (11 male; mean age 41±11 years; BMI=34±3 kg/m<sup>2</sup>) were also dosed at a 5-mm and an 8-mm injection depth. In both studies, PK parameters [AUC(0-<sub>last</sub>), AUC(0-∞), and C<sub>max</sub>] and PD parameters (G<sub>tot</sub>, R<sub>max</sub>) were log-transformed prior to analysis using a mixed effects model. The table shows PK and PD parameters for both studies.

**Conclusion:** There were no statistical differences in PK or PD of insulin lispro following administration at the 5-mm injection depth or 8-mm injection depth in either study. Injection depths in the 5-8 mm range did not affect the PK or PD of insulin lispro in either normal weight or obese subjects. These observations are consistent with clinical data in pediatric, adult, and obese patients with type 1 and type 2 diabetes mellitus, where the 5-mm needle was found to be as efficacious and safe as an 8-mm needle.

### Development of a clinical predictive score for requirement of hypoglycaemic agents for optimal control of blood glucose during glucocorticoid treatment

H. Morita<sup>1</sup>, M. Yamauchi<sup>1</sup>, I. Mori<sup>1</sup>, T. Ikeda<sup>1</sup>, Y. Kitada<sup>2</sup>, K. Taguchi<sup>3</sup>, K. Fujioka<sup>3</sup>, H. Okada<sup>4</sup>, T. Usui<sup>5</sup>, M. Kawashima<sup>1</sup>, K. Kajita<sup>1</sup>, T. Ishizuka<sup>3</sup>;

<sup>1</sup>Department of General Internal Medicine, Gifu University Graduate School of Medicine, <sup>2</sup>Department of General Internal Medicine, Hashima City Hospital, <sup>3</sup>Department of General Internal Medicine, Gifu Municipal Hospital, <sup>4</sup>Department of General Medicine, Gifu Prefectural Central Medical Center, <sup>5</sup>Department of General Medicine, Japanese Red Cross Gifu Hospital, Japan.

**Background and aims:** Long-term glucocorticoid (GC) treatment may be necessary for patients with various autoimmune diseases. The highest dose of GC is usually administered at the initiation of the therapy, which often causes hyperglycemia and needs hypoglycemic agents in some patients. The aim of the present study is to elucidate risk factors related to GC-induced hyperglycemia and to develop a simple method to predict in advance the requirement of hypoglycemic agents to achieve optimum control of blood glucose during GC treatment.

**Materials and methods:** We retrospectively evaluated 230 patients (57±19 years, 57% of whom were women) with autoimmune diseases admitted between 2004 and 2013 in our department to develop a predictive scoring system. Inclusion criteria indicated that the dosage of prednisolone treatment should be more than 5 mg/day for 4 weeks at least. Exclusion criteria included use of hypoglycemic agents before GC administration or concomitant use of anti-cancer drugs.

**Results:** Forty-three percent (Ninety-nine persons) of GC-administered patients required hypoglycemic agents (19% for oral hypoglycemic agents, 5% for a GLP-1 analog or 20% for insulin). A logistic regression analysis revealed that risk factors of requirement of hypoglycemic agents during GC administration should be raised in accordance with age and fasting plasma glucose (FPG). A ROC analysis showed that cutoff values of age and FPG were 58 years old and 101 mg/dl, respectively. We scored patient profiles as follows: 0 point for FPG less than 101 mg/dl and age less than 58 years old, 1 point for FPG more than 101 mg/d and age more than 58 years old, respectively. Mean of the sum of the points was 1.27 for patients requiring hypoglycemic agents and 0.64 for others, respectively. The percentages of patients requiring hypoglycemic agents in the sum of each point were 17% (12 / 72) at 0 point, 45% (48 / 106) at 1 point and 75% (39 / 52) at 2 points, respectively. The sensitivity and specificity were 87.9% and 45.8%, respectively, when 1 point was defined as the cut-off value of the sum of the scores.

**Conclusion:** Use of a scoring system composed in accordance with age and FPG is a simple and effective way to predict the requirement of hypoglycemic agents for hyperglycemia in patients treated with GC.

967

### Insulin antibodies are associated with lipatrophy in adults with type 2 diabetes mellitus

K. Takahashi, A. Hakozaiki, M. Narazaki, N. Takebe, Y. Ishigaki; Department of Diabetes and Metabolism, Iwate Medical University, Morioka, Japan.

**Background and aims:** The clinical significance of insulin antibodies (IA) cannot be ignored, even after the introduction of either recombinant human or analog insulin. Previous studies suggest potential associations of IA with hypoglycemia and hyperglycemia, as well as skin reactions. Furthermore, in recent studies, elevated IA levels were independent risk factors for coronary heart disease in insulin-treated elder adults, or for retinopathy in type 2 diabetic subjects with insulin therapy. In the subjects under insulin therapy, lipodystrophy, i.e. lipohypertrophy and lipatrophy, are common problems at frequently injected sites. We occasionally notice that some diabetic subjects developing lipodystrophy tend to show high levels of IA. Indeed, strong association of lipodystrophy with IA has been reported in children and adolescents with type 1 Diabetes. Herein, we endeavored to ascertain clinical and immunological factors that are associated with lipodystrophy in adults with type 2 diabetes.

**Materials and methods:** Subjects were inpatients of our University Hospital. The study groups consisted of 40 females and 42 males, of which mean age was 63± 12 years, duration of diabetes 15± 8.0 years, and HbA1c 9.0± 2.2%. After obtaining approval from the ethics committee of the University and

informed consent from all subjects, blood samples were collected. IA were measured by RIA kits of IA with reduced non-specific bindings (Yamasa Co, Tokyo, Japan.) Grading of lipodystrophy was applied as follows. Grade 0: no lipatrophy or lipohypertrophy at any injection site, grade 1: moderate lipohypertrophy without increased palpable density of subcutaneous tissue, grade 2: severe hypertrophy with increased density of the injection site, and grade 3: lipatrophy at any injection site. Statistical significance was analysed by the Mann-Whitney U test,  $\chi^2$  test, or multiple linear regression analyses.

**Results:** Thirty-eight out of 82 subjects (46.3%) receiving current or previous therapy with recombinant human or analogue insulin were IA positive (percent binding  $9.6 \pm 17\%$ ). We found lipatrophy (grade 3) of at least one injection site in 3 subjects, severe lipohypertrophy (grade 2) in 8 and moderate lipohypertrophy (grade 1) in 23 adults. No alteration (grade 0) was found in the remaining 48 subjects. Subjects with lipatrophy displayed significantly higher levels of percent binding with IA ( $66 \pm 21\%$ ) than those with severe lipohypertrophy ( $8.0 \pm 8.0\%$ ,  $P=0.03$ ) or those without lipodystrophy ( $3.3 \pm 6.3\%$ ,  $P=0.03$ ). Multiple regression analyses revealed that lipatrophy ( $\beta=0.78$ ,  $t=7.99$ ,  $P=0.000$ ) and percent binding with IA ( $\beta=0.65$ ,  $t=6.05$ ,  $P=0.000$ ,  $R=0.65$ ) could significantly predict each other.

**Conclusion:** To our knowledge, this is the first report that showed strong relationship between lipatrophy and IA in subjects with type 2 diabetes under insulin therapy. However, it is the chicken or the egg with lipatrophy and percent binding with IA. Further investigations should be needed to elucidate the pathological relationship between them. In conclusion, we propose that the emergence of IA and its concomitant adverse effects should be taken into account, when starting insulin therapy in subjects with type 2 diabetes mellitus.

## 968

### The immunogenicity of originator insulin glargine: incidence and absence of clinical sequelae

A. Vlajnic<sup>1</sup>, L. Traylor<sup>2</sup>, J. Frimpter<sup>2</sup>, H. Khatami<sup>1</sup>, H. Schellekens<sup>3</sup>;

<sup>1</sup>Sanofi, Bridgewater, <sup>2</sup>Sanofi US, Inc., Bridgewater, USA,

<sup>3</sup>Department of Pharmaceutical Sciences, Faculty of Sciences, Utrecht University, Netherlands.

**Background and aims:** The immunogenicity of various basal insulins appears to be variable, with no apparent clinical impact. This analysis assessed immunogenicity and its clinical relevance in trials of the originator insulin glargine (GLA) after > 10 years experience.

**Materials and methods:** This was a retrospective analysis of supporting data from published registration studies of GLA vs NPH insulin (NPH) in patients with type 1 diabetes mellitus (T1DM;  $n=4$ ) or type 2 diabetes mellitus (T2DM;  $n=3$ ). Assessments included: change in antibody (Ab) levels (%bound/total [%B/T]) against GLA (IGAb) and human insulin (HIAb); proportion of patients with predefined change in Ab levels ( $\geq 20$  units from baseline); and possible Ab-associated clinical effects.

**Results:** In the T1DM studies, baseline IGAb and HIAb levels ranged from 21.72–29.35 and 20.50–29.91 (%B/T), respectively. Significantly larger reductions in Ab levels from baseline were seen with GLA vs NPH in 2 studies for IGAb and HIAb (Table). The proportion of patients with predefined changes in Ab levels was low in all studies and treatment groups with available data: GLA, IGAb increase 2.0–14.5%, decrease 2.0–4.3% and HIAb increase 1.2–8.3%, decrease 2.8–4.3%; NPH, IGAb increase 0–1.2%, decrease 0–2.9% and HIAb increase 0–0.8%, decrease 0–2.7%. In most studies more GLA-treated patients showed an increase in IGAb; however, one study showed a decrease ( $p=0.0029$ ). In the T2DM studies, baseline HIAb and IGAb levels ranged from 9.86–17.97 and 6.83–17.57 (%B/T), respectively. Ab level increases were less marked in GLA-treated patients (significant in 2 studies) (Table). More T2DM patients had predefined changes in Ab levels vs T1DM patients: GLA, IGAb increase 0.01–3.1%, decrease 0–6.2% and HIAb increase 0.01–2.5%, decrease 0–9.2%; NPH, IGAb increase 0.01–13.3%, decrease 0–2.8% and HIAb increase 0.01–13.8%, decrease 0–2.8%. Significantly more NPH-treated patients had predefined increases in IGAb and HIAb in Study 3002 (overall and insulin-naïve subgroup; all  $p < 0.0001$ ). There was no evidence of insulin resistance, loss of glycaemic control, or increased hypoglycaemia associated with Ab level change in T1DM or T2DM patients. There was no association between changes in Ab levels and in  $HbA_{1c}$  in any treatment group; total insulin dose was unchanged or only slightly increased in a majority of T1DM patients. Two T2DM patients (1 GLA-treated and 1 NPH-treated) had isolated dose increases;  $HbA_{1c}$  decreased from baseline in both. No correlation was seen between changes in Ab levels and hypersensitivity.

**Conclusion:** Treatment with GLA is associated with generally low rates of Ab formation, without evidence of any clinical consequences. As some regulatory agencies require assessment of immunogenicity for biologics, including biosimilars, these data may provide a potential benchmark for consideration of emerging data from GLA biosimilar studies.

| Study                    | Duration (Weeks) | GLA |              | NPH |              | Adjusted Mean Difference (SE) <sup>a</sup> | p-Value |
|--------------------------|------------------|-----|--------------|-----|--------------|--|---------|

### Evaluation of immunogenicity of LY2963016 insulin glargine compared with insulin glargine in patients with type 2 diabetes mellitus

L.L. Ilag, M.A. Deeg, W.J. Huster, T.M. Costigan, J.S. Zielonka, R.K. Pollom, M.J. Prince, R.J. Konrad;

Eli Lilly and Company, Indianapolis, USA.

**Background and aims:** LY2963016 (LY IGLar) is an insulin glargine product, with an identical amino acid sequence to insulin glargine (Sanofi-Aventis; IGLar), which demonstrates similar pharmacokinetic and pharmacodynamic profiles and no clinically meaningful differences from IGLar in safety or efficacy in patients with type 2 diabetes mellitus (T2DM). When evaluating similar biological products, assessment of immunogenicity is important to examine potential differences between products in the incidence and severity of human immune responses and implications this might have for safety or efficacy.

**Materials and methods:** This was a 24-week, Phase 3, randomised, double-blind, parallel study to compare the efficacy and safety of LY IGLar (N=376) and IGLar (N=380) in patients with T2DM on  $\geq 2$  oral antidiabetic medications (OAMs). Patients were insulin-naïve ( $HbA_{1c} \geq 7.0\%$  to  $\leq 11.0\%$ ) or previously on IGLar ( $HbA_{1c} \leq 11.0\%$ ). Anti-insulin glargine antibodies (% binding) were measured for the overall 24-week treatment period. The relationships between anti-insulin glargine antibody levels or treatment emergent antibody responses (TEAR) and selected efficacy and safety measures were evaluated using ANCOVA.

**Results:** Approximately 40% of patients (LY IGLar, 41%; IGLar, 38%) entered the study on IGLar and the remainder (LY IGLar, 59%; IGLar, 62%) were insulin-naïve. Similar proportions of patients completed the 24-week treatment period (LY IGLar, 89%; IGLar 86%). As shown in Table 1, proportions (%) of patients with detectable antibodies at baseline and throughout the treatment period were similar for LY IGLar vs IGLar ( $p>.05$ ). There were no differences in TEAR incidence between patients randomised to LY IGLar vs IGLar and clinical outcomes ( $HbA_{1c}$ , basal insulin dose and total hypoglycaemia) were not affected by TEAR status (i.e.,  $p>.05$  for treatment-by-TEAR interaction for these outcomes) (Table 1). The incidence of treatment-emergent allergic events did not differ between LY IGLar and IGLar ( $p>.05$ ) (Table 1). Clinical outcomes were also not affected by insulin antibody levels ( $p>.05$ ).

**Conclusion:** These clinical safety data demonstrate a highly similar immunogenicity profile of LY IGLar to IGLar, with no effects of anti-insulin glargine antibodies on selected efficacy and safety outcomes in patients with T2DM.

Table 1 Incidence and Effect of Anti-insulin Glargine Antibodies on Clinical Outcomes

### Demonstration of differential immune modulation by originator and biological copies of insulin glargine in an in vitro model of human immunity

E. Luna<sup>1</sup>, P. Agrawal<sup>1</sup>, R. Mehta<sup>1</sup>, C. Vernhes<sup>1</sup>, C. Denys<sup>2</sup>, H. Khatami<sup>3</sup>, A. Schmidt<sup>4</sup>, N. Tennagels<sup>4</sup>, D.R. Drake III<sup>1</sup>;

<sup>1</sup>Sanofi Pasteur-Vaxdesign Campus, Orlando, USA, <sup>2</sup>Sanofi, Paris, France,

<sup>3</sup>Sanofi, Bridgewater, USA, <sup>4</sup>Sanofi, Frankfurt am Main, Germany.

**Background and aims:** Because the manufacture of insulin analogs require sophisticated production and purification procedures, it is possible originator and biological copies of insulin might have varied immunogenicity profiles based on differences in the structure (protein aggregation, denaturation), purity (contamination with endotoxins or others), and/or other characteristics of these products. To date, few studies have addressed the specific pathways of potential immune modulation triggered by biological copies of insulin glargine

**Materials and methods:** Here, we used an in vitro model of immunity, termed the MIMIC<sup>®</sup> system, to study antigen presenting cell (APC) activation and cytokine secretion induced by a range of doses of originator and biological copies of insulin glargine that are available in some countries

**Results:** By flow cytometric phenotype analysis, the originator and biological copy products triggered minimal changes in expression of activation markers on MIMIC<sup>®</sup> system-derived APCs. In contrast, some lots of the biological copies of insulin glargine, but not the originator product, were capable of inducing the secretion of some pro-inflammatory markers, such as IL-8, in the treated MIMIC<sup>®</sup> cultures. These immunogenicity differences appear to be due to the effect of the compounds on monocytic and/or lymphocytic populations in the in vitro human cell system. Of note, all insulin analogs included in this analysis were comparable in their insulin receptor activity in vitro and typically generated similar analytical profiles.

**Conclusion:** In contrast to the originator product, some of the biological copies of insulin glargine (variable by lot) triggered the induction of pro-inflammatory cytokines in the MIMIC<sup>®</sup> system, which might indicate a difference in the biochemical composition of some of these insulin biological copies. While the mechanism and differences causing these effects is still under investigation, and the potential clinical impact is unknown, the data presented here suggests there might be different immune modulation potentials between originator and copy insulin compounds. Further investigation of the potential clinical relevance and/or mechanisms regulating this response may be warranted.

### Binding kinetics, internalisation and localisation of long-acting basal insulin peglispro (BIL) and insulin receptor in cells

V.V. Kiselyov, J.S. Moyers, C.B. Volk, J.X.C. Cao, G.Y. Wu, L. Ding, M.D. Michael;

Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, USA.

**Background and aims:** BIL (LY2605541) is a novel, PEGylated insulin lispro that has a large hydrodynamic size. It has a prolonged duration of action which is related to a delay in insulin absorption and a reduction in clearance. We compared the binding kinetics, intracellular localization, in vitro clearance, and effect on activation and localization of human insulin receptor (hIR) of BIL with those of insulin lispro and biosynthetic human insulin (BHI).

**Materials and methods:** Cellular internalization and localization of BIL, BHI, insulin lispro, and tyrosine-phosphorylated hIR (hIR-pY) were observed by immunofluorescent confocal imaging in U2OS cells that overexpress hIR. Binding and kinetic properties of BIL and BHI were measured in IM9 cells using radio-ligand binding techniques. The in vitro clearances of BIL and BHI were studied in HEK cells overexpressing hIR.

**Results:** Co-localization studies using antibodies to insulin or PEG, and the early endosomal marker, EEA1, showed that the internalization and subcellular localization pattern of BIL were similar to those of BHI and insulin lispro; all were rapidly internalized and co-localized with EEA1. During ligand washout, concomitant loss of insulin, PEG methoxy group, and PEG polymer backbone immunostaining was observed for BIL similar to the loss of insulin immunostaining observed for insulin lispro and BHI. Co-localization studies using an antibody to the lysosomal marker LAMP2 did not reveal evidence of lysosomal localization for insulin lispro, BHI, or BIL, using either insulin or PEG immunostaining reagents. In vitro clearance studies showed efficient insulin receptor-mediated-clearance of BHI and the insulin portion of BIL. In contrast, the concentration of PEG polymer backbone appeared to decrease significantly more slowly. This is consistent with a process whereby, upon internalization of BIL, the insulin moiety is degraded, whereas the PEG backbone is recycled out of cells, and is consistent with the above observation that no PEG was detected in lysosomes. BIL and BHI both induced rapid phosphorylation and internalization of hIR. Co-staining of hIR-pY and EEA1 showed that hIR promptly entered early endosomes after BIL and BHI treatment. Minimal lysosomal localization of hIR-pY was detected with either ligand. Ligand washout studies suggested a more rapid dephosphorylation of hIR-pY after treatment with BIL than with BHI. Whole cell binding analysis performed with IM9 cells also showed slightly faster hIR dissociation kinetics for BIL than for BHI. The pH dependence of the dissociation rate and the magnitude of accelerated dissociation from the receptor at high concentrations of BIL were similar to those of BHI. Affinity of BIL for hIR was ~20-fold lower than that of BHI.

**Conclusion:** The mechanism of insulin receptor activation by BIL is similar to that of BHI as evidenced by preservation of pH and ligand concentration dependences of the dissociation rate. The reduction of affinity to the insulin receptor is attributable mainly to a decrease in the association rate constant. The insulin and PEG moieties of BIL undergo a dynamic cellular process of rapid internalization and transport to early endosomes after stimulation of hIR-pY followed by loss of cellular immunostaining in a manner similar to those of insulin lispro and BHI suggestive of efficient transport of the PEG backbone out of cells.

### Pharmacological evaluation of once-weekly potentials by combination of long-acting insulin with long-acting exendin4 in an animal model

S. Kwon<sup>1</sup>, C. Lim<sup>1</sup>, Y. Park<sup>1</sup>, J. Kim<sup>1</sup>, S. Jung<sup>1</sup>, I. Choi<sup>1</sup>, S. Lee<sup>1</sup>, J. Kang<sup>1</sup>, M. Trautmann<sup>2</sup>, M. Hompesch<sup>2</sup>, Y. Kim<sup>1</sup>;

<sup>1</sup>Hanmi Pharmaceutical, Seoul, Republic of Korea,

<sup>2</sup>Profil Institute, Chula Vista, USA.

**Background and aims:** Combination of basal insulin and GLP-1 receptor agonist could provide diabetic patients with improved efficacy and safety. However, the recently developed combination products require an once-daily administration, which is still frequent and thus negatively affects treatment adherence and efficacy. We have developed the novel long-acting basal insulin analog and exendin-4 analog, namely HM12470 (once-weekly regimen) and HM11260C (once-weekly or monthly regimen), respectively, using

LAPSCOVERY technology. Because of their prolonged and flatness pharmacokinetic (PK) / pharmacodynamic (PD) properties, the combination of HM12470 and HM11260C could maximize the dosing convenience as well as the therapeutic advantages. The objective of this study was to evaluate the once-weekly potentials of HM12470 and HM11260C combination in animal model.

**Materials and methods:** Human PK profile of HM12470 was predicted based on PK results of three different animal species using Wajima  $C_{ss}$ -MRT method and compared with that of HM11260C in human. *db/db* mice were chronically administrated with HM12470 and/or HM11260C. To evaluate the glucose lowering efficacy, 4h fasting blood glucose (FBG) levels were measured every 3-4days. Body weight was determined every 2days for proper drug administration. At the end of study, HbA<sub>1c</sub> levels were determined. To evaluate the PK profiles of combination treatment, serum concentration of HM12470 and/or HM11260C were quantified after single administration of HM12470 and/or HM11260C in SD rats.

**Results:** The half-life of HM12470 in human was predicted as 132hr which was similar with HM11260C (140hr), suggesting their once-weekly combination potentials. In *db/db* mice, once-weekly mimetic administration (Q2D) of HM12470 and HM11260C showed significantly reduced FBG levels compared to that of individual compounds. Consistent with FBG control, HM12470 and HM11260C combination group had lower HbA<sub>1c</sub> level (6.8±0.8%) than HM12470 (9.0±0.6%) or HM11260C (8.0±1.7%) groups, indicating improved glycemic control by combination treatment. Moreover, this improved glycemic control was maintained even by reducing HM12470 dose in combination treated group. Furthermore, combination treatment attenuated body weight gain observed in HM12470 only groups. As to the pharmacokinetic profiles, administration of HM12470 and HM11260C did not affect pharmacokinetic profiles of either individual compounds in SD rats, ruling out possible drug-drug interference.

**Conclusion:** Based on PK prediction results, HM12470 could be a best partner of HM11260C for the once-weekly combination therapy. Of note, combination of HM12470 and HM11260C not only improved glycemic control, but also controlled unwanted body weight gain by insulin drug in *db/db* mice. Given that there were no PK interference between HM12470 and HM11260C, our results collectively demonstrate that combination of HM12470 and HM11260C provide optimal convenience as well as therapeutic advantages, shedding light on ideal therapy for the management of diabetic patients.

## PS 079 Insulin treatment and hypoglycaemic reactions

973

**Hypoglycaemia in people with type 2 diabetes achieving vs not achieving HbA<sub>1c</sub> target levels over 4 years in routine clinical practice:**

**analysis of the CREDIT study**

L. Blonde<sup>1</sup>, N. Freemantle<sup>2</sup>, F. Calvi-Gries<sup>3</sup>, M. Vincent<sup>4</sup>, P. Home<sup>5</sup>;

<sup>1</sup>Ochsner Medical Center, New Orleans, USA, <sup>2</sup>University College London, UK, <sup>3</sup>AtlanStat, Rezé, France, <sup>4</sup>Sanofi, Paris, France,

<sup>5</sup>Newcastle University, Newcastle upon Tyne, UK.

**Background and aims:** To evaluate the incidence and rate of hypoglycaemia in people with type 2 diabetes achieving vs not achieving HbA<sub>1c</sub> < 7.0 % (53 mmol/mol) over 4 years after starting insulin therapy in routine clinical practice in Europe, Canada, and Japan.

**Materials and methods:** CREDIT (Cardiovascular Risk Evaluation in people with Type 2 Diabetes on Insulin Therapy) was a noninterventional study designed to examine the relationship between HbA<sub>1c</sub> and cardiovascular events and to provide insight into current, real-world practices of the use of insulin by 2999 people beginning insulin, with up to 54 months' follow up (n = 2272 with 4-year data). For this analysis, records of symptomatic, severe, and nocturnal symptomatic hypoglycaemia were collected for the 6 months prior to the 1, 2, 3, and 4-year follow-up intervals. Updated mean HbA<sub>1c</sub> was calculated as the average of normalized HbA<sub>1c</sub> measurements from 1 month after insulin initiation up to follow-up year values. Hypoglycaemia events were categorised by whether or not the person experiencing the event had updated mean HbA<sub>1c</sub> < 7.0 % or not at the follow-up visit closest to the event.

**Results:** Overall mean (SD) HbA<sub>1c</sub> declined from 80 (21) mmol/mol (9.5 [2.0] %) when starting insulin to 60 (14) mmol/mol (7.6 [1.3] %) at 4 years (median 56 mmol/mol [7.3 %]). During the last 6 months of year 1, 2, 3, and 4 follow-up, the proportion of people experiencing ≥ 1 hypoglycaemic event was higher for those who achieved target (range 17.7%-24.6%) than for those who did not (range: 15.8%-16.8%) (Table). This was also true for incidence rate of any documented symptomatic hypoglycaemia (1.18-1.40 vs 0.75-0.96 events/person), and nocturnal symptomatic hypoglycaemia (0.14-0.24 vs 0.12-0.20 events/person). The percentage of people who experienced ≥ 1 severe hypoglycaemic event for the 4 half-yearly follow-up periods was also higher for those to target (range 3.0%-4.6%) than for those not (0.9%-1.6%). Mean rates of severe hypoglycaemia were 0.04-0.20 vs 0.02-0.04 events/person, while severe nocturnal hypoglycaemia was 0.02-0.06 vs 0.00-0.01 events/person.

**Conclusion:** People with type 2 diabetes starting insulin who achieve updated mean target HbA<sub>1c</sub> levels in routine clinical practice do experience higher rates of symptomatic and nocturnal hypoglycaemia than those failing to achieve target HbA<sub>1c</sub>. However, the difference between groups in the percentage of individuals with hypoglycaemia seems to diminish over time, and rates for both groups are relatively modest. Moreover, the rate of severe hypoglycaemia is low and could not be distinguished by whether target HbA<sub>1c</sub> is achieved. Initiation of insulin in the CREDIT population was associated

with a significant improvement in glycaemia. These hypoglycaemia data are consistent with a positive benefit risk ratio for this therapeutic strategy.

Table: Hypoglycaemia in the last 6 months in people achieving and not achieving updated mean HbA<sub>1c</sub> of <7.0 % (target)

|                                  | Year 1      | Year 2      | Year 3      | Year 4      |

### IDegAsp lowers the rate of hypoglycaemia vs biphasic insulin aspart 30 in adults with type 2 diabetes achieving glycaemic target (HbA<sub>1c</sub> <7.0%): a meta-analysis

A. Vaag<sup>1</sup>, J.S. Christiansen<sup>2</sup>, L. Niskanen<sup>3</sup>, T. Johansen<sup>4</sup>, S. Rasmussen<sup>4</sup>, G. Fulcher<sup>5</sup>;

<sup>1</sup>Rigshospitalet and Copenhagen University, <sup>2</sup>Aarhus University Hospital, Denmark, <sup>3</sup>Faculty of Health Sciences, University of Eastern Finland, Helsinki, Finland, <sup>4</sup>Novo Nordisk A/S, Søborg, Denmark, <sup>5</sup>The University of Sydney, Australia.

**Background and aims:** Insulin degludec/insulin aspart (IDegAsp) is a soluble co-formulation of 70% insulin degludec and 30% insulin aspart. The objective of this post-hoc meta-analysis was to compare hypoglycaemia rates for IDegAsp, vs. biphasic insulin aspart 30 (BIAsp 30) in adults with type 2 diabetes (T2D) achieving the ADA/EASD target of HbA<sub>1c</sub> <7% at end of trial (EOT).

**Materials and methods:** This analysis included two 26-week trials (NN5401-3592/97) comparing twice-daily IDegAsp vs BIAsp 30. HbA<sub>1c</sub>, fasting plasma glucose (FPG) and insulin dose were analysed using an ANCOVA model; episodes of hypoglycaemia were analysed using a negative binomial regression model. Confirmed hypoglycaemia was defined as self-reported PG <3.1 mmol/L or severe (requiring third-party assistance); nocturnal confirmed hypoglycaemia had onset 00:01–05:59 am, inclusive.

**Results:** In total, 49.1% (426/868) of subjects achieved EOT HbA<sub>1c</sub> of <7% (IDegAsp: 49.2% [248/504]; BIAsp 30: 48.9% [178/364]) and were included in the meta-analysis. Treatment groups had similar EOT HbA<sub>1c</sub> levels (6.4% vs. 6.4%; estimated treatment difference [ETD]: 0.00% [-0.07; 0.07], p=0.996), whereas IDegAsp achieved a significantly greater reduction from baseline in FPG (-3.0 vs. -2.1 mmol/L; ETD: -1.1 mmol/L [-1.4; -0.9] p<0.0001). Mean daily insulin dose at EOT was significantly lower for IDegAsp than BIAsp 30 (0.9 vs. 1.1 U/kg; estimated dose ratio: 0.77 [0.72; 0.84]; p<0.0001). IDegAsp was associated with a significantly lower rate of overall confirmed hypoglycaemia (rate ratio [RR] IDegAsp/BIAsp 30: 0.70 [0.55; 0.90], p=0.0047) and a significantly lower rate of nocturnal hypoglycaemia than BIAsp 30 (RR: 0.34 [0.22; 0.51], p<0.0001). Severe hypoglycaemia rates were low and similar between groups.

**Conclusion:** The significant difference vs. BIAsp 30 in overall and nocturnal confirmed hypoglycaemia in adults achieving target glycaemia (HbA<sub>1c</sub> <7%) support the flat and stable pharmacodynamic profile of the basal degludec component in IDegAsp.

### New insulin glargine 300 U/mL: glycaemic control and hypoglycaemia in Japanese people with type 1 diabetes mellitus (EDITION JP 1)

M. Matsuhisa<sup>1</sup>, M. Koyama<sup>2</sup>, X. Cheng<sup>3</sup>, S. Shimizu<sup>4</sup>, T. Hirose<sup>5</sup>, on behalf of the EDITION JP 1 study group;

<sup>1</sup>Diabetes Therapeutics and Research Center, The University of Tokushima, <sup>2</sup>Asia Pacific TSU, Sanofi Japan, Tokyo, Japan, <sup>3</sup>Clinical Science & Operation, China R&D, Sanofi, Beijing, China, <sup>4</sup>Biostatistics and Programming, Sanofi Japan, <sup>5</sup>Division of Diabetes, Metabolism and Endocrinology, Department of Medicine, Toho University School of Medicine, Tokyo, Japan.

**Background and aims:** EDITION JP 1 studied the efficacy and safety of new insulin glargine 300 U/mL (Gla-300) versus glargine 100 U/mL (Gla-100) in Japanese people with T1DM using basal plus mealtime insulin.

**Materials and methods:** In the 6-month, multicentre, open-label, phase 3 trial, participants (n=243; mean age 45.2 years; T1DM duration 13.0 years; HbA<sub>1c</sub> 8.1 %) were randomised to once-daily Gla-300 or Gla-100 in combination with mealtime insulin. Basal insulin was titrated to target FPG 4.4–7.2 mmol/L (80 to 130 mg/dL). Primary endpoint was HbA<sub>1c</sub> change from baseline to month 6.

**Results:** Similar HbA<sub>1c</sub> decreases were seen with both Gla-300 and Gla-100 (LS mean [SE] -0.30 [0.06] % and -0.43 [0.06] %; LS mean difference 0.13 [95% CI: -0.03 to 0.29] %). Fewer participants who received Gla-300 experienced confirmed or severe nocturnal hypoglycaemic events versus Gla-100 over the 6-month study period, with the greatest difference observed during the first 8 weeks (Table). The rate of hypoglycaemic events per participant-year at any time of the day (24 hours) was lower with Gla-300 than Gla-100. Severe hypoglycaemia was infrequent in either group. Comparable numbers of adverse events were recorded in each group.

**Conclusion:** In Japanese people with T1DM using basal and mealtime insulin, Gla-300 provides comparable effective glycaemic control with less nocturnal hypoglycaemia, particularly in the first 8 weeks, and no increase in daytime hypoglycaemia versus Gla-100.

Table: Confirmed or severe hypoglycaemia in the EDITION JP 1 study (safety population)

**Glycaemic control and hypoglycaemia in Japanese people with type 2 diabetes mellitus receiving new insulin glargine 300 U/mL in combination with OADs (EDITION JP 2)**Y. Terauchi<sup>1</sup>, M. Koyama<sup>2</sup>, X. Cheng<sup>3</sup>, S. Shimizu<sup>4</sup>, T. Hirose<sup>5</sup>, on behalf of the EDITION JP 2 study group;<sup>1</sup>Department of Endocrinology and Metabolism, Yokohama City University Graduate School of Medicine, <sup>2</sup>Asia Pacific TSU, Sanofi Japan, Tokyo, Japan, <sup>3</sup>Clinical Science & Operation, China R&D, Sanofi, Beijing, China, <sup>4</sup>Biostatistics and Programming, Sanofi Japan, <sup>5</sup>Division of Diabetes, Metabolism and Endocrinology, Department of Medicine, Toho University School of Medicine, Tokyo, Japan.**Background and aims:** EDITION JP 2 studied the efficacy and safety of new insulin glargine 300 U/mL (Gla-300) versus glargine 100 U/mL (Gla-100) in Japanese people with T2DM using basal insulin plus OAD(s).**Materials and methods:** In this 6-month, multicentre, open-label, phase 3 study, participants (n=241; mean age 60.8 years; mean BMI 25.3 kg/m<sup>2</sup>; mean duration of T2DM 14.0 years; mean HbA<sub>1c</sub> 8.0 %) were randomised to receive once-daily Gla-300 or Gla-100 plus OAD(s). Insulin was titrated to target FPG 4.4–5.6 mmol/L (80–100 mg/dL). The primary endpoint was HbA<sub>1c</sub> change from baseline to month 6.**Results:** HbA<sub>1c</sub> decreased similarly in both groups (LS mean [SE] -0.45 [0.06] % for Gla-300 and -0.55 [0.06] % for Gla-100; LS mean difference 0.10 [95% CI: -0.08 to 0.27] %). Fewer participants experienced any hypoglycaemic events during 6 months with Gla-300 versus Gla-100. The number of participants with  $\geq 1$  confirmed ( $\leq 3.9$  mmol/L) or severe hypoglycaemic event (24 h and nocturnal) was consistently lower with Gla-300 compared with Gla-100, and rate per participant-year was lower with Gla-300 versus Gla-100 (Table). Severe hypoglycaemia was infrequent in both groups. LS mean (SE) weight change was -0.62 (0.19) kg for Gla-300 and 0.37 (0.19) kg for Gla-100. Similar safety profiles were observed in both groups.**Conclusion:** In Japanese people with T2DM using basal insulin plus OAD(s), Gla-300 provides comparable effective glycaemic control with fewer hypoglycaemic events, particularly during the first 8 weeks.**Table: Hypoglycaemia in the EDITION JP 2 study (safety population)**

|  |                           | Nocturnal Hypoglycaemia (00:00–05:59) |                 | Hypoglycaemia at any time of day (24 h) |                 |

**The beneficial effect of insulin degludec on nocturnal hypoglycaemia and insulin dose in type 1 diabetic patients: a systematic review and meta-analysis of randomised trials**K. Dzygalo<sup>1</sup>, D. Golicki<sup>2</sup>, A. Kowalska<sup>1</sup>, A. Szybowska<sup>1</sup>;<sup>1</sup>Department of Paediatrics, <sup>2</sup>Department of Experimental and Clinical Pharmacology, Medical University of Warsaw, Poland.**Background and aims:** Insulin degludec is a new-generation ultra-long acting basal insulin which offers a significantly more predictable glucose-lowering effect than other long-acting insulin analogues. To compare the effect of treatment with insulin degludec and long-acting insulin analogues glargine and detemir in type 1 diabetic (T1D) patients by means of a systematic review and meta-analysis.**Materials and methods:** The following electronic databases were searched up to January 2014: MEDLINE, EMBASE, The Cochrane Library. Additional references were obtained from the reviewed articles. There were included randomized controlled trials of at least 12 weeks' duration with basal-bolus regimen therapies in T1D patients.**Results:** Current analysis included 4 studies involving 1,846 T1D patients. The combined data from all trials showed a statistically significant reduction in the basal insulin dose (MD 0.042, 95% CI -0.067 to -0.018, p=0.001) and the total daily insulin dose (MD -0.072, 95% CI 0.016 to -0.027, p=0.002) in the degludec group compared to other long-acting analogues. There was also a significant reduction of nocturnal hypoglycaemia in the degludec group compared to the controls (Rate Ratio 0.697, 95% CI 0.617 to 0.786, p=0.000). There were no differences between the groups in terms of HbA<sub>1c</sub> values, fasting plasma glucose (FPG), adverse events.**Conclusion:** Basal-bolus treatment with insulin degludec was superior to long-acting insulin analogues detemir and glargine in reducing the rate of nocturnal hypoglycemia. In comparison to other long-acting analogues, treatment with insulin degludec was safe, patients obtained similar metabolic control expressed by HbA<sub>1c</sub> and FPG levels with the added benefit of a reduced basal and total insulin dose.

## 978

**Hypo-/hyperglycaemia alert based on online glucose prediction using a global model for type 1 diabetes**C. Yu<sup>1</sup>, C. Zhao<sup>1</sup>, Y. Fu<sup>2</sup>;<sup>1</sup>Control Science and Engineering, Zhejiang University, Hangzhou, China,<sup>2</sup>Control Science and Engineering, Becton Dickinson Technologies, Research Triangle Park, USA.**Background and aims:** Avoiding hypo/hyperglycemia is a major challenge for diabetes mellitus. A timely alert of hypo/hyperglycemia episodes before they occur can allow enough time for the patient to take necessary actions to avoid hypo/hyperglycemia.**Materials and methods:** A global model, which is developed based on one subject and then applied to new subjects without any customization, is used for early hypo/hyperglycemia alert based on online glucose prediction using clinical data provided by BD. Two autoregressive (AR) modeling methods are considered using standard least squares algebra: (i) global prediction model; (ii) subject-dependent model. Both are developed based on time-series glucose data with 2 min as sampling interval. Also, to evaluate the role of high-frequency glucose data, the glucose data are filtered by a first-order low-pass filter with 30min the as threshold. Online short-term glucose predictions are made for 15 subjects for alert of hyper/hypoglycemia based on filtered and non-filtered data.**Results:** The results are summarized in Table 1 as evaluated by time lag which is the time difference between the predicted hyper/hypoglycemia and the measured event.**Conclusion:** The results indicate that the accuracy of global model is comparable to or even better than that of subject-dependent model for alert of hyper/hypoglycemia based on the index of time lag. However, the sensitivity for hypoglycemia using global model is lower than that using subject-dependent model. Also, the model developed based on filtered glucose data can get smaller time

lag of hyper/hypoglycemia alert than that based on raw glucose data since the high-frequency noises are removed after low-pass filtering.

**Table 1.** Hyper/hypoglycemia alert accuracy for 15 subjects and 30 minute predictions (mean  $\pm$  standard deviation)

| Type of Model |                         | Time Lag for             | Sensitivity for    | Specificity for    | Time Lag for            | Sensitivity for   | Specificity for   |
|---------------|-------------------------|--------------------------|--------------------|--------------------|-------------------------|-------------------|-------------------|
|               |                         | hyper event<br>(samples) | hyper event<br>(%) | hyper event<br>(%) | hypo event<br>(samples) | hypo event<br>(%) | hypo event<br>(%) |
| non-filtered  | Global model            | 11.86 $\pm$ 5.75         | 62.86              | 100                | 0-0                     | 12.50             | 100               |
|               | Subject-dependent model | 11.64 $\pm$ 5.01         | 71.43              | 92.86              | 7.25-8.38               | 28.57             | 100               |
| filtered      | Global model            | 11.41 $\pm$ 5.12         | 82.15              | 100                | 7.50-8.66               | 25.00             | 100               |
|               | Subject-dependent model | 11.37 $\pm$ 5.09         | 77.14              | 92.86              | 6.88-7.45               | 50.00             | 100               |

The global model is developed based on subject #6; similar results are obtained for global model developed based on other subjects.

### Assessment of glycaemic control and risk of hypoglycaemia for two basal-bolus algorithms in hospitalised patients with diabetes mellitus type 2

J.K. Mader<sup>1</sup>, K.M. Neubauer<sup>1</sup>, L. Schaupp<sup>1</sup>, F. Aberer<sup>1</sup>, K. Donsa<sup>2</sup>, T. Augustin<sup>2</sup>, S. Spat<sup>2</sup>, B. Hoell<sup>2</sup>, P. Beck<sup>2</sup>, J. Plank<sup>1</sup>, T.R. Pieber<sup>1</sup>; <sup>1</sup>Internal Medicine / Endocrinology and Metabolism, Medical University of Graz, <sup>2</sup>HEALTH, Joanneum Research GmbH, Graz, Austria.

**Background and aims:** Current guidelines recommend pre-meal blood glucose (BG) levels of <7.8mmol/l in the hospital. The aim of this analysis was to compare two versions of a workflow-integrated algorithm for basal-bolus insulin therapy (REACTION algorithm) for glycaemic management in patients with diabetes mellitus type 2 (T2D) hospitalised at the general ward.

**Materials and methods:** For both algorithms BG measurements were performed four times daily (pre-breakfast, pre-lunch, pre-dinner, bedtime); insulin injections were given according to the algorithm. Advice for total daily dose (TDD) (50% basal insulin, 50% pre-meal bolus insulin) was generated once daily. In the initial algorithm bolus insulin dose was evenly distributed over the day; in the refined algorithm bolus insulin dose was redistributed whereas TDD and the 50:50 ratio remained unchanged.

**Results:** 52 (15 female, age 69 $\pm$ 11 years, HbA1c 76 $\pm$ 30mmol/mol, BMI 30 $\pm$ 6kg/m<sup>2</sup>, diabetes duration 14 $\pm$ 11 years) and 95 (42 female, age 68 $\pm$ 11 years, HbA1c 65 $\pm$ 21mmol/mol, BMI 31 $\pm$ 7kg/m<sup>2</sup>, diabetes duration 15 $\pm$ 11 years) T2D patients were treated with the initial and the refined algorithm respectively. Mean BG was 8.8 $\pm$ 1.8mmol/l (initial algorithm) vs. 8.5 $\pm$ 1.8mmol/l (refined algorithm). The overall risk of getting a hypoglycaemic episode (<3.9 mmol/l) during the first 10 treatment days was 3% vs. 1.3% (initial vs. refined algorithm). There was no significant change in hypoglycaemia occurrence over the treatment time and no influence of time of day between groups. Mean TDD was 45 $\pm$ 26U (basal: 22 $\pm$ 18U, bolus: 24 $\pm$ 16U) for the initial algorithm and 47 $\pm$ 26U (basal: 24 $\pm$ 18U, bolus: 24 $\pm$ 18U) for the refined algorithm.

**Conclusion:** The refined version of the REACTION algorithm could establish similar glycaemic control with reduced risk of hypoglycaemia. Insulin doses were comparable for the two versions of the algorithm. The REACTION algorithm has the potential to improve glycaemic management in the hospital setting.

### Sustained glycaemic control and less hypoglycaemia with new insulin glargine 300 U/ml vs 100 U/ml: 1-year results in type 2 diabetes with basal and mealtime insulin (EDITION 1)

M.C. Riddle<sup>1</sup>, H. Yki-Järvinen<sup>2</sup>, G.B. Bolli<sup>3</sup>, M. Ziemien<sup>4</sup>, I. Muehlen-Bartmer<sup>4</sup>, S. Cissokho<sup>3</sup>, P.D. Home<sup>6</sup>;

<sup>1</sup>Oregon Health & Science University, Portland, USA, <sup>2</sup>University of Helsinki, Finland, <sup>3</sup>University of Perugia, Italy, <sup>4</sup>Sanofi-Aventis Deutschland GmbH, Frankfurt am Main, Germany, <sup>5</sup>Keyrus Biopharma, Levallois-Perret, France, <sup>6</sup>Newcastle University, Newcastle upon Tyne, UK.

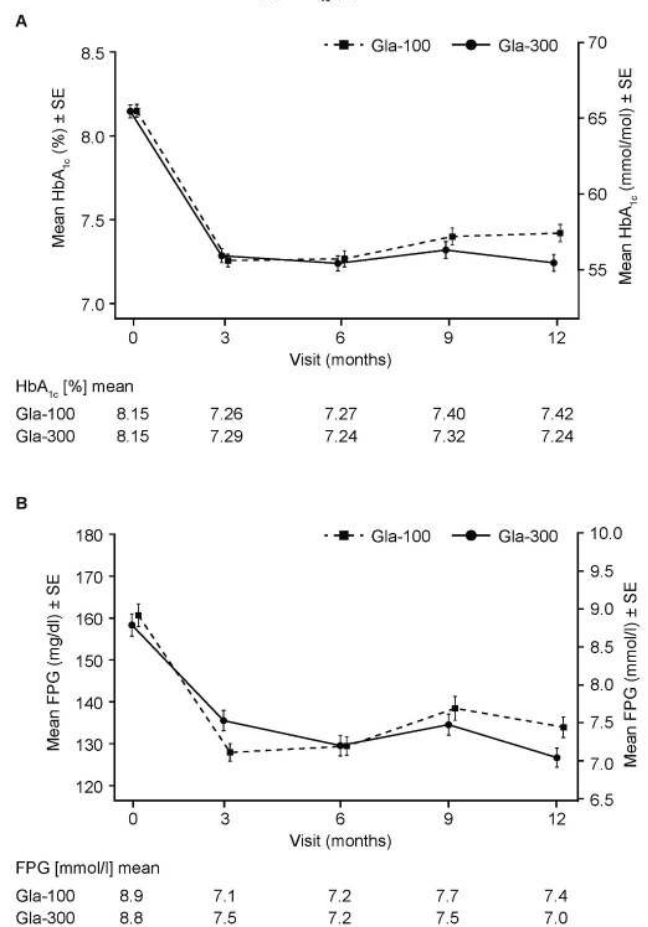

**Background and aims:** EDITION 1 studied the efficacy and safety of new insulin glargine 300 U/ml (Gla-300) versus glargine 100 U/ml (Gla-100) in people with type 2 diabetes mellitus using basal plus mealtime insulin.

**Materials and methods:** In EDITION 1, 807 people with elevated HbA<sub>1c</sub> were randomised to titrate Gla-300 or Gla-100 once daily in the evening for 6 months, continuing the mealtime insulin. In a 6-month open-label extension, participants continued Gla-300 or Gla-100; 89% and 88% completed 12 months of treatment.

**Results:** Improved glycaemic control was maintained over 12 months in both groups (LS mean difference Gla-300 vs Gla-100: -0.17 [95% CI: -0.30 to -0.05] % for HbA<sub>1c</sub> and -0.34 [95% CI: -0.69 to 0.01] mmol/l for FPG) (Figure). Basal insulin doses were higher with Gla-300 than Gla-100 after 12 months (1.03 vs 0.90 U/kg). During the 12 months of treatment, a similar percentage of participants had  $\geq 1$  confirmed ( $\leq 3.9$  mmol/l [ $\leq 70$  mg/dl]) or severe hypoglycaemic event at any time of the day (85.9% with Gla-300 vs 91.5% with Gla-100; RR 0.94 [95% CI: 0.89 to 0.99]). During the night this percentage was lower in Gla-300 (54.5% vs 64.7% in Gla-100; RR 0.84 [95% CI: 0.75 to 0.94]). Severe hypoglycaemia was reported by 6.7% of Gla-300- and 7.5% of Gla-100-treated participants. No between-treatment differences in adverse events were seen.

**Conclusion:** In conclusion, over 1 year of treatment in people with type 2 diabetes mellitus using basal and mealtime insulin, Gla-300 provided sustained glycaemic control with a lower incidence of hypoglycaemia compared with Gla-100.

### Acute and sub-acute effects of the endobarrier on glucose homeostasis and appetite in obese uncontrolled type 2 diabetes mellitus patients

G. Segal-Lieberman<sup>1</sup>, A. Lang<sup>2</sup>, M. Lahav<sup>2</sup>, N. Lieberman<sup>3</sup>, A. Paster<sup>1</sup>, N. Konvalina<sup>1</sup>, H. Kanety<sup>1</sup>, R. Hemi<sup>1</sup>, O. Cohen<sup>1</sup>;

<sup>1</sup>Institute of Endocrinology, Sheba Medical Center, Ramat-Gan,

<sup>2</sup>Institute of Gastroenterology, Sheba Medical Center, Ramat-Gan,

<sup>3</sup>Community Medical Division, Clalit Medical Services, Tel-Aviv, Israel.

**Background and aims:** Diabetes is a prevalent metabolic disease accompanied by an increased risk for cardiovascular disease as well as micro-vascular complications. To date, bariatric surgery has become one of the most effective means of providing durable, clinically-significant resolution of diabetes, with the majority of subjects with T2DM undergoing these procedures experiencing a remission of their disease. One of the theories behind the early resolution of diabetes after the Roux-en-Y Gastric bypass operation claims that the mediating factor lies within the bypassing of the duodenum by the ingested food. The Endobarrier gastrointestinal liner system (by GI Dynamics®) is an endoscopically-delivered device that mimics gastric bypass surgery by shielding the duodenum and upper jejunum from contact with chyme.

**Materials and methods:** An Endobarrier device was placed in the duodenum via an endoscopic procedure in 33 uncontrolled diabetic obese subjects. Acute and sub-acute effects of the device on glucose homeostasis were evaluated using a Continuous Glucose Monitoring (CGM) recording device for one week, as of two days prior to device implantation until four days after its removal. The effect of the device on appetite was evaluated using the 5-question visual analog scale, where each question was given a score between 1-10.

**Results:** Our population included 17 females and 16 males with mean diabetes duration of 10.4 (SD±5.8) years, most were insulin treated. Baseline HbA1c level was of 9.3% (SD±1.0) and baseline body mass index was 38.0 kg/m<sup>2</sup> (SD±5.0). CGM data revealed a significant decrease in average daily glucose levels from 243.2 mg/dL (SD±63.4) one day before the procedure to 227 mg/dL (SD±53.6) (p value = 0.002) on the day of the procedure, while the subjects were fasted most of the day. As of the first day after the procedure, despite the fact that eating was initiated, prandial medications were terminated and basal insulin dose was lowered by 50%, the recorded glucose levels continued to decrease and reached a decrease of 30.3 mg/dL (SD±69.4) (p value= 0.048) vs. baseline on the last day of CGM recording. Whereas no significant change in the VAS score was recorded after one week, one month after the Endobarrier insertion, a significant change of 1.1 points (SD±1.7) (p value=0.003) vs. baseline was recorded suggesting a significant decrease in appetite one month after the procedure, despite a weight loss of 4.2 kg at this time-point.

**Conclusion:** Endobarrier therapy in advanced uncontrolled obese diabetic patients significantly improves their glucose homeostasis, as early as the first day after the procedure. This improvement becomes even more prominent as days go by and eating becomes more regular. Despite a substantial weight loss, appetite is significantly suppressed one month after the insertion of the device. EndoBarrier seems to have an early lowering effect on blood glucose as well as a suppressive effect on appetite, rendering it an attractive option for the care of „diabesity“ in this challenging population.

### Effects of duodeno-jejunal bypass liner on bile acid homeostasis in patients with severe obesity

A.A. Young<sup>1</sup>, K.K. Brown<sup>1</sup>, J.D. Williams<sup>1</sup>, F. Pimentel<sup>2</sup>, A. Sharp<sup>2</sup>, P.P. Parra<sup>2</sup>, D. Turiel<sup>3</sup>, R. Munoz<sup>2</sup>, M. Arrese<sup>2</sup>, V. Irribarra<sup>2</sup>, J.F. Miguel<sup>2</sup>, L.M. Kaplan<sup>4</sup>, A. Levine<sup>4</sup>, D. Maggs<sup>5</sup>, A. Escalona<sup>2</sup>;

<sup>1</sup>GlaxoSmithKline, Research Triangle Park, USA, <sup>2</sup>Pontificia Universidad Católica de Chile, Santiago, Chile, <sup>3</sup>Obesity, Metabolism & Nutrition Institute, Massachusetts General Hospital, Boston, <sup>4</sup>Wyss Institute, Harvard University, Cambridge, <sup>5</sup>GI Dynamics, Lexington, USA.

**Background and aims:** Endoscopic placement of a duodenojejunal bypass liner (DJBL) elicited a 16.1 ± 1.6% loss of body weight in 17 morbidly obese

patients, and normalization of HbA1c (<6.3%) in 5/7 of the subset with type 2 diabetes. DJBL excludes nutrient contact with the duodenal mucosa and thus mimics aspects of Roux-en-Y gastric bypass surgery. Biliary and pancreatic secretions pass outside the liner until they mix with chyme in the proximal jejunum. We examined the effects of DJBL on plasma concentrations of bile acids (BA) and other markers of BA metabolism.

**Materials and methods:** Plasma total BA concentration was measured enzymatically. Primary and secondary bile acids, their taurine and glycine conjugates, and 7 $\alpha$ -hydroxy-cholest-4-ene-3-one (C4), an intermediate used as a correlate of BA synthetic rate, were determined by HPLC/MS in samples taken at fasting and over 3 hours after a standard (Ensure) test meal. Testing occurred before, 1, 12, 24, and 52 weeks after DJBL placement in severely obese patients (age 34.8±9.5 years; body mass index 42.6±5.2 kg/m<sup>2</sup>). FGF-19, a feedback inhibitor of BA synthesis secreted from the ileum, was measured by ELISA.

**Results:** One week after DJBL placement, fasting and post-meal total BA concentrations, and C4 concentrations abruptly decreased; FGF-19 concentrations increased. Thereafter, fasting and post-meal total BAs increased (1.7-fold, 2.3-fold, respectively, from baseline; each P<0.05). Changes were associated with 10-fold (fasting) and 5-fold (post-meal) increases in unconjugated primary and, respectively, 25-fold and 5-fold increases in unconjugated secondary BAs. Conjugated BAs did not change. Aside from the transient perturbations at week 1, FGF-19 progressively declined. This was especially apparent in the post-meal samples (arrows). Aside from week 1, C4 was unchanged.

**Conclusion:** Marked increase in circulating BAs with DJBL, attributable to unconjugated species, occurs without an apparent increase in BA synthetic rate (unchanged C4) but with a reduction in BA sensing in the ileum (reduced FGF-19). Possible mechanisms may include early bacterial deconjugation and passive absorption of secreted BAs. The contribution of these BA changes to the benefits of DJBL, and other procedures such as RYGBS, merits further study.

### Duodeno-jejunal bypass liner (DJBL) exerts prompt and robust metabolic changes in severely obese patients

R. Muñoz<sup>1</sup>, J. Miquel<sup>2</sup>, M. Arrese<sup>2</sup>, V. Irribarra<sup>3</sup>, F. Pimentel<sup>1</sup>, A. Sharp<sup>1</sup>, D. Turiel<sup>1</sup>, P. Pizarro Parra<sup>1</sup>, A. Young<sup>4</sup>, K.K. Brown<sup>4</sup>, D. Maggs<sup>5</sup>, A. Levine<sup>7</sup>, J. Cormier<sup>6</sup>, A. Escalona<sup>1</sup>;

<sup>1</sup>Department of Digestive Surgery, <sup>2</sup>Department of Gastroenterology,

<sup>3</sup>Department of Nutrition, Diabetes and Metabolism, Pontificia Universidad Católica de Chile, Santiago, Chile, <sup>4</sup>Enterendocrine Discovery Performance Unit, GlaxoSmithKline, Research Triangle Park, <sup>5</sup>GI Dynamics, Lexington,

<sup>6</sup>Wyss Institute, Harvard University, Cambridge, USA.

**Background and aims:** The endoscopically placed duodeno-jejunal bypass liner (DJBL) prevents nutrient contact with the duodenal mucosa, thereby replicating elements of gastric bypass surgery, and eliciting robust weight loss and metabolic improvement in obese subjects with or without diabetes. We examined the time-dependent effects of DJBL on clinical, metabolic and hormonal measures out to 52 weeks in a cohort of severely obese subjects (n=17; age 34.8±9.5 years; body mass index 42.6±5.2 kg/m<sup>2</sup>, 77% female) some of whom had overt type 2 diabetes (DM subset n=7; A1C 7.07±1.48%).

**Materials and methods:** Clinical endpoints (A1C, body weight) and mixed meal (Ensure) challenge samples were collected at baseline and 1, 12, 24, and 52 weeks for measurement of plasma glucose, FFA, triglycerides, c-peptide, glucagon, and GLP-1.

**Results:** In the overall cohort, there was prompt and robust weight loss observed that plateaued at 6–12 months (weight loss % at 52 weeks: overall -15.9%, non-DM -14.3%, DM -18.2%). A1C in the DM group decreased to  $6.24 \pm 1.18\%$  at 52 weeks. Lowering of both fasting and post-prandial glucose (see figure) in the DM group was observed 1 week post implant and was maintained to 52 weeks. GLP-1 responses were augmented and triglycerides and FFAs suppressed during meal challenges from 12 to 52 weeks ( $P < 0.05$  vs. baseline for AUC for all analytes). In addition, augmented c-peptide and suppressed glucagon was observed during meal challenge in the DM group (significant AUC changes observed 12 to 52 weeks).

**Conclusion:** The DJBL exerts prompt and robust effects on body weight and metabolic markers in obese subjects with or without dysglycemia. Enhanced incretin secretion and improved islet function may underlie some of the metabolic benefits. The unique combination of metabolic benefits following DJBL may offer an attractive alternative to pharmacological and surgical approaches.

### The duodenal-jejunal bypass liner (DJBL) effect of regression from prediabetes

V. Iribarra<sup>1</sup>, A. Sharp<sup>2</sup>, D. Turiel<sup>2</sup>, P.P. Pizarro<sup>2</sup>, S. Guzman<sup>2</sup>, R. Muñoz<sup>2</sup>, F. Pimentel<sup>2</sup>, A. Escalona<sup>2</sup>;

<sup>1</sup>Nutrition Diabetes and Metabolism, <sup>2</sup>Digestive Surgery, Pontificia Universidad Católica de Chile, Santiago, Chile.

**Background and aims:** The endoscopically delivered duodenal jejunal bypass liner (DJBL) has demonstrated clinically meaningful metabolic effects in obese individuals with type 2 diabetes (T<sub>2</sub>DM). Prediabetes is a high risk state for the development of T<sub>2</sub>DM. The aim of this study was to examine the DJBL effects on glycaemic control,  $\beta$  cell function and sensitivity to insulin in a group of severely obese subjects with prediabetes.

**Materials and methods:** DJBL was implanted for one year in 61 subjects with severe obesity (BMI  $\geq 35$  Kg/m<sup>2</sup>). Among these subjects, 18 were diagnosed with prediabetes. The included subjects were mostly females (mean  $\pm$  SD) age  $36.8 \pm 6.6$  years, BMI  $39.6 \pm 2.9$  Kg/m<sup>2</sup> and 17/18 were on metformin. Subjects were followed monthly for weight, fasting glucose, insulin and Hb A<sub>1c</sub>. Insulin sensitivity and  $\beta$  cell function were estimated with HOMA calculator ([www.dtu.ox.ac.uk/Homacalculator/index.php](http://www.dtu.ox.ac.uk/Homacalculator/index.php)). Statistical analyses (ANOVA for repeated measures) were performed with Statistical Package for Social Sciences 17.0. A  $p$ -value of  $< 0.05$  was considered significant.

**Results:** At implantation 17 out of 18 subjects were on anti diabetic medication that was withdrawn in 9/17 subjects, 8 subjects remained under metformin treatment. After implantation Hb A<sub>1c</sub> decreased from  $6.37 \pm 0.82\%$  (baseline) to  $5.9 \pm 0.56\%$  at 4 weeks and remained below 6%. At 52 weeks was

$5.88 \pm 0.52$  ( $p < 0.001$ ) and fasting glucose decreased from  $104 \pm 18$  mg/dL to  $95.9 \pm 14.8$  mg/dL (NS). We observed an important change in insulin secretion reflected as improvement of insulin resistance. HOMA-IR decreased progressively from  $3.1 \pm 1.0$  to  $1.7 \pm 0.7$  ( $p < 0.001$ ) and  $\beta$  cell function improved as insulin sensitivity increased from  $37.5 \pm 11.9\%$  to  $75.3 \pm 31.1\%$  ( $p < 0.001$ ). At the end of the study 50% of subjects achieved Hb A<sub>1c</sub>  $< 5.7\%$ .

**Conclusion:** The DJBL improved glucose metabolism in this group of prediabetic subjects, achieving normal glucose levels in half of them. The decrease of insulin resistance and recovery of  $\beta$  cell function observed in these patients opens new possibilities in order to obtain a regression from prediabetes.

## 985

### Acceptance of a truly non-invasive glucose monitoring device for home use

Y. Mayzel<sup>1</sup>, A. Gal<sup>1</sup>, I. Harman-Boehm<sup>2</sup>, A. Drexler<sup>3</sup>, E. Naidis<sup>1</sup>, N. Goldstein<sup>1</sup>, K. Horman<sup>1</sup>, S. Cohen<sup>1</sup>;

<sup>1</sup>Integrity Applications, Ashkelon, <sup>2</sup>Soroka University Medical Center, Beer-Sheva, Israel, <sup>3</sup>David Geffen School of Medicine, University of California, Los Angeles, USA.

**Background and aims:** Adherence to self-monitoring of blood glucose (SMBG) holds a key role in achieving tight glycaemic control in diabetic patients. The conventional blood glucose monitoring methods require performance of invasive measurements, which involve pain and a rather complex multi-step procedure. Thus, despite the clear advantages of conducting SMBG, invasive monitoring suffers from under-utilization. A Non-invasive (NI) glucose monitoring approach is expected to encourage frequent self-monitoring, mainly due to a pain-free alternative. To further motivate utilization, a NI device should be user friendly and simple-to-handle by a lay person in home use. GlucoTrack<sup>®</sup> is such a NI, CE Mark approved glucose monitoring device. The device suitability for home utilization was evaluated in regards to the impact of an unskilled user upon the device accuracy, ease and simplicity of use and general user satisfaction.

**Materials and methods:** Series of clinical trials were conducted by third party to assess usability, user satisfaction and possible user impact. All trials began with individual calibration and brief training by a proficient team. Then, usability and general impression from the device were assessed based on feedback received from 72 educated (high-school and higher) users (Home group). 30 participants of the Home group used the device at home for 5–7 days after calibration. 42 other subjects of the Home group conducted the measurements by themselves for three more days simulating home alike environment. Then, user impact on the measurements' accuracy was evaluated by comparing performances when measurements were conducted by a proficient team (Clinic group, consisting of 135 subjects) with measurements conducted by the subjects themselves (42 of Home group subjects).

**Results:** Clarke Error Grid analysis shows 95.7% and 96.2% of the points in the clinically accepted A+B zones in the Clinic and Home groups, respectively. Mean Absolute Relative Differences of 31.6% and 30.7% were observed in these groups, respectively. 86% of all subjects expressed willingness to use the device regularly. 78% were pleased with the device. GlucoTrack display appeared clear and understandable to 91% of Home users. The operation instructions were clear to 97% of high school graduated Home subjects and to 88% with higher education. 79% and 85% (high school and higher educated Home users, respectively) found measurement performance to be simple. 74% and 69% claimed the device is easy to use among high-school and higher-educated, respectively.

**Conclusion:** GlucoTrack performances show negligent dependence upon user skills, based on similar accuracy when used by proficient and new users. Using the device yields positive user feedback, high satisfaction of usability, ease of use and users' willingness to increase the frequency of SMBG. These advantages, along with its painless nature of measurements and long term cost-effectiveness of use, suggest GlucoTrack as a utilizable home-use device for enhanced SMBG.

Clinical Trial Registration Number: NCT00889668

## 986

**Improvement of metabolic control in type 1 diabetic children using ELKa toolset: a randomised controlled trial**

A. Kowalska, K. Piechowiak, A. Szybowska;

Department of Pediatrics, Medical University of Warsaw, Poland.

**Background and aims:** In intensive insulin therapy, prandial insulin doses should be calculated before each meal with carbohydrate (CHO) and fat/protein (FP) exchange counting. Therefore food weighing and complicated calculations need to be performed. ELKa system is an advanced toolset which helps performing calculation of food exchanges. It consists of ELKa software including database of various meals and nutrients and ELKaPlus digital kitchen scale. Among similar devices it is extraordinary due to opportunity of transmission weights in a real-time to a computer via USB port. After choosing the name of a particular product from the list, the program gives precise information about the amount of CHO and FP exchanges in a serving. It simplifies every-day calculations and it increases the precision of results. A number of our patients use the system and it appears to be useful accessory, but no clinical trials were performed yet. The aim of this study was to investigate the benefit of using ELKa toolset in comparison with standard method of CHO and FP counting on metabolic control in type 1 diabetic children.

**Materials and methods:** A randomized 26-week clinical trial was conducted on 106 patients (64 girls, 42 boys) aged  $11 \pm 4.2$  years (range 1.8 - 17.2 years), with mean BMI  $19.6 \pm 3.4$  (range 14.5 - 33.2), diabetes duration  $5 \pm 3.1$  years (range 1 - 14.3 years), and HbA1c  $7.5 \pm 1\%$  (range 5.1% - 10%). All patients were treated with insulin pumps. Patients were randomly assigned into two groups: the group A (n=53) using ELKa system for food exchange counting and the group B (n= 53) using standard method of food calculation. There were no significant differences between groups in mean baseline HbA1c levels (group A:  $7.6\% \pm 0.1$ ; group B:  $7.4\% \pm 0.1$ ;  $p=0.395$ ), BMI (A: 18.4; B: 19.7;  $p= 0.165$ ), duration of diabetes (A: 4.3 years; B: 4.6 years;  $p= 0.265$ ) and insulin/kg/24h (A: 0.8; B: 0.8;  $p=0.099$ ). Control group was slightly older ( $6.9$  years  $\pm 0.5$  vs.  $5.3$  years  $\pm 0.5$ ;  $p=0.042$ ). At follow-up visits after 3 and 6 months, HbA1c, BMI, daily insulin dose and blood glucose values were assessed. The group A also was asked about the frequency of using the toolset.

**Results:** 94 patients completed 26-week follow-up. There were no significant difference between groups with regard to HbA1c (group A -  $7.4\% \pm 0.2$ , n=43 vs. group B -  $7.6\% \pm 0.1$ , n=51;  $p= 0.222$ ). Patients who declared using the toolset everyday (86-100% of meals) or for the most part of the week (51- 85% of meals) had significantly lower HbA1c ( $6.9 \pm 0.2$ , n=21) in comparison with the control group ( $7.6 \pm 0.1$ , n=51;  $p=0.0005$ ). Moreover subgroup of patients who used ELKa only for 50-85% meals also achieved better result in a glycated hemoglobin than control group (HbA1c  $6.8\% \pm 0.2$ , n=14;  $p= 0.0009$ ).

**Conclusion:** Our results confirm the beneficial effect of using ELKa system in day-to-day calculations of CHO and FP exchanges. Diabetic children who used the system for more than 50% meals achieved better metabolic control than children who performed food calculations without this tool.

## 987

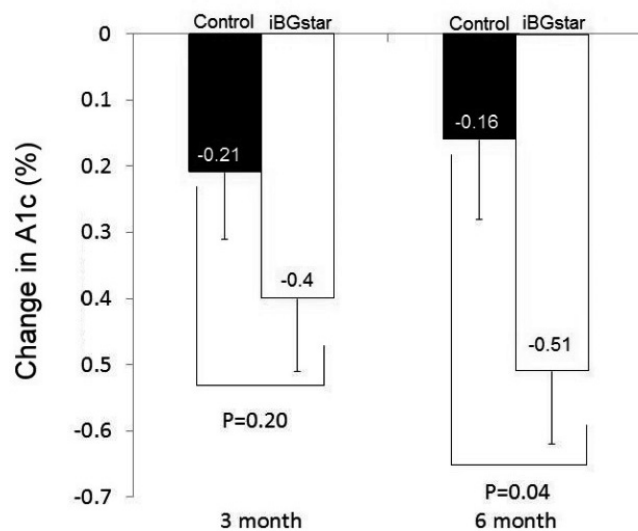

**Role of mobile technology to improve diabetes care in adults with type 1 diabetes: the REMOTE-T1D study**S.K. Garg<sup>1</sup>, W.R. Hiatt<sup>2</sup>, P.A. Gottlieb<sup>1</sup>, C.R. Beatson<sup>1</sup>, F. Flacke<sup>3</sup>, V.N. Shah<sup>1</sup>, J.K. Snell-Bergeon<sup>1</sup>;<sup>1</sup>Barbara Davis Center for Childhood Diabetes, University of Colorado Denver, <sup>2</sup>CPC Clinical Research, University of Colorado Denver, Aurora, USA, <sup>3</sup>Sanofi, Paris, France.

**Background and aims:** This study evaluated the role of mobile technology to improve diabetes care in adults with type 1 diabetes (REMOTE-T1D). We hypothesized that the use of mobile technology (iPhone plus iBGStar<sup>®</sup>) will result in improvement in Patient Reported Outcomes (PRO).

**Materials and methods:** This single-center, prospective, 6-month, open-label, investigator-initiated pilot study enrolled 100 adult patients with type 1 diabetes. Patients were randomized in a 1:1 fashion to an intervention group using self-monitoring of blood glucose (SMBG) with iBGStar vs. SMBG with Accu-Chek Nano<sup>®</sup> (control). All subjects wore a blinded, continuous glucose monitor (CGM) for four separate 7-day periods. Primary outcomes included PRO (hypoglycemia fear questionnaire) and the secondary outcomes included glucose control parameters. Insulin doses, hypoglycemic episodes and self-monitored blood glucose (SMBG) measures were obtained at each visit. At the conclusion of the study, satisfaction with the device was ascertained.

**Results:** Baseline demographics and A1c values were similar between the two groups (mean SD  $\pm$  A1c  $7.7 \pm 1.0$  and  $8.0 \pm 0.9$  in the control and iBGStar groups, respectively,  $p=0.15$ ). The Hypoglycemia Fear Scale improved compared to baseline in both groups to a similar extent at 3 months ( $-4.5 \pm 9.5$  in the iBGStar group vs.  $-3.0 \pm 8.4$  in the control group,  $p=0.65$  between groups) and the changes remained similar between groups at 6 months ( $-3.9 \pm 12.5$  in the control group vs.  $-1.4 \pm 10.0$  in the iBGStar group,  $p=0.31$ ). There was a significant improvement in change of A1c in the iBGStar group at 6 months when compared to baseline or the control group (Figure). The percentage of time spent in hypoglycemia (less than 70 mg/dL) as assessed by CGM readings was similar in the two groups throughout the study. There was a significant increase in insulin dose at 3 months in the iBGStar group ( $7.7 \pm 20.9$  units/day) but not in the control group ( $1.7 \pm 18.3$  units/day), with no difference in hypoglycemic episodes ( $21.5 \pm 15.5$  in the iBGStar group vs.  $25.5 \pm 31$  in the control group,  $p=0.48$ ) throughout the study. The number of SMBG tests per day was similar at baseline ( $4.8 \pm 1.1$  in the iBGStar group and  $5.2 \pm 1.1$  in the control group,  $p=0.07$ ) and decreased significantly from baseline in both groups at 6 months ( $-0.3 \pm 0.09$  in the iBGStar group vs.  $-0.4 \pm 0.9$  in the control group,  $p=0.48$ ). At the exit interview, when asked whether they would prefer the iBGStar vs. their past SMBG device, 87.5% preferred the iBGStar.

**Conclusion:** We conclude that the use of iBGStar in this REMOTE-T1D study which allowed for easier communication of SMBG readings with the treating center by its email function, improved A1c at 6 months with no increased risk of hypoglycemia or change in PRO. This device was well-received by patients.

**Change in A1c (%) in 3 and 6 Months**

**Long-term tele-monitoring of patients with type 2 diabetes mellitus: results of the Greek pilot of the renewing health multicentre randomised control trial**G.E. Dafoulas<sup>1</sup>, A. Mavrodi<sup>2</sup>, P. Gkiata<sup>3</sup>, H. Giannakakos<sup>4</sup>, P. Stafylas<sup>5</sup>, M. Delizona<sup>6</sup>, V. Aletras<sup>2</sup>, P. Pechlivangolou<sup>7</sup>, K. Theodorou<sup>1</sup>, G. Koukoulis<sup>6</sup>, A. Bargiota<sup>6</sup>;<sup>1</sup>Faculty of Medicine, University of Thessaly, Larisa, <sup>2</sup>Department of Business Administration, University of Macedonia, Thessaloniki, <sup>3</sup>Intermunicipal Digital Community of Central Greece, Trikala, <sup>4</sup>5th Regional Health Authority of Thessaly and Sterea, Larisa, Greece, <sup>5</sup>Health Information Management SA, Brussels, Belgium, <sup>6</sup>Department of Endocrinology and Metabolic Diseases, Regional University Hospital, Larisa, Greece, <sup>7</sup>Toronto Health Economics and Technology Assessment Collaborative, University of Toronto, Canada.

**Background and aims:** Evidence is required to assess the impact of long term telemedicine use in treatment of patients with type 2 diabetes mellitus (DMT2). The aim of the present study was to examine the impact of a long-term telemonitoring program for patients with DMT2 on glycemic control,

health-related quality of life (HRQOL), physical activity and compliance with the mediterranean diet compared to usual care.

**Materials and methods:** In the Greek pilot of a prospective, randomized, single-blinded, multicenter, one year study 154 patients with DMT2 capable to use the telemonitoring device, with an HbA1c > 53 mmol/mol (7.0 % according to NGSP) were studied after they were randomly assigned in the telemonitoring group (IG), (N=74) and in the control group (CG), (N=80) and having signed the informed consent form. In the (IG) group patients' blood glucose profiles were collected weekly using a mobile phone health platform, for a period of one year. Allocated health professionals provided by phone the appropriate counseling on lifestyle and medication changes when required. Patients in (CG) group received usual care with face-to-face consultations. HRQOL was assessed using a generic (SF36v2) questionnaire and a disease-specific questionnaire, the Problem Areas in Diabetes (PAID) scale. Physical activity was assessed using the self-administered short form instrument. International Physical Activity Questionnaire (IPAQ) and the compliance with the Mediterranean diet using the Mediterranean Diet Quality Index (KIDMED) adapted for Greek adults.

**Results:** The table shows the outcome of the variables studied in both groups. A greater reduction in HbA1c was observed in the IG compared to the CG at the end of the study. There was a statistically significant improvement in the generic HRQOL in the MCS, in the disease specific HRQOL and the physical activity in the IG compared with the CG, but there was no improvement in KIDMED in neither or the two groups.

**Conclusion:** Our preliminary results indicate that in patients with DMT2, home telemonitoring is more effective than usual care in improving glycemic control with concurrent improvement in patients quality of life and increase of their physical activity. However home telemonitoring does not seem capable to empower patients with DMT2 with to follow a healthier diet.

## PS 081 Improvements in continuous glucose monitoring

989

### Accuracy of Continuous Glucose Monitoring (CGM) under free-living conditions during three home closed loop studies

L. Leelarathna<sup>1</sup>, H. Thabit<sup>1</sup>, D. Elleri<sup>2</sup>, J.M. Allen<sup>1</sup>, A. Lubina-Solomon<sup>3</sup>, J.K. Mader<sup>4</sup>, C. Benesch<sup>5</sup>, M. Stadler<sup>6</sup>, T.R. Pieber<sup>4</sup>, S. Arnolds<sup>5</sup>, S.R. Heller<sup>3</sup>, S.A. Amiel<sup>6</sup>, D.B. Dunger<sup>2</sup>, M.L. Evans<sup>1</sup>, R. Hovorka<sup>1</sup>;  
<sup>1</sup>Institute of Metabolic Science, University of Cambridge, <sup>2</sup>Department of Paediatrics, University of Cambridge, <sup>3</sup>Academic Unit of Diabetes, Endocrinology and Metabolism, Department of Human Metabolism, University of Sheffield, UK, <sup>4</sup>Division of Endocrinology and Metabolism, Department of Internal Medicine, Medical University of Graz, Austria, <sup>5</sup>Profil Institut für Stoffwechselforschung GmbH, Neuss, Germany, <sup>6</sup>Diabetes Research Group, Kings College, London, UK.

**Background and aims:** Closed loop systems modulate insulin delivery based on glucose levels measured by commercial CGM devices. We evaluated the accuracy of Freestyle Navigator II CGM (Abbott Diabetes Care, CA, USA) against the capillary glucose measured by the in-built glucometer of Freestyle Navigator II CGM using Freestyle Lite glucose strips. Data collected during three unsupervised randomised open-label crossover home closed-loop studies were pooled for the current analysis.

**Materials and methods:** Paired CGM and capillary glucose values (10,616 pairs) were collected from 57 participants with type 1 diabetes [41 adults (age 39±12 years, HbA1c 7.9±0.8%; mean±SD) recruited at five centres; 16 adolescents (15.6±3.6 years, HbA1c 8.1±0.8%) recruited at one centre]. Participants were instructed to calibrate the sensor according to manufacturer instructions. Numerical accuracy was assessed by relative absolute difference (RAD) ( $|\text{sensor} - \text{capillary}| / \text{capillary}$ ) × 100% when capillary > 4.2 mM and by absolute difference (AD)  $|\text{sensor} - \text{capillary}|$  when capillary ≤ 4.2 mM. Clinical accuracy was assessed by the Clarke error grid analysis.

**Results:** Total duration of sensor use for whole cohort was 2,002 days (48,052 hours). The average number of capillary glucose values taken by adults and adolescents was 5.9 ± 2.0 and 4.3 ± 2.4 per day, respectively. Overall sensor accuracy for the entire capillary glucose range (1.1 to 27.8 mmol/L) was good with a median (IQR) RAD of 10.2% (4.5 - 19.0). Sensor accuracy stratified according to capillary glucose levels is shown in Table. Lowest RAD was observed in the hyperglycaemic range. Over 95% of pairs were in combined Clarke error grid zones A and B. Calculated per subject, median (IQR) RAD was 10.8% (8.7 - 11.5). Ninety percent of participants had a median ARD < 13.5%.

**Conclusion:** In a cohort comprising 57 subjects with T1D aged 12 years and older, we observed high and consistent accuracy of FreeStyle Navigator II. Particularly at glucose levels above 10 mmol/L, this facilitates safe operation of closed loop as otherwise insulin over-delivery due to overestimated glucose levels could lead to hypoglycaemia. Our results support the use of FreeStyle Navigator II in home closed loop studies and may contribute towards establishing performance criteria for CGM in home use.

**Table: Numerical and clinical accuracy of Freestyle Navigator CGM**

| Freestyle Navigator II             |                     |
|------------------------------------|---------------------|
| Number of paired points            | 10,616              |

### Comparison of paired and sensor-based glucose testing for meal bolus adjustment

G.A. Hayter, E.S. Budiman;  
Abbott Diabetes Care, Alameda, USA.

**Background and aims:** Meal boluses, whether based on carb counting or fixed bolus dosing, can benefit from periodic review of the post prandial glucose response. For carb counting, this can mean adjusting the carb ratio. For fixed bolus, this can be used to directly increase or decrease the fixed amount. The post prandial glucose response can be characterized by the difference between the peak glucose in response to the meal and the glucose at meal start. Two glucose testing methods for measuring this difference are considered. The first approach relies on a pair of discrete strip tests, one at the meal start and one at some fixed time after meal start. This method is confounded by the fact that peak meal times vary widely. The second approach utilizes sensor data which is sampled periodically. The benefit of this method is that the peak time can be estimated which provides a better estimate of the glucose difference. The precision of both methods will be compared, taking into account measurement error.

**Materials and methods:** Sensor data from a feasibility study of a 14-day sensor wear, comprising of 55 subjects with diabetes, is used. These data have a 1 minute sample rate and will represent “truth” for this analysis. True meal start and peaks have been previously identified. Paired testing is simulated using the truth data, with the first reading at the true meal start and the second reading at a predetermined fixed time interval (e.g., 60, 120 and 180 minutes). Sensor-based testing is simulated by decimating the truth data to longer sampling intervals (e.g., 5, 10, 15 minutes) and a meal detection algorithm is applied to these decimated data to estimate meal start and peak times.

**Results:** The figure summarizes the median and inter-quartile-range (IQR) of the relative difference (RD) between the “true” glucose meal response and the results from the six methods. The three sensor-based testing methods are shown to have much better precision than the paired testing methods; IQR RD for the best paired testing (Paired 120) is about 46% compared to about 25% for all of the sensor-based testing methods, and paired testing has substantially more negative bias. The difference in precision between the two test methods is primarily attributed to the wide variation in glucose meal

response from patient to patient; the sensor-based method estimates the peak time based on the data while the paired testing method assumes a fixed duration for the peak time. The figure also shows that performance for sensor-based testing is similar for sample periods up to 15 minutes.

**Conclusion:** The sensor-based testing method offers a more consistent characterization of meal response than the paired testing method, resulting in higher confidence that bolus adjustments can be made safely and effectively. The higher level of precision may allow dose titration that results in lower overall glucose levels with lower risk of hypoglycemia, but these results must be evaluated in prospective trials.

### A cell-based hybrid biosensor for automatic real-time quality control of islets and sensing of insulin demand

F. Lebreton<sup>1</sup>, M. Raoux<sup>1</sup>, Y. Bornat<sup>2</sup>, J.-B. Floderer<sup>2</sup>, D. Bosco<sup>3</sup>, J. Gaitan<sup>1</sup>, P. Meda<sup>4</sup>, T. Berney<sup>3</sup>, B. Catargi<sup>1,5</sup>, S. Renaud<sup>2</sup>, J. Lang<sup>1</sup>;  
<sup>1</sup>Dépt. Sciences & Technologies, Université de Bordeaux, UMR CNRS 5248, Pessac, <sup>2</sup>Institut Polytechnique de Bordeaux, UMR CNRS 5218, Talence, France, <sup>3</sup>Dépt de Chirurgie, Hôpitaux Universitaires de Genève et Université de Genève, <sup>4</sup>Dépt. Physiologie & Métabolisme, Université de Genève, Switzerland, <sup>5</sup>Hôpital St André, CHU de Bordeaux, France.

**Background and aims:** Glucose sensors have achieved considerable progress in the treatment of diabetes but require complex algorithms to match the complexity of everyday life. In contrast, pancreatic islets have been shaped during 0.5 billion years of evolution to secrete insulin not only in response to glucose, but also to other nutrients and to modulate their functioning to take physiological conditions into account via hormone receptors. Islets may provide the optimal sensor that uses changes in electrical activity as the first integrative signals of regulation. We have set out to develop recording and real-time analysis of these signals (i) for long-term analysis in drug testing, (ii) to provide a device for pre-transplantation control of donor islets and (iii) to advance in the development of a novel sensor for insulin demand.

**Materials and methods:** Mouse and human islets were cultured on multi-electrode arrays. Electrical activities received on each electrode were continuously amplified and analogically filtered. Output signals were recorded for off-line analysis or digitally converted and processed (for up to 60 electrodes in parallel) in real time using integrated circuits that were specifically designed on a custom electronics board.

**Results:** An acquisition system of islet electrical activity has been designed to process 60 channels in real time. This portable and autonomous system measures islet signals of extremely low amplitude (microvolts). Digital filters embedded on integrated circuits perform signal frequency separation, as well as frequency and statistical computation on individual signals. Extracellular recordings of human and mouse islet cells reveal two distinct glucose-dependent signals. According to pharmacology and experiments in Cx36-null mice, rapid action potentials (AP) are due to depolarization of single cells, whereas slower changes (slow waves, SW) result from coupling of multiple cells via gap junctions. In mouse islets, GLP-1 enhances SW frequencies at 8.2 mM glucose with maximal effect at 50 pM. In islets perfused with glucose, first increasing the concentration in small 0.5 mM steps from 3 to 11 mM and then decreasing by the same steps, both APs and SWs displayed a maximal effect at 10 mM. An exquisite glucose-dependency was present with a hysteric shape, characterized by a shift of the EC<sub>50</sub> from 7.5 mM for the increasing phase of the glucose ramp to 8.5 mM glucose for the decreasing phase. Similar characteristics were observed in human islets. Moreover, our algorithms correctly blind ranked signals recorded at different glucose concentrations.

**Conclusion:** Glucose and GLP-1 signatures can be automatically computed from AP and SW signals. The islets provide natural integrated hysteric

algorithms with rapid reaction to hyperglycemia and hormones as well as exquisite sensitivity to decreasing glucose levels, a safety latch against hypoglycemia. In the long-term, this system may also provide a unique biosensor for insulin demand.

### Hurdles in bioelectronics sensors: how to guide cells toward electrodes?

E. Pedraza<sup>1</sup>, A. Karajic<sup>2</sup>, F. Lebreton<sup>1</sup>, M. Raoux<sup>1</sup>, J. Gaitan<sup>1</sup>, V. Ravaine<sup>2</sup>, A. Kuhn<sup>2</sup>, J. Lang<sup>1</sup>;

<sup>1</sup>Dept. Sciences & Technologies, Université de Bordeaux, UMR CNRS 5248,

<sup>2</sup>Université de Bordeaux, UMR CNRS 5255, Pessac, France.

**Background and aims:** We are exploiting the innate, multi-parametric sensing ability of islets in order to develop a hybrid bioelectronics glucose sensor. In our sensor, multielectrode arrays (MEA) record the electrophysiological signal produced by beta cells in response to multiple environmental factors (glucose, lipids, hormones, etc.). Signal quality, and consequently overall sensor performance, relies critically on close cell-electrode proximity. However, attempts to improve cell-electrode co-localization, via chemical/physical modification of electrodes or dielectrophoresis, lead to additional cell stress and convoluted setups. In contrast, we present here a non-invasive method of further exploiting the electrical properties of beta cells to guide them directly toward electrodes via simple electrophoresis.

**Materials and methods:** The electrophoretic motion of clonal beta cells (INS-1 832/13) (1E6 cells/mL) and murine islets (60 islets) in an electric field was investigated using a low conductivity, isotonic buffer (5 mM HEPES, 280 mM mannitol, 5 mM glucose). The electric charge at the surface of the INS-1 cells was measured in terms of their zeta potential using a Zetasizer Nano. Computational models describing the distribution of the electric field and predicting the path of cell motion were created to optimize electrode configuration. INS-1 cells were subjected to an electric field for 10 min and subsequently assessed via proliferation assay (MTT) after 24 h, glucose stimulated response test after 48 h, and analysis of electrophysiological activity after 48 h. Student's t-test was used in statistical analysis. Differences were considered significant ( $p < 0.05$ ).

**Results:** Application of a minimum uniform electric field succeeded in displacing INS-1 cells and dissociated mouse islets (0.6 V/cm), as well as whole islets (10 V/cm), toward the positively charged electrode, suggesting that these cells possess a negative surface charge. This was confirmed by a zeta potential measurement of  $-27 \pm 1.43$  mV for INS-1 cells ( $n=9$ ). Based on the results of the computational models, an electric field was generated in the MEA by applying an electric potential across neighboring electrodes in an alternating pattern. When 1.5 V was applied to the MEA, INS-1 cells and dissociated mouse islets mirrored the electrode pattern by repelling away from negatively charged electrodes and co-localizing directly over positively charged electrodes. Cells persisted in this pattern even after removal of the electric field. Subsequent assessment of viability, insulin secretion function, and electrophysiological activity revealed that cells were not functionally altered by the process as compared to controls ( $n=3$ ) ( $p > 0.1$ ).

**Conclusion:** Our findings demonstrate that INS-1 beta clonal cells and dissociated mouse islets can be driven directly to target electrodes by applying an electric field. The positive results of the viability tests, insulin secretion tests, and electrical recordings demonstrate that this technique is not detrimental to the health and function of beta cells. Furthermore, its application can be extended to other cell types and other bioelectronics sensors. We are currently investigating how to adapt this technique to improve the manipulation of whole islets, a task which is complicated by their higher density compared to single cells.

### Sensor and software use for improved glucose control in individuals with diabetes managed by multiple daily injections of insulin: the SIGN study

R.A. Ajjan<sup>1</sup>, K. Abougila<sup>2</sup>, S. Bellary<sup>3</sup>, A. Collier<sup>4</sup>, B. Franke<sup>5</sup>, E. Jude<sup>6</sup>, G. Rayman<sup>7</sup>, A. Robinson<sup>8</sup>, B. Singh<sup>9</sup>;

<sup>1</sup>Molecular Vascular Medicine, Leeds University, <sup>2</sup>County Durham & Darlington NHS Foundation Trust, Durham, <sup>3</sup>Heart of England NHS Trust, Heartlands Hospital, Birmingham, <sup>4</sup>University Hospital Ayr,

<sup>5</sup>The Rotherham Hospital NHS Foundation Trust, Rotherham,

<sup>6</sup>Tameside Hospital NHS Foundation Trust, Ashton-under-Lyne,

<sup>7</sup>Ipswich Hospital, <sup>8</sup>Royal United Hospital, Bath,

<sup>9</sup>Royal Wolverhampton Hospital NHS Trust, New Cross Hospital, UK.

**Background and aims:** Studies investigating the role of continuous glucose monitoring (CGM) to improve glycaemic control in type 1 and type 2 diabetes patients remain relatively scarce. Our study aims were to: 1) Assess whether subjects with type 1 (T1D) or type 2 diabetes (T2D) managed by multiple daily injection (MDI) of insulin could improve glycaemic control by understanding CGM data and reviewing ambulatory glucose profiles (AGP) with their clinician. 2) Identify device features and glucose profile characteristics that enable improved clinical outcomes.

**Materials and methods:** A UK, multicentre ( $n=9$ ), 100 day study recruited 105 MDI treated diabetes patients aged 18-82 years with HbA1c of 58-108mmol/mol. Subjects were randomised to control or intervention group; the control group used a standard self-monitoring blood glucose device, FreeStyle Freedom Lite. The intervention group employed a FreeStyle Navigator CGM and were asked to disable the glucose alarm function. At days 30 and 45, subjects reviewed AGP and summary statistics with a clinician and completed a questionnaire at the end of the study. Post-hoc exploratory analysis evaluated the frequency of high glucose variability, defined to be, have at least one period of the day (by each patient's typical meals and bedtimes) with the 50th - 10th percentiles  $> 4.72$  mmol/L.

**Results:** In T1D intervention group ( $n=29$ ), within group analysis showed significant reduction in hypoglycaemia ( $< 3.9$ mmol/L) of  $0.6 \pm 1.4$ hrs/day (mean $\pm$ SD;  $p=0.0472$ ) and a marginal decrease of  $0.3 \pm 1.0$ hrs/day in time spent at  $< 3.1$ mmol/L ( $p=0.0760$ ), with no significant change in HbA1c ( $-3 \pm 8$  mmol/mol;  $p=0.58$ ). In T2D intervention group ( $n=28$ ), within group analysis showed a significant increase in time within 3.9-10.0mmol/L of  $1.4 \pm 3.5$  hrs/day ( $p=0.0427$ ) associated with a reduction in HbA1c of  $9 \pm 12$  mmol/mol ( $p=0.0002$ ) without an increase in hypoglycaemia. Subjects agreed or strongly agreed with the statements: i) glucose profile was easy to understand [T1 ( $n=29$ ) 93%, T2 ( $n=29$ ) 93%], ii) need for management change was clear [T1 ( $n=30$ ) 93%, T2 ( $n=28$ ) 100%], iii) changes made after consultation with attending physician were helpful [T1 ( $n=30$ ) 93%, T2 ( $n=29$ ) 100%]. In the intervention group, incidence of high glucose variability was greater for T1 than T2 patients at baseline [T1 19/25 (76%), T2 13/28 (46%),  $p=0.048$ ], with no significant changes detected at trial end [T1 19/25 (76%);  $p=1.00$  and T2 10/28 (36%),  $p=0.588$ ].

**Conclusion:** T1D and T2D subjects were able to understand glucose data independently and in review with their clinician. Using FreeStyle Navigator CGM over three months T1D subjects showed significantly reduced time in hypoglycaemia. T2D subjects showed significantly increased time in 3.9-10.0mmol/L and reduction in HbA1c without increasing hypoglycaemia. Further study is required to understand how to best manage glucose variability to further improve glycaemic control.

### CGM is not a limiting factor in artificial pancreas systems

A. Balo<sup>1</sup>, K. Nakamura<sup>1</sup>, T. Bailey<sup>2</sup>, A. Chang<sup>3</sup>, M. Christiansen<sup>4</sup>, D. Price<sup>1</sup>;

<sup>1</sup>Dexcom, Inc, San Diego, CA, USA, <sup>2</sup>AMCR, Inc, Escondido, CA, USA,

<sup>3</sup>John Muir Physician Network Clinical Research Center, Concord,

<sup>4</sup>Diablo Clinical Research Inc., Walnut Creek, USA.

**Background and aims:** CGM used for AP systems requires low glucose accuracy for safety, euglycemic and hyperglycemic accuracy to optimize insulin dosing determinations, and consistent performance across sensors and over time. A modified CGM designed specifically for the AP project was assessed in a clinical research study.

**Materials and methods:** The study enrolled 51 subjects from 3 US centers, 86% with T1D. Subjects wore sensors for up to 7 days and used self-monitored blood glucose to calibrate their CGM twice daily. Each subject was in-clinic for 12 hours on day 1, 4, or 7 to collect YSI reference venous glucose

every 15 minutes and capillary SMBG test every 30 minutes; glucose was manipulated to provide sufficient data in low and high glucose ranges.

**Results:** On average, the CGM provided glucose readings with a mean absolute relative difference (MARD) of 9% relative to temporally-matched reference YSI compared to 5% of that for the SMBG meter. The CGM readings were highly correlated with YSI with correlation coefficient of 0.97 comparing 0.99 of that for SMBG in the regression analyses. Using YSI reference, the CGM performed similarly as the SMBG meter. In particular, for hypoglycemia (< 70 mg/dL, i.e. 3.9 mmol/L), the mean absolute difference (MAD) was 6.4 mg/dL (0.36 mmol/L) for the CGM compared to 4.2 mg/dL i.e. 0.23 mmol/L for the SMBG; for hyperglycemia (> 180 mg/dL i.e. 10 mmol/L), the MARD was 8% for the CGM compared to 5% for the meter. The Clarke Error Grid (CEG) showed that 92% of CGM-YSI matched pairs fall in the clinically accurate A zone with 7% in the B zone, 0.0% in the C zone, and 0.5% in D zone for CGM; and 98.5% of SMBG-YSI matched pairs fall in the A zone with 1.1% in the B zone, 0.0% in the C zone, and 0.4% in the D zone.

**Conclusion:** The overall point accuracy, clinical accuracy, accuracy over the duration of wear, accuracy across the glycemic ranges, and reliability (98% of sensors lasted 7 days) were comparable to the SMBG meter. Accordingly, the CGM accuracy should not limit AP system development. Figure 1. Comparison of CGM-YSI vs. SMBG-YSI

### Glucose concentrations in blood and tissue: variable time lag

R. Chlup<sup>1,2</sup>, J. Krejci<sup>3</sup>, M. O'Connell<sup>4</sup>, B. Sebestova<sup>3</sup>, R. Plicka<sup>3</sup>, L. Brozova<sup>3</sup>, B. Doubravova<sup>3</sup>, H. Zalesakova<sup>2</sup>, J. Vojtek<sup>3</sup>, J. Bartek<sup>5</sup>;

<sup>1</sup>Dept. of Physiology and IInd Dept. of Medicine, Palacký University and Teaching Hospital, Olomouc, Czech Republic, <sup>2</sup>Institute of Gerontology and Geriatrics, Moravsky Beroun, <sup>3</sup>BVT Technologies, a.s., Strazek, Czech Republic, <sup>4</sup>Probe Scientific Ltd, Bedford, UK, <sup>5</sup>Dept. of Medical Chemistry and Biochemistry, Palacký University Olomouc, Czech Republic.

**Background and aims:** Time constants dealing with carbohydrate metabolism are hot topics of diabetes physiology. Current methods derive glucose concentrations from different tissues using subcutaneous and whole blood measures. The aim of this pilot study was to assess the time delay between glucose concentration in blood and tissue in the course of increase and decrease.

**Materials and methods:** Three healthy volunteers, 3 persons with type 1 diabetes (DM 1) and 4 persons with type 2 diabetes (DM 2) underwent concurrent glucose measurements using standard equipment (1) continuous glucose monitoring system (CGMS), namely, sensor Enlite, transmitter Minilink and monitor Guardian, Medtronic Minimed, CA, USA, calibrated by glucometer Calla, Wellion, Austria, and (2) Beckman analyser to estimate venous plasma glucose concentrations. Samples were taken in fasting state (just before drinking 300 ml tea with 50 g glucose) and then 4 times (hourly). This test was performed on 3 consecutive days. Carelink Personal and MS Excel were applied to plot the 4-hour evolution of glucose concentration obtained by CGMS and by Beckman, respectively. In each volunteer the time difference between ascending and descending plots was estimated and averaged for healthy persons, for DM 1 and for DM 2, respectively.

**Results:** The results are summarized in the Table showing 1) the mean time delay of defined glucose concentrations between the methods, 2) the mean period of time from the start of consumption of glucose to the maximum difference between the rising glucose concentrations, 3) the mean period of time from the start of consumption of glucose to the maximum glucose concentration, 4) the mean delay between the decreasing glucose concentrations. The results are relevant to common practice.

**Conclusion:** In persons with diabetes glucose tolerance testing resulted in slower transport of glucose into subcutaneous tissue than in healthy subjects. The rate of change of glucose between blood and tissue varies, introducing errors in CGMS readings when calibrations are made in non-steady state conditions. CGMS can provide reliable plasma glucose concentrations but only if the system is calibrated during steady state. Hence, before each calibration an appropriate algorithm to confirm the presence of a steady state should be applied.

### Glucose trend prediction in diabetic patients using Random Forests algorithm for analysis of CGM data

K. Tabakov<sup>1</sup>, N. Myakina<sup>2</sup>;

<sup>1</sup>Department of Information Technology, Novosibirsk State University, Russian Federation, <sup>2</sup>Laboratory of Endocrinology, Institute of Clinical and Experimental Lymphology, Novosibirsk, Russian Federation.

**Background and aims:** Avoiding both hypoglycemia and hyperglycemia is the critical difficulty in the management of diabetes because of the impact of multiple factors on glycemic trends. Despite this, the development of new approaches to analysis of data obtained in continuous glucose monitoring (CGM) provides an opportunity for prediction of glucose level without quantifying of these factors. The aim of the study was to evaluate the possibility of using the Random Forest algorithm for glucose level prediction based on CGM data.

**Materials and methods:** Total 50 records of 48 h CGM obtained from patients with type 1 and type 2 diabetes mellitus were analyzed. Based on this dataset using Random Forests algorithm and R-STUDIO software a 50 linear regression models were created for each case individually. Programming the Random Forests module was performed using the author's modification of the algorithm of local search, which allows you to automatically find the optimal settings of the program for a particular purpose. Various predictive windows of 50-360 min were chosen to predict glucose trends in these diabetic patients. The algorithm was trained individually for each case on a set of randomly selected segments of the CGM record that total was 50% of the entire record. Subsequently, the algorithm was verified on the data not included in the training set. Model adequacy was evaluated by the difference between the predicted and actual value and also by the mean square error of all the predicted values at hypoglycemic and hyperglycemic ranges.

**Results:** Overall, a valid prediction has been provided at normal, hypoglycemic and hyperglycemic ranges in 50-180 min predictive window: the mean squared prediction error was 8.1, 8.6 and 9.8, respectively (p=0.0001).

**Conclusion:** Random Forests algorithm can be successfully utilized to predict glucose levels in diabetic patients based the CGM data. At the predictive window of 50-120 min (an important period related to postprandial glycaemia) the model has a good predictive accuracy. Models like these could be employed in a semiclosed-loop device that can provide better glycemic control in diabetic patients.

## PS 082 Improving insulin pump treatment and continuous glucose monitoring use

997

**Time delay, reference measurement errors and number of reference measurements may strongly alter MARD values for CGM devices**

H. Kirchsteiger<sup>1</sup>, G. Freckmann<sup>2</sup>, L. Heinemann<sup>3</sup>, V. Lodwig<sup>4</sup>, G. Schmelzeisen-Redeker<sup>4</sup>, M. Schoemaker<sup>4</sup>, L. del Re<sup>1</sup>;

<sup>1</sup>Institute for Design and Control of Mechatronical Systems, Johannes Kepler University Linz, Austria,

<sup>2</sup>Institute for Diabetes-Technology GmbH, Ulm, <sup>3</sup>Science & Co, Düsseldorf,

<sup>4</sup>Roche Diagnostics GmbH, Mannheim, Germany.

**Background and aims:** As a parameter describing the measurement quality of CGM systems most often the median (or mean) average relative deviation (MARD) is stated. For calculation of MARD paired CGM readings and results of reference blood glucose measurements are used. However, this comparison is affected by: a) measurements are made in different compartments (blood, interstitial fluid) which leads to a time-delay between the results; b) reference values are also affected by measurement errors; c) the selection and number of time points used for computation has an effect as well.

**Materials and methods:** In order to evaluate the effect of these factors we re-analyzed data from a clinical study in which the performance of 3 different CGM systems (two of each kind, 6 in total) was evaluated in 12 patients with type 1 diabetes. We systematically varied the time delay between the two measurement methods to find the delay which results in the minimal MARD. The result was verified using a correlation based time delay analysis. We simulated measurement errors of the reference method and formulated an optimization problem, which gives as a solution the reference measurement values inside the error bounds, which result in the minimal MARD values. We also systematically selected different time points of paired reference and CGM measurements which were excluded from the MARD computation: a) repeatedly excluding the time-point which contributes the most to the MARD; b) repeatedly excluding the time-point which contributes the least to the MARD. This results in two functional dependencies of the MARD from the nr. of samples used with the actual MARD value being in between the extreme cases.

**Results:** MARD values decrease from originally 16.5%, 12.6%, and 16.7% for the CGM systems by 1.5%, 1.7%, and 2.5% when compensating for the effect of the time-delay. MARD values varied in the worst case in the range of 11.0\_21.8%, 6.9\_16.3%, 10.7\_21.6% when compensating for a 5% measurement error of the reference method and the estimated time-delay. The MARD values varied even more with different selections of the time-points of paired measurements: Reducing the number of paired measurements by 50% can result in an improvement (= lower value) by nearly 50% of the original MARD value. However, selecting different time points can also result in an MARD value twice as high as the original value.

**Conclusion:** MARD is greatly affected by various factors. Following a rigorous protocol that controls for certain factors that have an impact on MARD is crucial to enable uniform comparability among different clinical studies. POCT05-A guidelines should consider the effects discussed.

**Using of RT-CGMS during perinatal period with special focus on newborn hypoglycaemia occurrence: our ongoing experience**

K. Stechova<sup>1</sup>, K. Chaloupek<sup>2</sup>, D. Bartakova<sup>1</sup>, I. Spalova<sup>3</sup>, M. Cerny<sup>2</sup>;

<sup>1</sup>Dpt.of Internal Medicine, <sup>2</sup>NICU, Dpt.of Obstetrics and Gynaecology,

<sup>3</sup>Dpt.of Obstetrics and Gynaecology, University Hospital Motol, Prague, Czech Republic.

**Background and aims:** In babies of diabetic mothers perinatal complications including hypoglycaemia are still seen more frequently than in newborns of healthy mothers. In our study by using real time continuous Glucose monitoring system (RT-CGMS) we monitor pregnant women prior the labour and we continue to monitor their newborns after the birth as well to be able to follow complex glycaemia changes which influence the child prior and after

the birth and correlate them with the newborns' clinical status including hypoglycaemia occurrence.

**Materials and methods:** Newborns: We analysed by RT-CGMS 30 newborns of mothers suffering from pregestational diabetes, all mothers were treated by insulin. 23/30 of these children were born to type 1 diabetes (T1D) mothers, in 5/30 mothers were treated for T2D (type 2 diabetes) and in 2/30 cases the mother has MODY2 (maturity onset diabetes of the young). Median of gestation age in diabetes group was 37 weeks (range 31-38 weeks). Newborns were classified into four clinical status categories for further analysis. The first Enlite sensor was placed immediately after the birth (connected to Guardian real time device, Medtronic, Minneapolis, MN, USA). Eight term newborns born to healthy mothers were analysed as controls too. The median of monitoring in diabetes group was 5 days (range 3-8 days) and 4 days in controls (range 4-6 days). Mothers: in 9 T1D mothers their RT-CGMS records at least 3 days prior the labour and during the labour were available for the analysis too. In mothers the same type of RT-CGMS device was used as in newborns. Data were analysed by SPSS sw v.17. Notice - hypoglycaemia in newborns is considered as glycaemia  $\leq 2,5$  mmol/l.

**Results:** RT-CGMS revealed higher frequency of hypoglycaemia episodes in newborns of diabetic mothers (only 6/30 newborns of diabetic mothers were without any hypoglycaemia). These hypoglycaemia episodes were present not only shortly after the birth but after 3<sup>rd</sup> monitoring day as well ( $p=0.01$ ). In control newborns hypoglycaemia episodes were present too (4/8) but during the first 4 days of life only and were less frequent and shorter. In T1D group the occurrence and severity of hypoglycaemia were influenced by: the presence of macrosomia ( $p=0.022$ ), length of the newborn ( $p=0.001$ ), maternal HbA1c in 3<sup>rd</sup> trimester ( $p<0.001$ ), maternal weight gain ( $p=0.02$ ), maternal total insulin dose ( $p=0.001$ ) and by maternal age ( $p=0.03$ ). Of particular importance to newborn's clinical status and hypoglycaemia occurrence seems to be the difference between maternal glycaemia one hour prior the child's birth and newborn's glycaemia measured immediately after the birth ( $p<0.001$ ). Hypoglycaemia events were always confirmed in the laboratory and in general sensor readings correlated well with laboratory findings ( $r=0,82$ ,  $p=0,01$ ).

**Conclusion:** RT-CGMS can help not only to maintain maternal (near)normoglycaemia but is useful in revealing postnatal hypoglycaemia in her child which together with an adequate treatment can improve adaptation of newborns born to diabetic mothers.

**Efficacy and safety of insulin pump therapy in type 2 diabetes: the OpT2mise study**

Y. Reznik<sup>1</sup>, O. Cohen<sup>2</sup>, R. Aronson<sup>3</sup>, S. Runzis<sup>4</sup>, J. Castaneda<sup>4</sup>, S. De Portu<sup>4</sup>, S. Lee<sup>5</sup>, I. Conget<sup>6</sup>;

<sup>1</sup>Endocrinology and Diabetes Department, Caen, France, <sup>2</sup>Institute of Endocrinology, Tel Hashomer, Israel, <sup>3</sup>LMC Diabetes & Endocrinology, Toronto, Canada, <sup>4</sup>Medtronic International Trading Sàrl, Tolochenaz, Switzerland, <sup>5</sup>Medtronic Inc, Northridge, USA, <sup>6</sup>Endocrinology and Nutrition Department, Barcelona, Spain.

**Background and aims:** Multiple daily injection (MDI) regimens may be offered to patients with type 2 diabetes (T2D) not responding to basal insulin therapy but offer only marginally improved rates of success. Alternative approaches to insulin therapy have included continuous subcutaneous insulin infusion (CSII) which have been studied in prior randomized controlled studies in T2D patients but produced conflicting results. This study is the first large multicenter, randomized, controlled trial aiming to compare the efficacy and safety of CSII vs MDI in insulin-using patients with T2D who failed to respond to a basal-bolus regimen after active insulin titration.

**Materials and methods:** Subjects with poor glycemic control ( $n=495$ ) on multiple doses of insulin (MDI, basal-bolus using insulin analogs) were enrolled into a 9-week run-in period for insulin dose optimization ( $\geq 0.7$  and  $\leq 1.8$  U/kg/d). Subjects showing persistent hyperglycemia ( $HbA1c \geq 8\%$  and  $\leq 12\%$ ) at the end of this period were then randomly assigned to switch to CSII or to continue with MDI regimens for 6 months. Both arms underwent double-blinded continuous glucose monitoring (CGM) assessments at baseline and 6 months. The primary endpoint was the between-group difference in mean change in HbA1c from baseline to 6 months.

**Results:** A total of 331 subjects were randomized (45.6% women, mean $\pm$ SD age 56.0 $\pm$ 9.6 yr, BMI 33.4 $\pm$ 7.3 kg/m<sup>2</sup>, diabetes duration 15.1 $\pm$ 8.0 yr, HbA1c 9.0 $\pm$ 0.8%). Subjects assigned to CSII achieved significantly greater HbA1c reduction than MDI arm (-1.1 $\pm$ 1.2% vs. -0.4 $\pm$ 1.1%,  $p<0.001$ ), for a between-group difference favoring the CSII arm of -0.7% (95% CI, -0.9 to -0.4). The

percentage of subjects achieving HbA1c <8.0% was 57% in CSII arm vs. 27% in MDI arm (OR=1.9, 95% CI 1.47 to 2.46,  $P<0.001$ ) CGM analysis showed a significant reduction of duration of hyperglycemic events in the CSII arm compared to the MDI arm (-225 min vs -56 min,  $p<0.001$ ) while no difference in the time spent in hypoglycemia was observed between both arms. At the end of the study, total daily insulin dose was 20.4% lower in the CSII arm than in the MDI arm ( $97\pm 56$  U/d vs  $122\pm 68$  U/d,  $p<0.001$ ), and there was no significant between-arms difference in body weight change (CSII,  $+1.5\pm 3.5$  kg vs MDI,  $+1.1\pm 3.6$  kg,  $p=0.215$ ). No ketoacidosis occurred in either group, and one episode of severe hypoglycemia occurred in the MDI group.

**Conclusion:** The OpT2mise study demonstrates that CSII provides a significant advantage in glycemic control over MDI in T2D patients who fail to achieve HbA1c target and therefore represents a new option for the treatment of T2D.

### Multi-centre closed-loop insulin delivery trial points to variability in keeping glycaemia in a pre-defined target range at the individual level

E.M. Renard<sup>1,2</sup>, H. Zisser<sup>3,4</sup>, B. Kovatchev<sup>5</sup>, C. Cobelli<sup>6</sup>, D. Bruttomesso<sup>6</sup>, R. Nimri<sup>7</sup>, B.A. Buckingham<sup>8</sup>, P. Chase<sup>9</sup>, F.J. Doyle III<sup>4</sup>, L. Magni<sup>10</sup>, P. Calhoun<sup>11</sup>, J. Lum<sup>11</sup>, Control to Range Study Group;

<sup>1</sup>Department of Endocrinology, Diabetes, Nutrition, Montpellier University Hospital, <sup>2</sup>Institute of Functional Genomics, University of Montpellier 1, France, <sup>3</sup>Sansum Diabetes Research Institute, Santa Barbara, <sup>4</sup>Chemical Engineering Department, University of California, Santa Barbara, <sup>5</sup>University of Virginia, Charlottesville, USA, <sup>6</sup>University of Padova, Italy, <sup>7</sup>Schneider Children's Medical Center of Israel and Sackler Faculty of Medicine, Tel Aviv, Israel, <sup>8</sup>Stanford University, Stanford, <sup>9</sup>Barbara Davis Center for Childhood, Aurora, USA, <sup>10</sup>University of Pavia, Italy, <sup>11</sup>Jaeb Center for Health Research, Tampa, USA.

**Background and aims:** Closed-loop insulin delivery aims at keeping blood glucose close to normal in patients with Type 1 diabetes (T1D) based on continuous glucose monitoring (CGM) and insulin administration according to a control algorithm. The performance of a model predictive control (MPC) algorithm in reaching a predefined glucose target range in a large number of patients at the individual level was investigated.

**Materials and methods:** Fifty-three T1D patients (27 adults: 15M/12F, age: 41+/-11, BMI: 24+/-3, HbA1c: 7.7+/-0.6%, T1D duration: 25+/-11 yrs; 26 adolescents: 13M/13F, age: 15+/-1, BMI: 23+/-4, HbA1c: 8.1+/-0.9%, T1D duration: 8+/-3 yrs) underwent a 22-hour (9AM-7AM) closed-loop insulin delivery trial in 7 Clinical Research Centers. Each admission included 3 meals with normal announced bolus before each meal and no exercise. The closed-loop system included the Dexcom Seven Plus CGM (San Diego, CA), the OmniPod insulin pump (Insulet Corp, Bedford, MA) and a laptop computer running an MPC algorithm. The inter-device communication was automated by the Artificial Pancreas Software. Control was evaluated for its ability to maintain glycemia in 71-180 mg/dl range from YSI-measured glucose every 15 min for 90 min post-meal and every 30 min between meals and overnight.

**Results:** For adults, mean glucose was 159 mg/dl and the mean percentage in target range was 66% overall, 59% daytime, and 82% overnight. At least one YSI value was >300 mg/dl and at least one ≤60 mg/dl in 22% and 19% of admissions, respectively. For adolescents, mean glucose was 166 mg/dl and the mean percentage in target range was 62% overall, 53% daytime, and 82% overnight. At least one YSI value was >300 mg/dl and at least one ≤60 mg/dl in 32% and 20% of admissions, respectively. In 33 cases, out-of-range excursions included only post-meal hyperglycemia. In 18 cases, hypoglycemia occurred as late post-meal events, following previous hyperglycemia in most cases. An alternative glycemic pattern, observed in 4 cases, included several hypoglycemic excursions during day and/or night without any post-meal hyperglycemia. Individual patterns of out-of-range excursions under closed-loop could be related to inaccurate estimations of insulin sensitivity and CHO/insulin ratio from pre-investigational individual data in open-loop control conditions.

**Conclusion:** Our data analysis points to the inter-individual variability of closed-loop glucose control contrasting with overall acceptable performance. It supports the necessity of both closed-loop studies in large populations including patients with various characteristics, and individualization of control algorithm parameters.

### The impact of exercise and reductions in insulin pump basal delivery implemented prior to exercise on circulating insulin levels in people with type 1 diabetes

S.A. McAuley<sup>1,2</sup>, J.C. Horsburgh<sup>2</sup>, G.M. Ward<sup>1,3</sup>, J.L. Gooley<sup>2</sup>, R.J. MacIsaac<sup>1,2</sup>, D.N. O'Neal<sup>1,2</sup>;

<sup>1</sup>Department of Endocrinology & Diabetes, St Vincent's Hospital,

<sup>2</sup>Department of Medicine, University of Melbourne,

<sup>3</sup>Department of Pathology, University of Melbourne, Australia.

**Background and aims:** Minimal data guides optimisation of insulin pump basal insulin infusion rate (BIIR) reductions prior to exercise. This study investigates the effect of a reduction in subcutaneous BIIR, and the effect of exercise itself, on circulating free insulin levels.

**Materials and methods:** In a two-stage randomised crossover study, 11 adults with type 1 diabetes using insulin pump therapy were studied fasting following a night on a single BIIR (6M/5F, mean ± SD: age 43 ± 10 years, diabetes duration 22 ± 9 years, HbA<sub>1c</sub> 7.1 ± 0.5 %, BIIR per kg body weight 0.011 ± 0.001 U/h/kg). Insulin, insulin pump and pump consumables were standardised. The exercise stage (ES) and non-exercise stage (NES) were in random order, separated by 1 to 6 weeks. In both stages, after 60 min of rest, BIIR was reduced by 50% for 210 min. Venous samples were collected at 15 min intervals from 60 min pre- until 210 min post-BIIR reduction. During NES participants were observed at rest without exercise. During ES participants exercised for 30 min on a stationary bicycle (target workload 65-70% of age-predicted maximal heart rate) commencing 60 min post-BIIR reduction, then rested for 120 min. Plasma insulin was measured by RIA; plasma was pre-treated with polyethylene glycol to precipitate bound insulin when antibodies were present. Data are presented as mean ± SEM.

**Results:** Following the BIIR reduction in NES, free insulin levels reduced by 5.3 ± 3.2 %, 16.2 ± 2.4 % and 16.4 ± 3.5 % from baseline at 1h, 2h and 3h, respectively (baseline vs 1h  $p = 0.09$ ; 1h vs 2h  $p < 0.001$ ; 2h vs 3hr  $p = 0.81$ ). The rate of insulin level decline post-BIIR reduction in NES did not correlate with baseline BIIR per kg body weight ( $r = 0.18$ ,  $p = 0.59$ ). Exercise for 30 min increased free insulin levels by 0.8 ± 0.3 mU/l compared to rest ( $p = 0.02$ ). Insulin levels subsequently declined more rapidly over the first hour post-exercise compared to NES (-2.2 ± 0.4 mU/l vs -0.7 ± 0.2 mU/l;  $p = 0.006$ ) [see figure].

**Conclusion:** The NES data demonstrate that when preparing for exercise, an interval of at least two hours is required after a 50% BIIR reduction to impact circulating free insulin levels. However, even by three hours post-reduction, insulin levels remain above 80% of baseline. Supplemental carbohydrate and/or a greater reduction in insulin dosing may be required to avoid exercise-induced hypoglycaemia. A transient increase in free insulin levels occurred during 30 min moderate-intensity exercise, consistent with initial enhanced absorption from the subcutaneous insulin depot due to increased blood flow during exercise. The subsequent more rapid decline in insulin levels over the first hour post-exercise could partly relate to this prior enhanced absorption. These findings may guide optimisation of BIIR reductions prior to exercise.

**Factors associated with successful continuous subcutaneous insulin infusion therapy in type 2 diabetes patients - the OPT2MISE trial**

O. Cohen<sup>1</sup>, Y. Reznik<sup>2</sup>, I. Conget<sup>3</sup>, R. Aronson<sup>4</sup>, J. Castañeda<sup>5</sup>, S. Huang<sup>6</sup>, S. Lee<sup>6</sup>, J. Shin<sup>6</sup>, OpT2mise Study Group;

<sup>1</sup>Ch. Sheba Medical Center, Tel-Hashomer, Israel, <sup>2</sup>Centre Hospitalier Régional Universitaire de Caen Côte de Nacre, France, <sup>3</sup>Endocrinology and Nutrition Department, University Hospital Clinic, Barcelona, Spain, <sup>4</sup>LMC Diabetes & Endocrinology, Toronto, Canada, <sup>5</sup>Medtronic Bakken Research Center, Maastricht, Netherlands, <sup>6</sup>Medtronic, Northridge, USA.

**Background and aims:** The recent randomized study OpT2mise, demonstrated that insulin pump therapy (CSII) provided significant improvement in glycemic control, as compared with injection therapy (MDI) in type 2 diabetes (T2D). We aimed to assess the association between baseline or treatment related factors with glycemic improvements seen in the CSII arm of the study.

**Materials and methods:** Sub-optimally controlled (HbA1c  $\geq 8\%$ ) T2D subjects, despite an MDI optimization period, were randomly assigned to CSII or continuing an MDI regimen. Simple and multiple linear regression analysis were performed to assess the association of A1c change at 6 months and factors such as age, gender, duration of diabetes, baseline A1c, BMI, treatment satisfaction score (DTSQs), total daily insulin dose, cognitive state score (MoCA) and glucose self-measurements (SMBG). Analyses were adjusted by baseline A1c.

**Results:** A total of 331 subjects were randomized (45.6% women, age  $56.0 \pm 9.6$  yr, BMI  $33.4 \pm 7.3$  kg/m<sup>2</sup>, diabetes duration  $15.1 \pm 8.0$  yr, HbA1c  $9.0 \pm 0.8\%$ ). Subjects assigned to CSII achieved significantly greater A1c reduction ( $p < 0.001$ ) and more treatment satisfaction ( $p < 0.001$ ) than MDI arm. The effect of CSII and MDI in A1c change was dependent on baseline A1c ( $p < 0.001$ ). CSII was superior to MDI in the observed range of baseline A1c values and the advantage of CSII over MDI increased with higher baseline A1c (between group difference =  $-0.4 \pm 0.9\%$  for subjects with baseline A1c  $\leq 9.0\%$  and  $-1.0 \pm 1.4\%$  for subjects with baseline A1c  $> 9.0\%$ ,  $p < 0.01$  in both cases). Older age, longer duration of diabetes, low cognitive score and low SMBG use did not diminish the effect. In the CSII arm only 6 month satisfaction and number of boluses were associated with A1c reduction (a 3 point higher DTSQs was associated with a reduction of  $-0.02\%$  in A1c and one additional bolus was associated with a reduction of  $-0.2\%$  in A1c,  $p < 0.01$ ).

**Conclusion:** CSII in sub-optimally controlled T2D patients was associated with greater improvement in A1c compared to MDI. Baseline A1c was a major predictor of glycemic response with improved CSII advantage over injection therapy for subjects with worst glycemic control. Further A1c improvement in CSII arm was associated with treatment satisfaction and number of boluses without increase in total daily dose. Although CSII treatment involves the use of advanced technology, patients who used lower frequency of SMBG, had lower cognitive state or older in age achieved comparable improvement in glycemic control with CSII.

**Effects of automatic insulin pump interruption on duration and weekly rate of nocturnal hypoglycaemic events in the ASPIRE In-Home Study**

R. Weiss<sup>1</sup>, B. Bode<sup>2</sup>, T. Bailey<sup>3</sup>, F. Schwartz<sup>4</sup>, R. Brazg<sup>5</sup>, R. Bergenstal<sup>6</sup>, J. Thrasher<sup>7</sup>, R. Weinstock<sup>8</sup>, A. Ahmann<sup>9</sup>, D. Klonoff<sup>10</sup>, R. Slover<sup>11</sup>, S. Garg<sup>11</sup>, J. Welsh<sup>12</sup>, M. Mao<sup>12</sup>, ASPIRE In-Home Study Group;

<sup>1</sup>Human Metabolism and Nutrition, Hebrew University, Jerusalem, Israel, <sup>2</sup>Atlanta Diabetes Associates, <sup>3</sup>AMCR Institute, Escondido, <sup>4</sup>Ohio University, Athens, <sup>5</sup>Rainier Institute of Clinical Research, Renton, <sup>6</sup>International Diabetes Center at Park Nicollet, Minneapolis, <sup>7</sup>Arkansas Diabetes Clinic and Research Center, Little Rock, <sup>8</sup>Joslin Diabetes Center, Syracuse, <sup>9</sup>Oregon Health and Sciences University, Portland, <sup>10</sup>Diabetes Research Institute, Mills–Peninsula Health Services, San Mateo, <sup>11</sup>University of Colorado, Denver, <sup>12</sup>Medtronic Inc, Northridge, USA.

**Background and aims:** The ASPIRE In-Home Study was designed to evaluate the Threshold Suspend (TS) feature of sensor-augmented pump therapy, which automatically suspends insulin delivery at a pre-set sensor glucose (SG) value. We evaluated the duration and weekly rate of nocturnal hypoglycemic (NH) events that occurred during the study

**Materials and methods:** An NH event was defined as lasting  $>20$  min with SG values  $\leq 65$  mg/dL that started between 10PM and 8AM. Subjects with type 1 diabetes with  $\geq 2$  NH events during a run-in phase were eligible. A total of 247 patients were randomized to SAP therapy with the TS feature (TS group,  $n=121$ ) or without the TS feature (Control group,  $n=126$ ). NH event durations throughout the 2-week run-in and 3-month study phases were enumerated and categorized as lasting  $<2$  hours, 2–4 hours, or  $>4$  hours

**Results:** In panel A, 68% of NH events during the run-in phase lasted  $<2$  h, 20% lasted 2–4 h, and 13% lasted  $>4$  h. During the study phase in the TS group, 79% of the NH events lasted  $<2$  h and 3% lasted  $>4$  h, while in the Control group, 64% lasted  $<2$  h and 12% lasted  $>4$  h; these between-group differences were significant ( $p < 0.001$  for each) and reflect shorter NH events in the TS group. In Panel B, the rate of NH events per patient-week was higher in the run-in phase than in the study phase, regardless of treatment group. During the study phase, the rate of NH events was significantly lower in the TS group than in the Control group, regardless of event duration. Compared to the Control group, the rate of NH events lasting  $<2$  h was reduced by 15% ( $p=0.02$ ), the rate of NH events lasting 2–4 h was reduced by 47% ( $p < 0.001$ ), and the rate of NH events lasting  $>4$  h was reduced by 84% in the TS group ( $p < 0.001$ ). There was no severe hypoglycemia in the TS group and 4 events in the Control group.

**Conclusion:** In subjects with type 1 diabetes prone to hypoglycemia, use of TS was associated with favorable changes in the duration of NH events, with an increase in the proportion of short-duration events and a corresponding decrease in the proportion of long-duration events. Use of the TS feature was also associated with a reduction in the weekly rate of number of NH events, especially those lasting  $>4$  h, suggesting a preventive effect and a reduction in the risk of progression to severe hypoglycemia.

1004

**Glucose variability outcome for type 1 diabetic patients switching to CSII: improved complexity patterns beyond glucose dispersion reduction**

M. Lytrivi, L. Crenier; Endocrinology, Erasme Hospital, Brussels, Belgium.

**Background and aims:** Standard Deviation (SD) and MAGE are commonly reported indices of glucose variability (GV). However, they represent measures of glucose dispersion rather than true quantifications of instability. These indices are also directly proportional to the mean, making them inappropriate for comparisons of glucose profiles at different glucose levels. The aim of this work was therefore to study the evolution of GV in type 1 diabetic patients switching to continuous subcutaneous insulin infusion (CSII) in terms of both dispersion and complexity of the displayed patterns. For this purpose, we used metrics independent of the mean, as the Coefficient of Variation (CV), Approximate Entropy (ApEn) and the Detrended Fluctuation Analysis (DFA) method, which are, contrary to CV, sensitive to intrinsic complexity and self-similarities of glucose patterns rather than to value scattering.

**Materials and methods:** CV, ApEn ( $m=1, r=0.2 \times SD$ ) and DFA- $\alpha$  were computed from blinded Continuous Glucose Monitorings (CGMs) of 48h duration (iPro2 with Enlite<sup>®</sup> sensors, Medtronic MiniMed, Northridge, CA) obtained from 20 adults with type 1 diabetes on MDI (baseline) and 6 months after initiation of CSII. Mean and SD of glucose, HbA1c, MAGE, the number of hypoglycemic episodes and time in hypoglycemia (TH) were also recorded. **Results:** CV was reduced by  $4.9 \pm 9.7$  ( $p=0.036$ ) on CSII, while change in CV ( $\Delta CV$ ) was strongly correlated with baseline CV (Pearson's  $r=-0.77, p<0.0001$ ) but not with baseline HbA1c, glucose mean or SD. ApEn was found to increase on CSII (see panel A), indicating an increase in complexity of the glucose profiles. Although CV and ApEn were independent, changes in ApEn were inversely correlated with  $\Delta CV$  (Spearman's  $\rho=-0.48, p<0.041$ ), meaning that larger CV reductions were concurrent with greater increases of ApEn (see panel B). ApEn was found to be inversely correlated with DFA- $\alpha$  ( $r=-0.93, p<0.00001$  on CSII) confirming that high ApEn glucose profiles obtain a DFA- $\alpha$  closer to 1 (DFA- $\alpha$  values ranged from 1.08 to 1.65 on CSII), meaning increased complexity with more self-similar structures and long-range correlations as described in CGM profiles of healthy subjects. Additionally, SD, MAGE, mean glucose, HbA1c and TH ( $<50$  mg/dl) were reduced by  $17 \pm 24$  mg/dl ( $p=0.004$ ),  $35 \pm 52$  mg/dl ( $p=0.008$ ),  $22 \pm 40$  mg/dl ( $p=0.022$ ),  $0.69 \pm 0.79\%$  ( $p=0.001$ ) and  $0.77 \pm 1.21$  h/day ( $p=0.01$ ), respectively.

**Conclusion:** CV on MDI predicts GV outcome on CSII. Patients with the highest baseline CV demonstrated the greatest reduction on CSII. In these responders, CSII increased also Approximate Entropy. This brings the glucose control closer to physiology, not only in terms of dispersion, but also in terms of the complexity exhibited in the glucose patterns. To our knowledge, this property of the CSII treatment had never been investigated.

**PS 083 On the way to optimise pump treatment**

1005

**PaQ<sup>®</sup>, a simple 3-day basal/bolus insulin delivery device, may optimise insulin delivery in type 2 diabetes as determined by continuous glucose monitoring**

R. Mazze<sup>1</sup>, E. Strock<sup>1</sup>, J. Mader<sup>2</sup>, L. Lilly<sup>3</sup>, F. Aberer<sup>2</sup>, T. Pieber<sup>2</sup>;

<sup>1</sup>International Diabetes Center, Minneapolis, USA,

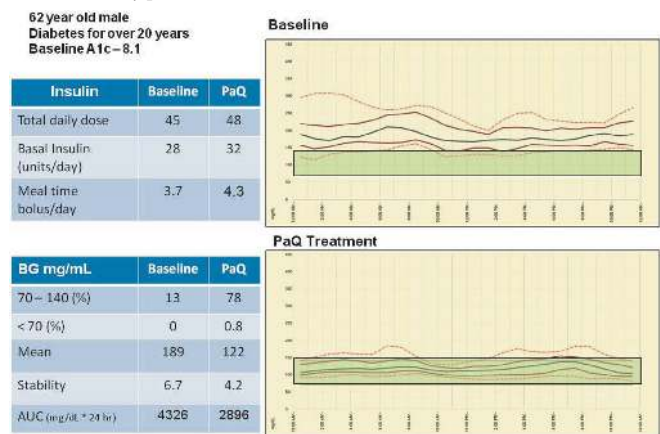

<sup>2</sup>University of Graz, Austria, <sup>3</sup>CeQur, Marlborough, USA.

**Background and aims:** PaQ (CeQur SA) is a simple patch-on device that provides set basal rates and bolus insulin on demand.

**Materials and methods:** A 6-week open-label single-arm study utilized blinded continuous glucose monitoring (CGM) to assess the effect of glycemic control achieved with PaQ compared to multiple daily injections (MDI) of insulin. Twenty patients (age  $59 \pm 5$  y, T2D duration  $15 \pm 7$  y, A1C  $7.7 \pm 0.7$  %), on a stable MDI regimen were enrolled and 18 completed. The study was comprised of three 2-week periods; baseline (MDI), transition to PaQ, and PaQ therapy. There was no attempt to treat to target. CGM data was analyzed by Ambulatory Glucose Profile (AGP) reporting system. AGP is used to graphically and statistically represent parameters of glycemic control for each period of CGM and treat data collected over a period of days as if it were measured on the same (modal) day.

**Results:** An overall trend toward improved glycemia was seen with an average reduction in glucose exposure from 4024 to 3834 mg/dL/24hrs ( $P=0.18$ ) and improved glucose fluctuations from 10.9 to 9.7 mg/dL/hr ( $P=0.07$ ) while participants used the same total daily dose of insulin during Baseline and PaQ treatment periods. Analysis of by-patient CGM modal days revealed that 11 participants improved their glycemic control (see accompanying figure).

**Conclusion:** A larger study utilizing CGM is needed to further assess the insulin delivery potential of PaQ.

This participant showed improvement in overall glycemic control with all AGP parameters. The proportion of time in the target range (green box) increased from 13 to 78%. Overall glucose exposure decreased from 4326 mg/dL/24 hours to 2896 mg/dL/24 hours with no significant decrease in hypoglycemic events. This participant's AGP was close to those found in subjects with normal glucose tolerance.

**Association of late eating habit and sleep duration with glycaemic control in adult type 1 diabetes patients treated with insulin pumps**

B. Matejko<sup>1</sup>, B. Kieć-Wilk<sup>1,2</sup>, M. Malecki<sup>1,2</sup>, T. Klupa<sup>1,2</sup>;

<sup>1</sup>Department of Metabolic Diseases, Jagiellonian University,

<sup>2</sup>University Hospital, Krakow, Poland.

**Background and aims:** The most important benefit of continuous subcutaneous insulin infusion (CSII) is customized, flexible basal and bolus dosing to meet patients' individual insulin requirements. This system of insulin delivery appears to offer not only improvement in metabolic control, but also increased physiological and psychological wellbeing. However, concerns have also been raised that, by enabling more freedom, CSII could potentially give rise "unhealthy" behaviors, which in turn could lead to the deterioration of

metabolic control. The goal of this research was to examine if sleep duration and late eating habit in CSII treated T1DM patients were associated with glycaemic control as assessed by HbA1c level and mean self-monitoring blood glucose (SMBG) readings.

**Materials and methods:** We included 148 adult T1DM patients on insulin pump (100 females and 48 males) who filled a questionnaire concerning sleep duration ( $\leq 6$ h and  $> 6$ h) and late eating (snacking after 10 p.m. - rarely, sometimes, often). Other sources of information about the patients included available medical records together with the results of biochemical tests (HbA1c measured with high performance liquid chromatography method-HPLC), memory read-outs from insulin pumps, data from blood glucose meters. Data from personal insulin pumps and blood glucose meters were downloaded regularly to the computer and analysed via CareLink Professional (Medtronic) and Accu Chek 360 (Roche) software. Tests for differences between the two groups, univariate correlations analysis, and multivariate regression analysis were used.

**Results:** The patients' mean age was 26 yrs, mean T1DM duration 13.4 yrs, mean HbA1c level 7.2%, mean BMI 23.3 kg/m<sup>2</sup>, while mean nighttime sleep duration was 7.2 h. Short sleep duration (26.3% of patients) as compared to long sleep duration was associated with worse glycaemic control - HbA1c: 7.6 vs. 7.1%,  $p=0.0293$ ; mean SMBG readings: 159 vs. 149 mg/dl,  $p=0.0491$ , respectively. Additionally, in a univariate correlation analysis we found an association between frequent late snacking (rarely: 54.1%, sometimes: 38.5%, often: 7.4%) and worse HbA1c level ( $r=0.19$ ,  $p=0.0287$ ) and SMBG readings ( $r=0.21$ ,  $p=0.0135$ ). In the multivariate regression analysis (dependent variables - age, T1DM duration, gender, BMI, sleep duration and frequency of late snacking), independent predictors for HbA1c were the patient's age ( $\beta=-0.34$ ,  $p=0.0013$ ), T1DM duration ( $\beta=0.21$ ,  $p=0.0440$ ) and sleep duration ( $\beta=-0.23$ ,  $p=0.0061$ ). The analyzed model was significant ( $p=0.0017$ ). In the multivariate regression analysis for mean SMBG readings, the same variables except for T1DM duration were significant.

**Conclusion:** In summary, short sleep duration seems to be associated with poorer glycaemic control in T1DM patients treated with CSII but late snacking is not.

## 1007

### Factors predictive of overnight closed loop performance during free living in children and adults with type 1 diabetes

M. Tauschmann<sup>1</sup>, H. Thabit<sup>1</sup>, L. Leelarathna<sup>1</sup>, D. Elleri<sup>1</sup>, J.M. Allen<sup>1</sup>, A. Lubina-Solomon<sup>2</sup>, M. Stadler<sup>3</sup>, E. Walkinshaw<sup>2</sup>, A. Iqbal<sup>2</sup>, P. Choudhary<sup>3</sup>, S.R. Heller<sup>2</sup>, S.A. Amiel<sup>3</sup>, M.L. Evans<sup>1</sup>, D.B. Dunger<sup>1</sup>, R. Hovorka<sup>1</sup>;

<sup>1</sup>Wellcome Trust-MRC Institute of Metabolic Science, University of Cambridge, <sup>2</sup>Academic Unit of Diabetes, Endocrinology and Metabolism, Department of Human Metabolism, University of Sheffield, <sup>3</sup>Diabetes Research Group, Kings College London, UK.

**Background and aims:** Overnight closed-loop (CL) insulin delivery is feasible, safe, and effective in the home setting but outcomes vary between individuals. Understanding the factors influencing the performance of overnight CL under free-living conditions may help target those likely to benefit most while improving the control algorithm.

**Materials and methods:** We combined data collected during two randomized home studies in 16 adolescents (age  $15.6 \pm 3.6$  years; mean  $\pm$  SD) and 24 adults (age  $43.2 \pm 11.7$ ) with type 1 diabetes on insulin pump therapy (pooled HbA1c  $8.0 \pm 0.8\%$ ; duration of diabetes  $20.0 \pm 14.0$  years, BMI  $24.3 \pm 3.7$  kg/m<sup>2</sup>, total daily insulin dose  $46.2 \pm 17.3$  U/day). Participants underwent, in random order, two periods of sensor augmented insulin pump therapy (SAP) or SAP combined with overnight CL insulin delivery, each lasting three-weeks (adolescents) or four-weeks (adults). Associations between baseline characteristics (age, HbA1c, duration of diabetes, BMI, total daily insulin dose and gender) and the performance of overnight CL (time in target, mean glucose) were examined using correlation analysis (Spearman's correlation coefficient,  $r$ ).

**Results:** We analysed data on 866 CL nights at home. Lower baseline HbA1c ( $r = -0.43$ ,  $p < 0.01$ ) was associated with lower mean glucose during CL, but not with greater time in the glucose target range (3.9 to 8.0 mmol/l). Longer duration of diabetes was inversely associated with time in target ( $r = -0.44$ ,  $p < 0.01$ ). Other baseline characteristics such as gender, age, BMI, and total daily dose showed no association with either mean glucose or time in target. Baseline HbA1c (range 6.2–9.6%), age, duration of diabetes, and total daily dose were not associated with improvements (difference between conventional pump therapy and CL) in mean glucose or time in target during CL as compared to

SAP treatment. Females showed a greater improvement in mean overnight glucose during CL than males ( $r = 0.33$ ,  $p = 0.037$ ).

**Conclusion:** In adolescents and adults with type 1 diabetes, the extent of glucose improvements during CL is seen irrespective of baseline HbA1c. Reasons for reduced efficacy in patients with longer duration of diabetes as well as gender-specific differences in improved mean glucose warrant further investigations.

### High reported treatment satisfaction in people with type 1 diabetes switching to latest generation insulin pump regardless of previous therapy

K. Barnard<sup>1</sup>, M. de Lange<sup>2</sup>, M. Halbron<sup>3</sup>, B. Levy<sup>4</sup>, M. Lévy<sup>5</sup>, B. Lippmann-Grob<sup>6</sup>, K. Walshe<sup>7</sup>, R. Ziegler<sup>8</sup>;

<sup>1</sup>Human Development and Health, University of Southampton, Southampton, UK, <sup>2</sup>Groene Hart Hospital, Gouda, Netherlands,

<sup>3</sup>Diabetology Department, AP-HP, Hôpital Pitié-Salpêtrière, Paris, France,

<sup>4</sup>LifeScan Inc., Pennsylvania, USA, <sup>5</sup>Hôpital de Nanterre, France, <sup>6</sup>Diabetes

Klinik, Bad Mergentheim, Germany, <sup>7</sup>Lagan Valley Hospital, Lisburn, UK,

<sup>8</sup>Diabetes Clinic for Children and Adolescents, Muenster, Germany.

**Background and aims:** Literature is lacking on how people with type 1 diabetes (T1D) cope with different insulin delivery therapies. CHOICE (Comparing perception of insulin tHerapies for T1D patients with the aim to Improve quality of CarE) is an ongoing, multicentre, multinational, prospective observational study designed to fill this knowledge gap. A key aim is to compare treatment satisfaction (TS) between insulin pump naïve (IPN) and insulin pump experienced (IPE) people, after switching to a latest generation insulin pump (LGIP).

**Materials and methods:** People with T1D from 5 EU countries were included, comprising an IPN group and an IPE group. To optimise treatment homogeneity, only one LGIP (Animas Vibe) was used. An online participant survey including demographics, questions about LGIP use and the Insulin Treatment Satisfaction Questionnaire (ITSQ) was used to collect data. ITSQ is a psychometrically validated questionnaire available in different languages (including French and English), developed to evaluate TS with a range of insulin therapies, and provides a basis upon which new data are compared.

**Results:** Interim data (see table) are reported for participants ( $n=190$ ; age range 12–79 years; disease duration 0–71 years) from 3 countries: France, the UK, and Ireland. There were no major cross-country differences between participants in gender, disease duration or previous treatment. French participants were 5 years younger than those in the UK and Ireland. Participants aged 12–29 reported higher fasting glucoses and higher pump use prior to LGIP. There was no significant difference in ITSQ overall satisfaction score with Animas Vibe, between participants previously treated with an insulin pump versus participants previously treated with multiple daily insulin injections. There was good internal consistency of the ITSQ Scale. The mean ITSQ-SumScore (range 0–100) of 72.3 (SD 17.5) was similar to the 2004 confirmatory sample value (71.4; SD 16.5).

**Conclusion:** Data show that TS is very high in participants using an LGIP such as Animas Vibe regardless of previous insulin therapy. In this study, LGIP facilitated a good psychosocial functioning, important to optimal quality of life. Different people will use their insulin pump in different ways in the

context of their lived experience to support their own diabetes self-management. This study is ongoing, and final data are pending.

### OpT2mise study: the impact of insulin pump therapy on treatment satisfaction and resource utilisation in patients with type 2 diabetes

R. Aronson<sup>1</sup>, O. Cohen<sup>2</sup>, I. Conget<sup>3</sup>, S. de Portu<sup>4</sup>, A.-S. Racault<sup>4</sup>, J. Shin<sup>5</sup>, Y. Reznik<sup>6</sup>;

<sup>1</sup>LMC Diabetes & Endocrinology, Toronto, Canada, <sup>2</sup>Institute of Endocrinology, Ch. Sheba Medical Center, Tel Hashomer, Tel Aviv, Israel, <sup>3</sup>Endocrinology & Nutrition Dept, Hospital Clínic i Universitari, Barcelona, Spain, <sup>4</sup>Medtronic Int, Tolochenaz, Switzerland, <sup>5</sup>Medtronic Inc, Northridge, USA, <sup>6</sup>Endocrinology & Diabetes Dept, CHU Côte de Nacre, Caen, France.

**Background and aims:** Achieving glycemic outcomes in insulin-using type 2 diabetes (T2D) patients often requires multiple daily injections (MDI) with basal and bolus insulin types. Insulin pump therapy (CSII) has recently been evaluated in T2D patients in a large prospective randomized controlled trial. Patient outcomes have been found to be positively associated with treatment satisfaction and safety, contributing to improved health and reduced healthcare costs. We assessed the effects of CSII on treatment satisfaction (TS) and on medical resource utilization, in suboptimally controlled T2D patients participating in the OpT2mise study.

**Materials and methods:** T2D subjects, suboptimally controlled (HbA1c ≥ 8%) despite an MDI optimization period, were randomly assigned to CSII or continuing MDI. The primary endpoint was the between-group difference in mean HbA1c change from baseline to 6 months. TS was measured by means of the Diabetes Treatment Satisfaction Questionnaire, status (DTSQs) and change (DTSQc). DTSQs questionnaires were collected at baseline and at 6 months; DTSQc was completed at 6 months. Data on medical resource use including diabetes-related hospitalizations, insulin usage and number of glucose testing strips were collected at each visit.

**Results:** 331 subjects were randomized (45.6% women, mean±SD age 56.0±9.6 yr, BMI 33.4±7.3 kg/m<sup>2</sup>, diabetes duration 15.1±8.0 yr, HbA1c 9.0±0.8%). Subjects assigned to CSII achieved significantly greater HbA1c reduction than MDI arm (-1.1±1.2% vs. -0.4±1.1%, p<0.001). DTSQs scores at baseline and at 6 months were available for 283 patients. Mean DTSQs score increased significantly in the CSII arm after 6 months, with no change in the MDI arm (difference between groups = 5.0, 95% CI=3.39-6.62, P < 0.001) with significant improvements in treatment convenience, flexibility, understanding of diabetes, willingness to recommend the treatment, satisfaction to continue treatment, and perceived frequency of hyperglycemia (all P < 0.001). There was no difference in the perceived frequency of hypoglycemia. Greater HbA1c decrease at 6 months was significantly associated with improved satisfaction, in the CSII arm only (P<0.05). Results were consistent in both DTSQs and DTSQc. Despite improved HbA1c outcome, mean total daily insulin dose (TDD) significantly declined from baseline to end of study in the CSII arm (112.1 ± 54 to 96.9 ± 55.8, P < 0.001). Mean TDD increased in the MDI arm over the same period (106.1 ± 49.2 to 121.7 ± 68.2, P < 0.05). Both groups had a statistically significant decline in daily strip use over the study. There was no significant difference in the number or length of stay of diabetes-related hospitalizations.

**Conclusion:** CSII therapy in suboptimally controlled T2D patients was associated with greater improvement in HbA1c at 6 months than patients continuing MDI therapy. In addition, CSII was associated with a significant increase in treatment satisfaction, with a significant reduction in total daily insulin usage. In T2D patients, suboptimally controlled with MDI therapy, CSII provides improved outcomes with greater treatment satisfaction.

### Insulin pump failures: a prospective study

A. Esvant<sup>1</sup>, I. Guilhem<sup>1</sup>, S. Breitel<sup>2</sup>, M. Cuggia<sup>3</sup>, A.-M. Leguerrier<sup>1</sup>, J.-Y. Poirier<sup>1</sup>;

<sup>1</sup>Diabetes Department, University Hospital of Rennes, <sup>2</sup>AIR de Bretagne, Rennes, <sup>3</sup>Pôle Pharmacologie et Investigation cliniques, unité „Fouille de données“, University Hospital of Rennes, France.

**Background and aims:** The rate of insulin pump failures in our centre had been evaluated by a prospective observational study published in 2009. During this six-year study (2001-2007), 36% of our pumps had broken down after a median time of 15 months. We had recorded substantial rates of severe pump failures with a complete failure in 44% of cases. The aim of this study was to update our data from 2008.

**Materials and methods:** This was a single-centre prospective observational study on 314 new pumps provided between 2008 and 2011 and maintained by the same institution. The pumps were used by adult type 1 diabetic patients treated in the Diabetes Department of a University Hospital in an ambulatory setting. There were 74 Animas®2020 and 240 Medtronic® including 40% Paradigm®Vevo pump, 45% Paradigm®522/722 and 15% Paradigm®512-515/712-715. Pump failures were recorded until December 2013. We focussed on malfunctions directly related to the pump itself. Patients could not contact the manufacturer directly to exchange the pump. All pump failures were documented by a healthcare professional. We studied Kaplan-Meier survival curves. Logrank test, Cox model, t-test and  $\chi^2$  (or non-parametric tests when necessary) were used to compare the two brands. Statistical analyses were performed with the SPSS software (version 22; IBM, USA).

**Results:** The mean duration of pump use was 25±12 months (mean±SD) (CI 95%: 24-27) and did not differ between the two brands (p NS). Malfunctions occurred in 220 pumps (70%). Median time of survival was 27 months (CI 95%: 25-29). The rate of malfunction was 33 per 100 pump-years. We recorded 25 (11%) complete failures (pumps were immediately unusable), 16 (7%) alarms, 79 (36%) mechanical malfunctions that required pump replacement as recommended by the manufacturer, 94 (43%) minor defects. The cause of the defect could not be determined in 6 (3%) situations. Complete failures were mainly due to inoperative keypad (n=14); mechanical defects were mostly related to cracks in reservoir or battery compartment (n=60) and minor defects to screen display defects (n=48). Median time of survival in case of complete failure was 12 months (CI 95%: 9-16) versus 23 months (CI 95%: 21-25) in case of others defects (p<0.001). Survival curves of Medtronic® and Animas® pumps did not differ. Duration of survival of Paradigm®Vevo pumps was longer than that of Animas® pumps (HR=0.65, CI 95%: 0.45-0.94, p=0.023). However the proportion of severe pump failures (complete failures

and alarms) was higher with Paradigm®Veo pumps (33%) compared to Animas® pumps (12%) ( $p=0.007$ ).

**Conclusion:** Pump malfunctions remain common with modern pumps. In this study, we reported less complete failures than in our previous study. This may reflect an improvement of the pumps. However, the current high rates of mechanical and minor defects suggest changes in our practice and may be explained by the greater attention paid by patients and healthcare professionals to pump defects. A multi-centre evaluation of pump failures is needed.

## 1011

### A randomised three-period trial to compare the pharmacodynamics and pharmacokinetics of different glucagon dosages at different blood glucose levels

T. Jax<sup>1,2</sup>, H. Blauw<sup>3,4</sup>, J. DeVries<sup>4</sup>, T. Heise<sup>5</sup>, for the PCDIAB consortium;  
<sup>1</sup>Cardiometabolic Research, Profil Institut für Stoffwechselforschung GmbH, Neuss, <sup>2</sup>Klinik für Kardiologie, Herzzentrum Wuppertal, Universität Witten/Herdecke, Germany, <sup>3</sup>Inreda Diabetic BV, Goor, Netherlands, <sup>4</sup>Academic Medical Centre at the University of Amsterdam, Netherlands, <sup>5</sup>Profil Institut für Stoffwechselforschung GmbH, Neuss, Germany.

**Background and aims:** Bihormonal closed-loop systems deploy the administration of glucagon in case of imminent or actual hypoglycaemia. The administration of glucagon in such a closed-loop system will not necessarily be limited to hypoglycaemia, but can also be done preemptively, trying to avoid hypoglycemia. Thus more information is needed about the pharmacodynamic effects of small doses of glucagon at non-hypoglycaemic blood glucose (BG) levels. We evaluated the pharmacokinetics and pharmacodynamics of different dosages of s.c. glucagon at different BG levels.

**Materials and methods:** The study was conducted as an open, randomized 3-period cross-over experiment in six otherwise healthy patients with T1DM. At each of the 3 periods, different BG levels were established in 4 consecutive steps (144, 108, 72, and 50.4 mg/dl) and glucagon was given s.c. at each BG level in a randomized sequence (A: 0.11 mg at first 3 BG levels and 1.00 mg at the fourth, B: 3 x 0.22 mg and 0.66 mg, C: 3 x 0.44 mg and 0.33 mg).

**Results:** Glucagon raised BG in a dose-dependent fashion at all BG levels. Mean glucose excursion ranged from 48.7 mg/dl to 111.0 mg/dl (Figure). The response after repeated dosing tended to decrease only with the 0.44 mg glucagon dose (mean glucose excursion from 97.3 mg/dl to 71.0 mg/dl), possibly due to hepatic glycogen depletion. Time till maximum glucose concentration showed a dose dependency, with mean values increasing from 41.3 min to 79.2 min. Maximum plasma glucagon concentration increased with increasing glucagon dosage and was reached after around 10–25 minutes. For the 0.11 mg glucagon dose, plasma glucagon concentration tended to increase with decreasing baseline BG levels and in 3 patients no clear increase in glucagon concentration was seen at BG level of 144 mg/dl.

**Conclusion:** In conclusion, s.c. administered glucagon produces a predictable pharmacodynamic response at lower doses than the usual rescue dose and across a range of hypo- to hyperglycaemic BG levels. This supports the use of small glucagon doses in closed-loop systems to prevent impending hypoglycaemia. The results of this study can be used to further optimize the control algorithms of bihormonal closed-loop systems.

### The impact of insulin pump therapy on glycaemic profile of patients with type 2 diabetes: data from the OpT2mise study

I. Conget<sup>1</sup>, O. Cohen<sup>2</sup>, R. Aronson<sup>3</sup>, J. Castaneda<sup>4</sup>, R. Re<sup>4</sup>, J. Shin<sup>4</sup>, Y. Reznik<sup>5</sup>,  
<sup>1</sup>Diabetes Unit, Endocrinology Department, Hospital Clinic i Universitari, Barcelona, Spain, <sup>2</sup>Institute of Endocrinology, Ch. Sheba Medical Center, Tel Hashomer, Israel, <sup>3</sup>LMC Diabetes & Endocrinology, Toronto, Canada, <sup>4</sup>Medtronic, Northridge, USA, <sup>5</sup>Endocrinology and Diabetes Department, Centre Hospitalier Régional Universitaire de Caen Côte de Nacre, Caen, France.

**Background and aims:** Previous studies did not conclusively demonstrated a benefit of continuous subcutaneous insulin infusion (CSII) in patients with Type 2 Diabetes (T2D) previously treated with basal-bolus multiple daily injections (MDI). The OpT2mise study is a multicenter, randomized trial comparing CSII to MDI in a large cohort of T2D subjects suboptimally controlled despite MDI therapy. Aim: To further understand the mechanism underlying the differences between both types of therapies, a study on the glucose metrics, as a secondary endpoint, was performed.

**Materials and methods:** Subjects with poor glycemic control ( $n=495$ ) on MDI were enrolled into a run-in period for insulin dose optimization (Total Daily Dose  $\geq 0.7$  and  $\leq 1.8$  U/kg/d). Those showing an HbA<sub>1c</sub>  $\geq 8\%$  and  $\leq 12\%$  were then randomly assigned to CSII or continuing on MDI for 6 months. Blinded Continuous Glucose Monitoring (CGM, iPro2, Medtronic) data was collected for a 6 day period before and 6 months after randomization and changes in glucose metrics were evaluated (Glucose exposure, Glucose Variability and Glucose Ranges).

**Results:** A total of 331 patients were randomized, aged  $56.0 \pm 9.6$ , 45.6% women, BMI  $33.4 \pm 7.3$ , diabetes duration  $15.1 \pm 8.0$  yr, and HbA<sub>1c</sub>  $9.0 \pm 0.8\%$ . CSII achieved significantly greater HbA<sub>1c</sub> reduction than MDI ( $-1.1 \pm 1.2\%$  vs.  $-0.4 \pm 1.1\%$ ,  $p < 0.001$ ). Data on CGM were available for 290 patients (143 and 147; 123 and 112 in the CSII and MDI arms at baseline and at 6 month, respectively). After 6 months, compared to MDI, 24h sensor glucose (SG) was reduced significantly more in CSII group ( $-17.1$  mg/dl,  $p < 0.05$ ), with less exposure to SG  $> 180$  and SG  $> 250$  mg/dl ( $-12.2\%$ ,  $p < 0.001$  %, and  $-6.4\%$ ,  $p < 0.05$ ), more time in target (70–180 mg/dl; 11.8 %,  $p < 0.001$ ) and no difference in time exposure to SG  $< 70$  mg/dl. Concerning glucose variability, there were no difference in 24h Standard Deviation (SD) SG, coefficient of variation (CV) or in mean amplitude of glucose excursions (MAGE).

**Conclusion:** In comparison with MDI, CSII treatment in suboptimally controlled patients with T2D provides a significant improvement in glucose profile with increased time spent in target, less exposure to hyperglycemia and without an increase in the risk of hypoglycemia.

#### Impact of a built-in insulin calculator feature on diabetes control: pilot study

T. Haak<sup>1</sup>, M. Diamant<sup>2</sup>, T. Danne<sup>3</sup>, G. Freckmann<sup>4</sup>,  
<sup>1</sup>Research Institute of the Diabetes Academy Mergentheim (FIDAM), Bad Mergentheim, Germany, <sup>2</sup>VU University Medical Centre, Amsterdam, Netherlands, <sup>3</sup>Diabetes Zentrum für Kinder und Jugendliche Kinderkrankenhaus auf der Bult, Hannover, <sup>4</sup>Institut fuer Diabetes-Technologie Forschungs- und Entwicklungsgesellschaft mbH an der Universitaet Ulm, Germany.

**Background and aims:** To evaluate the impact of the FreeStyle InsuLinx meter with a built-in insulin bolus calculator on glycaemic control by observing time spent in euglycaemia (3.9 to 10.0mmol/L) in the assessment phase vs. the baseline phase for the intervention group (primary endpoint), and measures of glycaemic control from a continuous glucose monitor (e.g. time spent in hypoglycaemia, secondary endpoints). Additional secondary endpoints considered in the study were: total daily dose of insulin (TDD), Hypoglycaemia Fear Survey (HFS), Diabetes Distress Scale (DDS) and Diabetes Treatment Satisfaction Questionnaire (DTSQ) results.

**Materials and methods:** The pilot study was a multicentre, randomised, two arm (control and intervention), parallel study conducted at 4 European study centres, with Type 1 diabetes subjects on Multiple Daily Injections (MDI, 3 or more per day) using U100 insulin (n=49). All subjects wore a masked FreeStyle Navigator Continuous Glucose Monitor (CGM) for 14 days (baseline phase) where upon randomisation, 33 entered the intervention group (one subject was excluded from analysis as their Navigator had alarms switched on for both CGM phases) and 16 the control group. The intervention group proceeded to use the InsuLinx meter with built-in insulin calculator in either Easy (n=7, fixed dose meal time insulin calculator) or Advanced mode (n=25, rapid acting Insulin calculator with carb counting) for 45 days, the control group used a FreeStyle Freedom Lite meter for 45 days. After this time both arms continued with their designated meter together with a masked CGM for 14 days (assessment phase).

**Results:** When comparing baseline versus assessment phase in the intervention group, no significant difference in time spent in euglycaemia (3.9 to 10.0mmol/L) was found (primary endpoint). Study statistics found a decrease in the number of excursions per day <3.9mmol/L (-0.24, p<0.05) and on the DTSQ, the treatment satisfaction scale was significantly improved by 2.0 points within the intervention group. When separated into InsuLinx easy mode vs. advanced mode, there was a significant reduction of the number of excursions per day <3.9mmol/L (-0.5, p<0.05) compared to baseline when the meter was used in easy mode. When comparing the intervention group versus the control group, the use of the InsuLinx meter in easy mode resulted in a significant reduction of time spent <3.9mmol/L (-1.1 hours/day from baseline of 2.2, p<0.05). The HFS found that using the InsuLinx meter in advanced mode, resulted in a significant reduction in the total worry score (by 3.9, p<0.05) compared to the control group. TDD of insulin increased significantly (p<0.05) for subjects in the intervention group compared to the control group.

**Conclusion:** The indications from this pilot study are that use of a meter with a built-in insulin calculator can lead to improvements in diabetes control, particularly in reducing the prevalence of hypoglycaemic events, can reduce worry of hypoglycaemia and improve treatment satisfaction. It is postulated that patients first try to avoid hypoglycaemia and next focus on reducing hyperglycaemia; hence the relatively short length of the study may have prevented an increase in time in euglycaemia.

#### Does frequent use of an automated bolus advisor improve glycaemic control in pediatric patients treated with insulin pump therapy?

##### First results of the BABE study

R. Ziegler<sup>1</sup>, C. Rees<sup>2</sup>, N. Jacobs<sup>1</sup>, C.G. Parkin<sup>3</sup>, M.R. Lyden<sup>4</sup>, B. Petersen<sup>5</sup>, R.S. Wagner<sup>2</sup>;

<sup>1</sup>Diabetes Clinic for Children and Adolescents, Muenster, Germany,

<sup>2</sup>Roche Diagnostics, Indianapolis, <sup>3</sup>CGParkin Communications, Inc., Boulder City, <sup>4</sup>Biostat International, Tampa, USA,

<sup>5</sup>Roche Diagnostics GmbH, Mannheim, Germany.

**Background and aims:** Studies have shown that use of an automated bolus advisor improves glycemic control in type 1 and insulin-treated type 2 diabetes; however, the relationship between frequency of bolus advisor use and glycemic improvement has not been well studied.

**Materials and methods:** The Bolus Advisor Benefit Evaluation (BABE) study was a single-center, retrospective cohort study that assessed the impact of frequent use of the Accu-Chek Aviva Combo system bolus advisor (BA) feature on glycemic control among pediatric type 1 diabetes patients on insulin pump treated at a pediatric diabetology clinic in Germany. Measurements of HbA1c, hypoglycemia (<60 mg/dL), therapy changes, mean blood glucose and glycemic variability (SD) were assessed at baseline and after 3 and 6 months of BA use. A total of 104 pediatric patients with mean (SD) baseline: HbA1c 8.0(1.6)%, age 12.7(4.9) years, diabetes duration 46.7(43.7) months, and 58.7% female were assessed. Baseline differences in HbA1c, diabetes duration and age were accounted for by ANCOVA analyses.

**Results:** After 6 months of BA use, 71 patients reported high frequency (HF) of device use (≥50%) versus 33 patients who reported low frequency (LF) use (<50%) during the study period. Mean (SE) HbA1c among HF users was significantly lower than LF users: 7.5(0.1)% vs. 8.0(0.2)% (p=0.0252). There was with no between-group difference in the percentage of hypoglycemia values (<60 mg/dL) within 30 days prior to 6-month visit: 5.5 (4.5)% vs. 5.9(5.8)%, p=0.6526. More HF than LF users received therapy changes during the 6-month period: 62(87.3%) vs. 22(66.7%), p=0.0174. HF users showed significantly lower mean blood glucose (164.4 [29.78] vs. 194.5 [38.70] mg/dL, p<0.0001) and less glycemic variability as assessed by standard deviation (80.1 vs. 100.6, p=0.0001) than LF users.

**Conclusion:** Frequent use of an automated bolus advisor was associated with significant improvements in glycemic control and more therapy changes with no increase in hypoglycemia associated with BA use in pediatric patients treated with CSII therapy.

<sup>1</sup>Research Institute of Diabetes Academy Mergentheim (FIDAM),

Bad Mergentheim, <sup>2</sup>Roche Diagnostics, Mannheim, Germany.

**Background and aims:** Intensive insulin therapy relies on correct prandial insulin dose adaptation dependent from current glucose level, amount of planned carbohydrate intake and the consideration of other situational factors like physical activity or circadian fluctuation of insulin sensitivity. People with diabetes and intensive insulin therapy should be able to estimate carbohydrates and calculate insulin bolus correctly, while regarding the factors mentioned above. An assessment tool for the measurement of the ability of carbohydrate estimation and bolus calculation is missing. The objective of this study was the development and psychometric evaluation of an assessment tool for carbohydrate estimation and bolus calculation ("aSSessment of the Ability of Bolus Calculation and Carbohydrate estimation" SMART). Of special interest were the associations of both abilities with glycaemic control.

**Materials and methods:** The SMART consisted of one scale for the assessment of bolus calculation (BOLUS) with 10 items and a scale for carbohydrate estimation (CARB) with 12 items. People with type 1 or type 2 diabetes on an intensive insulin regimen were invited to participate. HbA1c and stored data of blood glucose meters were used to determine glycaemic control.

**Results:** 411 patients participated (age 42.9 ±15.7, 58% female, HbA1c 8.6 ±1.8%, 28% with CSII-treatment) and approx. 56,000 blood glucose meter readings could be obtained. The reliability of both scales was sufficient (Cron-

bachs alpha for BOLUS  $r = 0.78$  and the CARB  $r = 0.67$ ). Better bolus calculation was associated with a higher level of education ( $r = 0.24$ ,  $p < .05$ ), lower HbA1c ( $r = -0.27$ ,  $p < .05$ ), lower mean blood glucose ( $r = -0.29$ ,  $p < .05$ ), and a lower standard deviation of blood glucose values ( $r = -0.43$ ,  $p < .05$ ). Better carbohydrate estimation was associated with a lower body mass index ( $r = -0.2$ ,  $p < .05$ ), lower mean blood glucose ( $r = -0.3$ ,  $p < .05$ ), a lower frequency of hyperglycaemia ( $r = -0.27$ ,  $p < .05$ ), and a higher frequency of euglycaemia ( $r = 0.26$ ,  $p < .05$ ). Patients with an insulin pump were better on both scales than patients with multiple daily insulin injections (BOLUS:  $7.2 \pm 2.4$  vs.  $6.4 \pm 2.7$ ,  $p < .01$ ; CARB:  $7.8 \pm 2.1$  vs.  $7.1 \pm 2.6$ ,  $p < .01$ ). Patients with previous diabetes education performed significantly better on both scales (BOLUS:  $6.8 \pm 2.5$  vs.  $5.7 \pm 2.8$ ,  $p < .01$ ; CARB:  $7.4 \pm 2.4$  vs.  $6.5 \pm 2.6$ ,  $p < .01$ ).

**Conclusion:** SMART provides a reliable and valid assessment of the ability to estimate the correct amount of carbohydrates and to calculate the appropriate prandial insulin dose. SMART is also sensitive to depict effects of diabetes education and of CSII treatment in comparison to multiple daily insulin injections. In summary SMART can assist the identification of people with diabetes on an intensive insulin regimen, who are in need for improvements in carbohydrate estimation and/or calculation of prandial insulin dose.

## 1016

### A clinical evaluation of blood sampling practices in patients with diabetes: impact on fingerstick blood volume and pain

M. Grady<sup>1</sup>, M. Pineau<sup>2</sup>, M. Pynes<sup>2</sup>, L.B. Katz<sup>3</sup>, B. Ginsberg<sup>4</sup>;

<sup>1</sup>Clinical Affairs, LifeScan Scotland Ltd, Inverness, UK, <sup>2</sup>Clinical Research, Facet Technologies, Kennesaw, <sup>3</sup>Clinical Affairs, LifeScan, Wayne,

<sup>4</sup>Diabetes Consultants, Wyckoff, USA.

**Background and aims:** There is a perception that patients with diabetes struggle to produce sufficient blood to fill glucose test strips, including strips with 1  $\mu$ l fill requirements. The purpose of this study was to determine the volume of blood expressed when these patients perform routine fingersticks using their own lancing device and sampling technique, and to evaluate the relationship between blood volume and pain. In addition, a survey was used to explore patient perceptions and preferences regarding blood sampling.

**Materials and methods:** Each of the 64 subjects (type 1 or type 2 diabetes mellitus) performed 8 fingersticks using their own lancing device, preferred depth setting and lancing technique. Eight different commercially available lancing systems were used (8 subjects/system). Blood volume and perceived pain were recorded after each fingerstick. Subjects used the same depth setting typically used at home to lance. In addition, they were instructed to express capillary blood from their fingertips using the same technique they typically use at home and consistent with their specific lancing device instructions.

**Results:** Average blood volume generated across all subjects was 3.1  $\mu$ l (SD=2.1  $\mu$ l, from 512 fingersticks) with 97% of subjects expressing an average of  $\geq 1.0 \mu$ l of blood. There was no significant contribution due to lancing system on individual or mean blood volume ( $F=1.623$ ;  $p=0.15$ ). There was no correlation between pain response and the volume of blood expressed ( $r=-0.054$ ;  $p=0.67$ ). Similarly, there was no statistically significant correlation ( $r=0.164$ ;  $p=0.19$ ) between lancing depth setting and the pain reported by the subject. Nearly all subjects agreed they could easily and comfortably obtain a 1  $\mu$ l blood sample, and most subjects actually preferred a larger drop size when doing blood glucose tests to ease sampling and avoid wasting strips.

**Conclusion:** These results provide evidence across 8 lancing systems that challenges the current perceptions that patients with diabetes struggle to produce sufficient blood samples to fill most test strips, including those with 1  $\mu$ l fill requirements, and that obtaining larger volumes of blood is more painful.

These results are consistent with previous literature suggesting patients (1) derive no real benefits from test strips with very low blood sample volumes and (2) generally prefer a blood drop size that enables them to confidently fill their test strip.

## Average fingerstick blood volume

97% subjects expressed  $> 1 \mu$ l blood

Data shown for all 64 subjects, organized by lancing device

Each point represents the average of 8 fingersticks per subject

Clinical Trial Registration Number: NCT01914302

## 1017

### System accuracy evaluation of 10 SMBG systems with 3 lots each following ISO 15197:2013 against 2 different comparison methods

G. Freckmann, M. Link, A. Baumstark, C. Schmid, S. Pleus, C. Haug; Institut für Diabetes-Technologie Forschungs- und Entwicklungsgesellschaft mbH an der Universität Ulm, Germany.

**Background and aims:** High quality blood glucose (BG) monitoring systems are required for adequate self-monitoring of blood glucose (SMBG). The international standard ISO 15197, which was revised in 2013, stipulates performance requirements for SMBG systems. Prior to the revision, ISO 15197 prescribed a system accuracy evaluation against the manufacturer's measurement method. This was changed so that any method traceable according to ISO 17511 may be used. In order to investigate possible effects on apparent SMBG system accuracy, 10 SMBG systems with 3 lots each were evaluated against 2 comparison methods.

**Materials and methods:** In this study, system accuracy of 10 SMBG systems was evaluated with 3 different reagent system lots each. Each lot was tested on 100 capillary blood samples from different subjects following investigational procedures of the international standard ISO 15197:2013. Comparison measurements were performed with the YSI 2300 STAT Plus™ glucose analyser (glucose oxidase method (GOD)) and the Cobas® c111 (hexokinase method (HK)). Both methods were traceable according to ISO 17511 as required by ISO 15197:2013. Compliance with accuracy criteria stipulated in ISO 15197:2013 was assessed for each reagent system lot by calculating the percentage of results within  $\pm 15\%$  or within  $\pm 15$  mg/dL of the comparison method results for BG concentrations above or below 100 mg/dL, respectively, and by calculating the percentage of results within Consensus Error Grid zones A and B across all 3 lots of a system. Additionally, accuracy criteria of ISO 15197:2003 were applied by calculating the percentage of results within  $\pm 20\%$  or within 15 mg/dL of comparison method results above or below 75 mg/dL, respectively.

**Results:** Seven of 10 systems (Accu-Chek® Performa; BGStar®; Contour® next USB; Contour® XT; FreeStyle InsuLinx; mylife™ Pura™; MyStar Extra®) fulfilled the minimum accuracy criteria of ISO 15197:2013 (at least 95% of results within  $\pm 15\%$  or  $\pm 15$  mg/dL of the comparison method results and at least 99% within Consensus Error Grid zones A and B) with all 3 tested reagent system lots, independent from the comparison method applied. In

the evaluation against the respective system's manufacturer's measurement method (GOD for 7 systems, HK for 3 systems), individual reagent system lots showed 90% to 100% of results within  $\pm 15\%$  or  $\pm 15$  mg/dL of the comparison method results, with 23 of 30 lots having at least 95% within these limits. When evaluated against the alternate comparison method, between 83% and 100% of results were within these limits for individual lots and 25 of 30 lots showed at least 95% within the limits. Eight of 10 systems fulfilled the minimum accuracy criteria of ISO 15197:2003 (at least 95% of results within  $\pm 20\%$  or  $\pm 15$  mg/dL of the comparison method results) against the respective manufacturer's measurement method. Individual lots showed between 94.5% and 100% of the results within these limits and 28 of 30 lots showed at least 95% within these limits.

**Conclusion:** In this evaluation, 7 of 10 systems met the minimum system accuracy criteria of ISO 15197:2013. Analysis of individual reagent system lots showed that specific evaluation results differed depending on the comparison method. These data suggest that the comparison method used in an evaluation can have an influence on an SMBG system's apparent system accuracy. Investigator-initiated study supported by Sanofi

## 1018

### Is fingerstick calibration beneficial for stable and consistent sensors?

E.S. Budiman;

Abbott Diabetes Care, Alameda, USA.

**Background and aims:** Subcutaneously inserted glucose monitoring systems typically require fingerstick calibrations. Calibrations allow for sensor specific adjustment and can correct for any sensor drift over the wear duration. When sensors can be manufactured with a sufficiently low in-vitro lot sensitivity CV and can remain stable in-vivo, fingerstick calibration may no longer be beneficial. Universal calibration provides a shared, one-time calibration factor for all sensors from the same lot. This analysis computes the expected average and expected 90<sup>th</sup> percentile sensor performance in fingerstick and universal calibration studies. Per-sensor mean absolute relative difference (MARD) distribution is used for the comparison.

**Materials and methods:** A total of 33 subjects with diabetes were enrolled to wear four sensors simultaneously. Sensors from a lot with low in-vitro sensitivity CV ( $=2.9\%$ ) were used in the study. To examine the effect of fingerstick error, an emulator that allows raw sensor data from the actual clinical study to be recalibrated with any meter was used. No difference in per-sensor MARD distribution was observed when the same meter type from a different clinical study data was used for calibration ( $z$ -test  $p$ -value = 0.80). The fingerstick calibration study was repeated 1000 times using a simulated 15/15 error meter (i.e. 95% of the values within 15 mg/dL below 100 mg/dL reference value, and within 15% at or above 100 mg/dL). The universal calibration study is also repeated 1000 times, each time randomly selecting 3 sensors and using the median of the per-sensor sensitivities to calibrate the rest.

**Results:** Each study generated a distribution of per-sensor MARD values. After repeating the study 1000 times, the range of average per-sensor MARD from the fingerstick calibration studies has a mean and standard deviation of 13.7% and 0.24%, respectively (Table 1). The table also shows the average from the 1000 universal calibration studies, as well as the 90<sup>th</sup> percentile of both studies. The per-sensor MARD distribution of the universal calibration studies, both in terms of the average and 90<sup>th</sup> percentile, is statistically better than that of the fingerstick calibration studies ( $p < 0.0001$ ).

**Conclusion:** Fingerstick calibration can be a necessary element to ensure good and consistent sensor performance. However, stable sensors with low in-vitro sensitivity variation do not appear to benefit from fingerstick calibration.

|   | per-sensor MARD (from 1000 studies)        |  |
|---|--|--|
|   | average<br>[mean $\pm$ standard deviation] | 90 <sup>th</sup> percentile<br>[mean $\pm$ standard deviation] |
| Fingerstick calibration<br>(simulated 15/15 error meter)  | 13.7% $\pm$ 0.24%                          | 18.9% $\pm$ 0.63%  |
| Universal calibration<br>(randomized median of 3 sensors) | 13.5% $\pm$ 0.88%                          | 18.0% $\pm$ 1.61%  |
| $z$ -test $p$ -value                                      | <0.0001                                    | <0.0001  |

### Standardised procedure for the assessment of new-to-market continuous glucose monitoring (CGM) systems (Space2)

J. Kropff<sup>1</sup>, D. Bruttomesso<sup>2</sup>, W. Doll<sup>3</sup>, A. Farret<sup>4</sup>, S. Galasso<sup>2</sup>, Y.M. Luijckx<sup>1</sup>, J.K. Mader<sup>3</sup>, J. Place<sup>4</sup>, F. Boscari<sup>2</sup>, T.R. Pieber<sup>3</sup>, E. Renard<sup>4</sup>, J.H. DeVries<sup>1</sup>;

<sup>1</sup>Department of Internal Medicine, Academic Medical Centre, Amsterdam, Netherlands, <sup>2</sup>Department of Clinical and Experimental Medicine, University of Padova, Italy, <sup>3</sup>Department of Internal Medicine, Medical University Graz, Austria, <sup>4</sup>Department of Endocrinology, Montpellier University Hospital, France.

**Background and aims:** This study assessed the accuracy and reliability of the two most widely used continuous glucose monitoring (CGM) systems.

**Materials and methods:** We studied the G4 Platinum (DG4P) and Veo Enlite (ENL) CGMs, in 24 patients with type 1 diabetes. CGMs were tested during six day home use and a nested six hour clinical research center (CRC) visit. During the CRC visit, frequent venous blood glucose samples were used as reference while patients received a meal with an increased insulin bolus to induce an aggravated postprandial glucose nadir. At home, patients performed at least six reference capillary blood measurements per day. Wilcoxon signed-rank test was performed using all data points  $\geq 15$  min apart.

**Results:** Overall Mean Absolute Relative Difference (MARD) (SD) measured at the CRC was 13.6% (11.0) for DG4P and 16.6% (13.5) for ENL ( $p < 0.0002$ , CI  $\Delta = 1.7$ -4.3%,  $n = 530$ ). Overall MARD assessed at home was 12.2% (12.0) for DG4P and 19.9% (20.5) for ENL ( $P < 0.0001$ , CI  $\Delta = 5.8$ -8.7%,  $n = 839$ ). During the CRC visit, MARD in the hypoglycaemic range ( $\leq 70$ mg/dL) was 17.6% (12.2) for DG4P and 24.6% (18.8) for ENL ( $p < 0.005$ , CI  $\Delta = 3.1$ -10.7%,  $n = 117$ ). Both sensors showed higher MARD during hypoglycemia compared to euglycemia (70-180mg/dL) (DG4P 17.6% vs. 13.0% and ENL 24.6% vs. 14.2%).

**Conclusion:** During circumstances of intended use, including both a CRC and home phase, the Veo Enlite sensor was noticeably less accurate than the G4 Platinum sensor. Both sensors showed lower accuracy in the hypoglycaemic range. DG4P was less affected by this negative effect of hypoglycemia on sensor accuracy than ENL.

Clinical Trial Registration Number: NCT01751932

Supported by: Dexcom, USA.

## 1020

### How current continuous glucose monitoring (CGM) users translate CGM data into diabetes management: results of a survey

S.V. Edelman<sup>1</sup>, J.H. Pettus<sup>1</sup>, D.A. Price<sup>2</sup>;

<sup>1</sup>University of California, <sup>2</sup>Dexcom, San Diego, USA.

**Background and aims:** The use of real time (RT) CGM devices is becoming the standard of care for treating patients with type 1 diabetes (T1D) as several studies have shown that children and adults that regularly use CGM improve their glycemic control. However, the specific interventions that patients make on a day-to-day basis in response to the CGM information have not been determined. This study was conducted to learn more about current CGM

practices and assess how CGM users respond to their CGM information in a real-world setting.

**Materials and methods:** A 70 question clinical scenario-based survey was developed that probed 5 topics: subject characteristics and general CGM use, treating and preventing incidental and mealtime hypo- and hyperglycaemia and nocturnal issues. The survey was extensively beta-tested to make sure questions were clearly written and unambiguous. Clinicians that actively prescribe CGM from across the US were contacted and asked to recruit and provide a survey web link to regular Dexcom CGM users (>6 days a week on average) from their practice.

**Results:** 222 of 300 respondents had T1D and are analyzed in this abstract: mean age ( $46 \pm 14$  years), duration of T1D ( $22 \pm 14$  years), self-reported HbA1c ( $6.9\% \pm 0.8\%$ ), 52% male, 75% used CSII and 25% MDI (75% had used CGM >1 year), education- 65% university graduates or had another advanced degree. Key findings: The majority of the participants viewed the RT information (51%) or hypo/hyper alarms (30%) as the most important information; only 3.6% of subjects thought the computer downloads analysis was most helpful. To prevent hypoglycemia, 70% of participants reported they would prophylactically consume carbohydrates in response to a displayed glucose of 120mg/dl with a decreasing trend (angled or downward rate of change arrow). 42% of respondents stated that at least one time in the last 6 months, their CGM device alerted somebody around them to respond to their hypoglycemia alarm when they themselves were unable to. 70% and 66% of participants report waking up at night at least once per week in response to alerts for hypo- and hyperglycemia respectively. In a scenario-based question about response to a low alert waking them up at midnight, 50% of respondents stated they would treat the low glucose without confirming with their meter. 65% of participants reported that since starting CGM, the number of boluses they took per day had increased. Daytime and nighttime glucose targets commonly changed- 57% lowered their daytime glucose targets. Participants reported a mean increase in correction insulin dose (unrelated to a meal) for 1 arrow up was 111%, a mean decrease in the correction dose for 1 arrow down was 41%, relative to the correction dose with a flat arrow. For a 50 gram glucose meal at euglycemia, the meal dose increased by 81% for 2 arrows up and decreased by 53% for 2 arrows down, relative to the meal dose with a flat arrow. Most (59%) participants also reported they adjusted the insulin timing in each of the scenarios, based on the direction and rate of change.

**Conclusion:** Patients use CGM data in many of their clinical decisions and for multiple aspects of their diabetes management. These changes contribute to safer diabetes management and improved outcomes. The adjustments reported by patients in this survey to their mealtime and correctional insulin doses are much larger than current recommendations.

## PS 085 Psychological distress

### 1021

#### Metabolic control in type 1 diabetic children with self report depression: 3-year follow-up

B.M. Zdunczyk<sup>1</sup>, K. Dzygala<sup>2</sup>, K. Piechowiak<sup>3</sup>, A. Szypowska<sup>2</sup>;

<sup>1</sup>Clinical Child and Adolescent, Clinical Hospital,

<sup>2</sup>Department of Pediatrics, Clinical Hospital,

<sup>3</sup>Department of Pediatrics, Clinical Hospital, Warsaw, Poland.

**Background and aims:** Many studies show there is a higher risk of depression in patients with diabetes than in healthy population. Depression has been associated with worse disease outcomes and readmissions in adults with diabetes. Less is known about the effect of depression on metabolic control and hospital admissions in children and adolescents with type 1 diabetes. The aim of this study was to examine if depression is associated with worse metabolic control and repeat hospitalisations in children and adolescents with type 1 diabetes in 3-year follow-up.

**Materials and methods:** In years 2010-2012 we screened 477 children for depression: during the routine visit in the outpatient clinic 252 girls and 225 boys, with diabetes duration > 1 year filled in Polish version of Children's Depression Inventory by M. Kovac, a self-report questionnaire consisting of 27 items. At the same time other data was collected: sex, age, diabetes duration, HbA1c, BMI, daily insulin dose. Medical parameters of 139 children (65 boys, 74 girls, age  $11.38 \pm 1.85$  diabetes duration  $4.53 \pm 3.05$ , ins/kg  $0.81 \pm 0.20$ , BMI  $19.18 \pm 0.2$ , HbA1c  $7.5 \pm 1.3$  at baseline), collected for 3 years were analysed.

**Results:** 5% (22/137 participants scored  $\geq 13$ , indicating elevated depressive symptoms. There was no difference between children with CDI  $\geq 13$  and CDI < 13 in diabetes duration ( $p = 0.483$ ) and age ( $p = 0.329$ ). We found significant relationship between scores in CDI and HbA1c in subsequent years of follow up: 2010 -  $r = 0.1753$   $p = 0.039$ , 2011 -  $r = 0.1349$   $p = 0.037$  and 2013 -  $r = 0.2629$   $p = 0.0018$  but not 2012 -  $r = 0.1159$   $p = 0.183$ . CDI scores were not associated with daily insulin dose for all years but the baseline (2010  $r = 0.181$ ,  $p = 0.033$ , 2011  $r = 0.139$   $p = 0.125$ , 2012  $r = 0.099$ ,  $p = 0.273$ ). We didn't find the difference between participants with CDI  $\geq 13$  and CDI < 13 in HbA1c ( $p = 0.573$ ), daily insulin dose ( $p = 0.113$ ) or BMI ( $p = 0.541$ ). At the same time children with CDI  $\geq 13$  had higher insulin dose/kg/d ( $p = 0.024$ ). Surprisingly we didn't find the difference between children with CDI  $\geq 13$  and CDI < 13 in the number of hospitalisations ( $p = 0.797$ ) or psychological care ( $p = 0.064$ ).

**Conclusion:** 15% participants show elevated depressive symptoms as assessed with Children's Depression Inventory at the baseline. Children and adolescents with higher scores on the CDI don't differ from patients without depressive symptoms in age, BMI and daily insulin dose. Although depressive symptoms are associated with worse metabolic control children with higher scores in CDI achieve the same HbA1c level as their peers with lower CDI scores. This trend is seen for the whole period of follow-up. Our results show that depressive symptoms are not associated with higher use of hospital facilities. Still it is necessary to pay attention to emotional wellbeing of children and adolescents with diabetes type 1 regardless of HbA1c.

### 1022

#### The assessment of factors related to depressive symptoms in adult patients with type 1 diabetes

A. Duda-Sobczak, D. Zozulinska-Ziolkiewicz, D. Pisarczyk-Wiza,

B. Wierusz-Wysocka;

Department of Internal Medicine and Diabetology,

Poznan University of Medical Sciences, Poland.

**Background and aims:** Depressive disorders are more common among people with diabetes compared with general population. The presence of depressive symptoms may reduce motivation and the treatment adherence and in fact worsen the treatment outcomes. The aetiology of depression is complex and not only related to diagnosed chronic disease. The aim of this study was to assess factors related to depressive symptoms in adult patients with type 1 diabetes.

**Materials and methods:** 304 subjects (164 women), aged 43 (33-52) years, type 1 diabetes duration 26 (33-31) years, HbA<sub>1c</sub> 7.8 (7.1-8.8)% were included. Subjects diagnosed with chronic complications causing disability (blindness, end stage renal disease, painful peripheral neuropathy, limb amputation) were excluded to avoid the presumable impact of irreversible dis-

ability on questionnaire answers. Depressive symptoms were assessed using Beck Depression Inventory (BDI). Additionally, Problem Areas in Diabetes Questionnaire (PAID), Multidimensional Fatigue Symptom Inventory-Short Form (MFSI-SF) were completed. Data on social, economic and lifestyle factors were collected. Metabolic control expressed by HbA<sub>1c</sub> and medical history was assessed via medical chart review. The studied group was divided into two subgroups according to the presence or absence of depressive symptoms based on the BDI standard cut-offs.

**Results:** 41% of study participants presented any depressive symptoms. They were more frequent among women ( $p<0.0001$ ), less educated, unemployed and not physically active participants ( $p=0.016$ ,  $p=0.015$ ,  $p=0.0014$  respectively). Fear of hypoglycaemia and diagnosed chronic complications of diabetes appeared more frequently among patients exhibiting depressive symptoms ( $p=0.013$ ,  $p=0.04$  respectively). The intensity of depressive symptoms correlated with fatigue as well as with degree of coping with diabetes ( $r=0.56$ ,  $p<0.0001$ ;  $r=0.42$ ,  $p<0.0001$  respectively). No relation of metabolic control (HbA<sub>1c</sub>) with depressive symptoms was demonstrated.

**Conclusion:** In adult type 1 diabetic patients depressive symptoms are related not only to chronic disease, but also to sex, socioeconomic status and lifestyle. The results of this study may be useful in delineating the complex treatment plan including nonpharmacological and psychological interventions.

## 1023

### The effect of a diabetes-specific cognitive behavioural treatment programme (DIAMOS) for people with diabetes and subthreshold depression

B. Kulzer, A. Schmitt, A. Gahr, T. Haak, N. Hermanns;  
Research Institute of Diabetes Academy Mergentheim (FIDAM),  
Bad Mergentheim, Germany.

**Background and aims:** Subthreshold depression is one of the most frequent mental comorbidities in people with diabetes and is associated with a poorer long-term prognosis. Since specific intervention concepts are missing a new self-management oriented group programme (DIAMOS) was developed for this patient group and evaluated in a randomised trial.

**Materials and methods:** The active control group (CG) received diabetes education. DIAMOS consisted of cognitive behavioural interventions aiming at the reduction of diabetes distress. Patients completed several questionnaires at baseline and follow-up: The Center of Epidemiological Studies-Depression Scale (CES-D), the Patient Health Questionnaire (PHQ 9), the Problem Areas in Diabetes Questionnaire (PAID) and the Diabetes Distress Scale (DDS). Primary outcome was the reduction of depressive symptoms. Secondary outcomes were diabetes distress, well-being, self-care behaviour, diabetes acceptance, diabetes treatment satisfaction, HbA<sub>1c</sub> and inflammatory markers. 214 participants were randomised.

**Results:** Baseline characteristics (age  $43.3 \pm 13.3$  yrs., female gender 56.5%, diabetes duration  $14.2 \pm 10.5$  yrs., type 2 diabetes 34.1%, BMI  $28.7 \pm 7.1$  kg/m<sup>2</sup>) were comparable between both interventions groups except BMI and diabetes type. At 12-month follow-up there was a significant greater reduction of the CES-D- and PHQ 9-scores in DIAMOS compared to the CG ( $\Delta$  -3.7, 95%-CI 0.57 to 6.85  $p=0.021$  respectively  $\Delta$  -1.49, 95%-CI 0.08 to 2.90;  $p=0.039$ ). The risk of incident major depression was reduced (OR 0.63, 95%-CI 0.42 to 0.96,  $p=0.028$ ) Also PAID-scores ( $\Delta$  -8.3 95%-CI 3.33 to 12.72,  $p=0.001$ ) and DDS-scores ( $\Delta$  -0.22 95%-CI 0.02 to 0.42,  $p=0.042$ ) were significantly reduced. C-reactive protein was significantly more lowered ( $\Delta$  -0.25 95%-CI 0.02 to 0.48  $p=0.035$ ). No effect of the intervention was observed in other inflammatory markers (IL1RA, IL6 and adiponectin).

**Conclusion:** DIAMOS is more effective in lowering depressive symptoms and diabetes related distress in diabetic patients with subthreshold depression. DIAMOS also has a preventive effect regarding the incidence of major depression.

Clinical Trial Registration Number: NCT01009138

### Non severe hypoglycaemia does not affect the prevalence of diabetes related stress

N. Kuniss, G. Kramer, N. Müller, C. Kloos, G. Wolf, U.A. Müller;  
Endocrinology, University Hospital Jena, Germany.

**Background and aims:** The occurrence of hypoglycaemia is supposed to be associated with lower quality of life in patients with type-2 diabetes. Furthermore hypoglycaemia is suspected to be a trigger for depression. We investigated the association of hypoglycemic events with diabetes related stress in a large outpatient cohort with diabetes type 1 (DM1) and type 2 (DM2).

**Materials and methods:** In a cross-sectional study we assessed hypoglycaemia and diabetes related stress with the PAID questionnaire in 785 people with diabetes in an university outpatient department for metabolic diseases over a period of three months (1.11.2012 to 31.01.2013). A PAID score  $\geq 40$  indicates a depressed mood. 193 people (24.6%) had DM1 (HbA<sub>1c</sub> 7.2%, age 54.5J, diabetes duration 22.3J, BMI 27.0kg/m<sup>2</sup>), 182 (23.2%) had DM2 without insulin therapy (HbA<sub>1c</sub> 6.6%, age 63.5J, diabetes duration 8.6J, BMI 31.1kg/m<sup>2</sup>) and 410 (52.2%) had DM2 with insulin therapy (HbA<sub>1c</sub> 7.1%, age 68.0J, diabetes duration 18.6J, BMI 33.6kg/m<sup>2</sup>). Patients with and without hypoglycaemia were compared. Mild hypoglycaemia was defined as a condition with typical symptoms (e.g. sweating, impaired concentration) disappearing quickly after carbohydrate ingestion or plasma glucose  $<2.7$  mmol/l with or without typical symptoms. Severe hypoglycaemia was diagnosed if intravenous glucose injection or intramuscular glucagon injection was necessary. HbA<sub>1c</sub> was adjusted according to the mean normal value of healthy people in the DCC trial (5.05%).

**Results:** People with DM1 had 1.09 mild hypoglycaemia/week and 0.04 severe hypoglycaemia/last 12 months. There were no significant differences in diabetes related stress comparing people with DM1 with ( $n=111$ ) and without ( $n=82$ ) mild hypoglycaemia (PAID score  $19.0 \pm 14.6$  vs.  $16.5 \pm 14.6$ ,  $p=0.284$ ), as well as with ( $n=7$ ) and without ( $n=186$ ) severe hypoglycaemia ( $20.7 \pm 18.0$  vs.  $18.1 \pm 15.8$ ,  $p=0.666$ ). The mean PAID score of both groups is well below the threshold for depressive mood (PAID score  $<40$ ). The frequency of mild hypoglycaemia/week in people with DM2 without and with insulin therapy is low (without insulin 0.03, with insulin 0.1). People with DM2 treated without insulin with ( $n=4$ ) and without ( $n=178$ ) mild hypoglycaemia have no different PAID score ( $20.3 \pm 15.0$  vs.  $15.5 \pm 14.5$ ,  $p=0.515$ ). People with DM2 on insulin with ( $n=33$ ) and without ( $n=377$ ) mild hypoglycaemia as well show no differences in the PAID score ( $16.7 \pm 11.2$  vs.  $16.9 \pm 14.8$ ,  $p=0.945$ ). Severe hypoglycaemia/last 12 months did not occur in people with DM2 in this study group.

**Conclusion:** In an outpatient setting neither in people with diabetes type-1 nor type-2 mild and severe hypoglycaemia are associated with increased diabetes related stress or increased incidence of depressive mood.

## 1025

### Psychosocial distress in a clinical setting: Is PAID 1 a valuable tool to disclose distress

K.E. Nielsen, M. Glindorf, H.U. Andersen;  
Steno Patient Care Center, Steno Diabetes Center, Gentofte, Denmark.

**Background and aims:** Psychosocial problems are common among patients with diabetes and often not recognized and addressed in the relatively short and busy meeting with the health care professional in daily clinical setting. Problem Areas in Diabetes (PAID) 1 (question 12: 'Worrying about the future and the possibility of serious complications') has been identified as a one-item screening tool, with high sensitivity and specificity for the recognition of diabetes-related emotional distress. In a specialized diabetes clinic we have in 2011 implemented PAID 1 at the biennial status examination performed by the diabetes nurse to evaluate whether this is a feasible screening tool in the daily clinical setting.

**Materials and methods:** 3274 patients, aged  $54.7 \pm 42.3$  years, male 56.6 %, Type 1 diabetes 67 %, disease duration 22,8 (0-80) years, are included in this material. The result of the screening is registered in the Electronic Patient File from where data is worked up. PAID is a questionnaire for self-administration developed to explore and screening for diabetes-related emotional issues from the patient's perspective. The table is built on a 5 point Likert scale from a point „not a problem“ to the „serious problem“.

**Results:** 41 % type 1 and 36 % type 2 diabetes patients show significant distress (PAID 1 score  $>2$ ), not dependent on diabetes duration, confirming data from previous PAID studies. No influence of gender was seen. A previous

study has found PAID score to be weakly related to HbA1c. In our study, PAID 1 score is also related to poor metabolic control, figure 1.

**Conclusion:** We conclude that PAID 1 is suitable as a rapid tool to disclose emotional distress in a busy clinical setting. PAID 1 has been easily implemented by the nurses and it is found valuable as an opening question in the consultation in order to discuss emotional distress and worries related to diabetes treatment, complications and daily life. Next step will be to study change in PAID 1 over time and how we can manage further screening and treatment of emotional distress in a structured way.

## 1026

### Associations between glycaemic control, depressed mood, clinical depression and diabetes distress

H. Ascher-Svanum<sup>1</sup>, D. Schuster<sup>1</sup>, H. Schmitt<sup>2</sup>, L. Marangell<sup>1</sup>, E. Dennehy<sup>1</sup>, A. Zagar<sup>1</sup>, D. Jiang<sup>1</sup>, D. Kendall<sup>1</sup>, J. Raskin<sup>3</sup>, R. Heine<sup>1</sup>;  
<sup>1</sup>Eli Lilly and Company, Indianapolis, USA, <sup>2</sup>Lilly, Brussels, Belgium, <sup>3</sup>Lilly, Toronto, Canada.

**Background and aims:** Although depression has been associated with poor glycaemic control in patients with type 2 diabetes (T2DM), the available data are inconsistent and both methodological approaches and data quality vary significantly across studies. Specifically, depression has been defined and measured in multiple ways, including identification of a clinical syndrome, use of a depression rating scale and as measured by distress linked to diabetes and its management. This exploratory, post hoc analysis assessed the association between depression, evaluated by these 3 methods, and glycaemic control over 2 years in patients with T2DM initiating insulin in a single treatment trial.

**Materials and methods:** We analyzed data from a 24-month, prospective, observational study that evaluated glycaemic response in patients with T2DM who initiated insulin therapy (N=985) in 5 European countries. Secondary measures included patient-reported diagnosis of depression at baseline, severity of depressed/anxious mood (EuroQol (EQ)-5D item) and diabetes-related distress (Psychological Distress domain of the Diabetes Health Profile, DHP-18). The latter two measures were assessed at baseline and 5 time points throughout the study. Glycaemic control was measured by A1c at these same time points. Analyses employed t-tests to assess the unadjusted baseline difference in A1c between patients with and without the respective depression parameter. The potential effect of demographic and clinical confounding variables was controlled through a linear model structure.

**Results:** At baseline, A1c of patients with depressed mood (moderately or extremely depressed/anxious) was higher, but not statistically significantly different from patients without depressed mood (9.6% vs. 9.5%, respectively,  $p=.303$ ). However, patients with depressed mood had higher A1c values throughout the 24 months follow up ( $p<.001$ ). Patients with clinical depression had a higher baseline A1c than patients without clinical depression (10.8% vs. 9.4%, respectively,  $p<.001$ ) and higher A1c values during the first 6 months ( $p<.010$ ) following insulin initiation. Significant group differences were not observed at subsequent time points. Patients with high diabetes distress had higher A1c at baseline as compared to patients with low distress (9.9% vs. 9.4%, respectively,  $p<.001$ ) and higher A1c values were observed in the high distress group throughout the 24 months follow up ( $p<.001$ ). Reported results are based on the unadjusted group comparisons.

**Conclusion:** In this exploratory, post hoc analysis we demonstrated consistent and significant associations between poorer glycaemic control and each of the 3 depression parameters: depressed mood, clinical depression and diabetes distress. The associations with poorer A1c were observed concurrently at baseline for clinical depression and diabetes distress and longitudinally for

all 3 depression parameters. Our findings support - in this patient group - the previously reported association between depression and diabetes control. However, this analysis was not designed to assess causality and will require replication. The similar, but not identical findings, of the 3 unique depression measures suggest that each tool may capture a different but interrelated condition that may require assessment and management to optimize glucose control in patients with T2DM.

## 1027

### Association of the presence and severity of depression with demographic, socioeconomic, glycaemic and metabolic risk factors in type 2 diabetes

C. Verras, S. Vrakas, A. Angelidi, A. Foutris, A. Ganotopoulou, V. Katsouri, V. Liosi, C. Sagia, G. Cristofilidis, A. Dimitriadou, V. Foustieris, A. Melidonis; Diabetes Center, Tzanio General Hospital, Piraeus, Greece.

**Background and aims:** Depression is a serious mental disease quite prevalent. Surveys have shown a strong association between depression and diabetes mellitus with poor outcomes in disease control. The purpose of this study is to explore possible correlations between demographic, socioeconomic and metabolic parameters with the presence and severity of depression in people with type 2 diabetes.

**Materials and methods:** 269 patients (132 males, aged  $65 \pm 10.2$  years) with type 2 diabetes were included in the study. Information regarding demographic characteristics, socioeconomic status, anthropometric and metabolic parameters, glycaemic control, type of antidiabetic treatment and the presence of complications of diabetes were collected from all patients. The questionnaire scale BDI-II is widely used for depression and consists of 21 questions each answer being scored on a scale value of 0 to 3. The total score ranges from 0 to 63. Higher total scores indicate more severe depressive symptoms. Statistical analysis was performed using STATA 9.0 software.

**Results:** Severity of depression showed a statistically significant relationship with the following parameters: age (Coefficient=-0.21,  $p<0.0001$ ), living with their children (Coefficient=4.6,  $p=0.012$ ), menopause (Coefficient=-10.3,  $p=0.039$ ), bmi (Coefficient=0.53,  $p=0.001$ ), HbA1c (Coefficient=1.68,  $p=0.002$ ), oral hypoglycaemic agents (Coefficient=-5.5,  $p=0.035$ ) and insulin (Coefficient=5.5,  $p=0.006$ ). On multivariate analysis, HbA1c showed significant positive association with the severity of depression (Coefficient = 1.73, 95% CI: 0.42 - 3.04,  $p = 0.010$ ). Moreover, analysis regarding glycaemic control revealed that participants with HbA1c < 7% had lower BDI-II score than those with HbA1c > 7% ( $p=0.023$ ).

**Conclusion:** Higher HbA1c levels appear to act favorably to the presence and severity of depression. Furthermore, good glycaemic control is inversely associated with depression in people with type 2 diabetes.

## 1028

### Improvement in depressive symptoms is associated with reduced markers of inflammation and oxidative damage in type 2 diabetic patients

M. Vucic Lovrencic<sup>1</sup>, M. Pibernik-Okanovic<sup>2</sup>, D. Ajdukovic<sup>2</sup>, M. Sekerija<sup>3</sup>, N. Hermanns<sup>4</sup>;

<sup>1</sup>Merkur University Hospital, <sup>2</sup>Merkur University Hospital, University Clinic for Diabetes, <sup>3</sup>Croatian National Institute of Public Health, Zagreb, Croatia, <sup>4</sup>Forschungsinstitut Diabetes-Akademie Bad Mergentheim (FIDAM GmbH), Bad Mergentheim, Germany.

**Background and aims:** Processes of inflammation and oxidative damage in diabetic patients suffering from subsyndromal depression have not been sufficiently clarified. This study was aimed at examining one-year changes in inflammatory and pro-oxidative biomarkers in patients treated for elevated depressive symptoms that did not reach criteria for clinical depression.

**Materials and methods:** A randomized controlled comparison of two behavioural interventions for subsyndromal depression - six-week psychoeducation and physical exercise, and a control condition consisting of brief diabetes re-education - was performed in a sample of 209 type 2 diabetic patients with subsyndromal depression (aged  $57 \pm 6$  yrs, 54% female, with diabetes duration of  $11 \pm 8$  yrs, 32% insulin treated, with HbA1c of  $7.3 \pm 1.2$  [ $56 \pm 12.3$  mmol/mol] and BMI of  $30 \pm 5$  kg/m<sup>2</sup>). Clinical depression was excluded by using a Structured Clinical Interview for the DSM-IV Axis I disorders. A level of depressive symptoms, endogenous inflammatory markers (leukocytes, CRP), indicators of antioxidant capacity (myeloperoxidase index [MPXI], plasma

uric acid), and markers of oxidative damage (sialic acid, urinary-8-OH-deoxyguanosine [u-8-OH-dG]) were assessed at baseline, and after six- and twelve months. Repeated measures ANOVAs were employed to determine within- and between-group differences in depressive symptoms and measured biomarkers at follow-ups.

**Results:** Participants in the psychoeducational, physical exercise and the control group improved equally in depressive symptoms from baseline to 12-month follow-up (time versus time x group effect;  $F=12.51$   $p<.0001$   $\eta^2=0.07$  and  $F=0.609$   $p=0.656$   $\eta^2=0.007$ , respectively). Total leukocytes significantly decreased in all three groups ( $7.7\pm 1.8$  to  $7.1\pm 1.6$   $F=15.72$   $p<.0001$   $\eta^2=.119$ ) as did sialic acid ( $2.1\pm 0.3$  to  $1.8\pm 0.3$   $F=135.67$   $p<.0001$   $\eta^2=0.323$ ) and u-8-OH-dG ( $1.1\pm 0.5$  to  $0.99\pm 0.5$   $F=10.66$   $p<.0001$   $\eta^2=0.06$ ). No within- and between-group changes were observed with respect to CRP and MPXI. Uric acid increased significantly during one year in all three groups ( $295.1\pm 84.9$  to  $315.8\pm 84.4$   $F=12.53$   $p<.0001$   $\eta^2=0.07$ ), with time effects being greater in women in comparison with men ( $\eta^2=0.13$  versus  $\eta^2=0.03$ ).

**Conclusion:** Lowering depressive symptoms in subsyndromally depressed type 2 diabetic patients was found to be associated with long-term improvements in biomarkers of inflammation and oxidative stress. Treatment of even mild depressive symptoms may have favourable clinical implications.

Clinical Trial Registration Number: ISRCTN05673017

Supported by: EFSO

**Conclusion:** A higher level of socioeconomic deprivation seemingly may predispose to severe neuropathic pain in diabetes requiring pharmacological intervention. Targeted allocation of healthcare resources to this group may offer significant clinical benefits.

## 1029

### Socioeconomic deprivation independently predicts symptomatic painful diabetic neuropathy in type 2 diabetes

S.G. Anderson<sup>1</sup>, R.P. Narayanan<sup>2</sup>, N.S. Malipatil<sup>3</sup>, H. Roberts<sup>4</sup>, G. Dunn<sup>5</sup>, A.H. Heald<sup>4,6</sup>,

<sup>1</sup>Cardiovascular Sciences Research Group, University of Manchester,

<sup>2</sup>Department of Obesity and Endocrinology, The University of Liverpool,

<sup>3</sup>Vascular Research Group, The University of Manchester, <sup>4</sup>Department of Medicine, Leighton Hospital, Crewe, <sup>5</sup>Department of Podiatry, East Cheshire NHS Trust, Macclesfield, <sup>6</sup>The school of Medicine and Manchester Academic Health Sciences Centre, The University of Manchester, UK.

**Background and aims:** Painful peripheral neuropathy in people with type 2 diabetes is a disabling complication. We explored associations of this condition with socioeconomic deprivation in an area of the UK, Cheshire which has a wide variation in demographic profile.

**Materials and methods:** The Townsend index of socioeconomic deprivation was examined in the pseudonymised GP records of 15388 (44.1% female) individuals with type 2 diabetes in Cheshire UK, and related to prevalence of drug treated painful diabetic neuropathy. We also analysed prescription trends with respect to pharmacotherapy for neuropathy pain relief.

**Results:** Treatment for neuropathic pain was initiated in 3266 (21.2%) of patients. Those on treatment were older [68.2 (95% CI 67.8-68.7) vs 66.6 (66.4-66.8) years] than those not on treatment. There was no difference in HbA1c (7%, 55 mmol/mol). The odds of having treated painful peripheral neuropathy increased by 3.8 % for each 5 years of increasing age of the patient odds ratio (OR) 1.05: 95% confidence interval (CI) 1.04-1.07;  $p<0.0001$ . There was a 3% increased chance for each unit increase in BMI OR 1.03: 95% CI 1.02-1.03;  $p<0.0001$ , but no relation with HbA1C. (OR 1.0: 95% CI 0.99-1.0;  $p=0.58$ ). There were significant differences between the groups for the Townsend deprivation index, with a greater proportion (30.6% vs 22.8% of patients with treated neuropathic pain) having a score of  $\geq 1$  ( $X^2=83.9$ ,  $p<0.0001$ ). Multivariate logistic regression analyses indicated that each unit increment in the Townsend index was associated with an 6% increased odds of requiring neuropathic pain treatment [odds ratio (95%CI) 1.06 (1.05-1.08),  $p<0.0001$ ] independent of five year age band, BMI, gender, systolic BP, eGFR, HbA1C and total cholesterol.

## PS 086 Psychology and quality of life

**Physicians' challenges when discussing the type 2 diabetes diagnosis with patients: insights from a cross-national study (IntroDia™)**

W.H. Polonsky<sup>1</sup>, A. Belton<sup>2</sup>, S. Down<sup>3</sup>, M. Capehorn<sup>4</sup>, V. Gamerman<sup>5</sup>, F. Nagel<sup>6</sup>, J. Lee<sup>6</sup>, D. Clark<sup>6</sup>, S. Edelman<sup>7</sup>;

<sup>1</sup>Department of Psychiatry, University of California San Diego and Behavioral Diabetes Institute, San Diego, USA, <sup>2</sup>International Diabetes Federation, Brussels, Belgium, and The Michener Institute for Applied Health Sciences, Toronto, Canada, <sup>3</sup>Somerset Partnership NHS Foundation Trust, Bridgwater, <sup>4</sup>National Obesity Forum and Clifton Medical Centre, Rotherham, UK, <sup>5</sup>Boehringer Ingelheim Pharmaceuticals, Inc., Ridgefield, USA, <sup>6</sup>Boehringer Ingelheim Pharma GmbH & Co. KG, Ingelheim, Germany, <sup>7</sup>Division of Endocrinology and Metabolism, University of California San Diego and Veterans Affairs Medical Center, San Diego, USA.

**Background and aims:** Physician communication at diagnosis of type 2 diabetes (T2D) may impact patient self-care, quality of life, and outcomes. IntroDia™ is a survey of ~17000 T2D patients and physicians in 26 countries to investigate early physician-patient communication and its potential consequences.

**Materials and methods:** As part of IntroDia™, we surveyed 6753 physicians from Asia, Europe, America, Africa, and Australia using an online survey that included a novel questionnaire of 12 challenges that physicians may encounter at T2D diagnosis, and the Jefferson Scale of Physician Empathy.

**Results:** Across countries, 76-100% of physicians (88% overall) agreed that conversations with patients at T2D diagnosis impact on patients' disease acceptance and treatment adherence. 92% of physicians wanted tools to help patients sustain behavioural change. Using factor analysis, the 12 items resulted in loading onto 2 factors (Table): Discouraged with Patients at Diagnosis (DPD;  $\alpha = 0.87$ ), comprising 8 related challenges, and Frustrated with Situation at Diagnosis (FSD;  $\alpha = 0.72$ ), comprising 4 challenges. Correlation between these 2 factors suggested related, but distinct, groups of challenges ( $r = 0.64$ ,  $p < 0.0001$ ). Factor scores varied globally (DPD highest in France; FSD in Japan). Upon adjusting for demographic/clinical practice variables, regression models showed a negative relationship between physician empathy and perceived challenges for total score (all 12 items) as well as DPD and FSD (all  $p < 0.0001$ ).

**Conclusion:** Many physicians, especially those scoring lower on empathy, report significant challenges and frustrations during conversations with patients at diagnosis of T2D. Most physicians wanted tools to help patients sustain behavioural change. Supporting use of empathy-related skills may contribute to better patient outcomes.

| 12-item Questionnaire: "Challenges at Diagnosis"   | % physicians answering in ... diagnosis conversations (n=6753) |          |         |         |        | Factor |

**Health-related quality of life and the relation to metabolic syndrome, type 2 diabetes, degree of obesity and low-grade inflammation in obese individuals**

S.N. Slagter, M.M. van der Klauw, J. van Vliet-Ostaptchouk, J.C. Keers, H.L. Lutgers, A.P. van Beek, B.H.R. Wolffenbuttel; Endocrinology, University Medical Center Groningen, Netherlands.

**Background and aims:** We assessed the differences in health-related quality of life (HRQL) in obese participants with and without metabolic syndrome (MetS) and type 2 diabetes (T2D), by degree of obesity and level of inflammation (high sensitive C-reactive protein (hsCRP)). HsCRP is related to Obesity, MetS and T2D.

**Materials and methods:** Participants were derived from the random population-based LifeLines study in the Netherlands. In total, 53,266 subjects (39,540 normal weight and 13,726 obese; BMI >30 kg/m<sup>2</sup>), aged 18-80 years, were included. Subjects with diabetes were those with known T2D or had a fasting blood glucose >7.0 mmol/L. HRQL was assessed with the Short Form-36. Sex-corrected physical (PCS) and mental component score (MCS) were calculated. MetS was measured with the NCEP ATP III (2005). ANCOVA was used to compare the PCS and MCS score, with age as covariate. Clinically relevant differences in PCS and MCS were defined as a minimum difference score of respectively, 2 and 3 points between groups of patients. We defined a poor outcome on individual scales of the PCS and MCS as a score below 80 points. Results on individual scales were stratified by gender.

**Results:** PCS and MCS: Compared to normal weight individuals, obese subjects had a significantly lower PCS (ranging from 3.1-7.5 points difference), pending on their MetS and T2D status, degree of obesity and level of inflammation. However, no clinically relevant changes were found for MCS. Obese subjects with MetS had a significant lower PCS (49.7 vs. 51.1) and MCS (50.4 vs. 51.2) than obese subjects without MetS, however these differences were small. Having T2D only affected the PCS (50.7 vs. 47.5;  $p < 0.001$ ). Increasing BMI was associated with a worse score of both PCS and MCS. However, test for linearity was only significant for PCS ( $p < 0.001$ ). Subjects with elevated hsCRP had a lower PCS than those with normal hsCRP (test for linearity,  $p < 0.001$ ). Individual scales: Among obese males, MetS affected physical functioning, role physical and general health within the physical health domain, compared to obese men without MetS (all  $p < 0.01$ ). Within the dimension mental health, only social functioning and role emotional was affected by MetS. In obese women all scales of the physical and mental health domain was affected by MetS. Higher BMI among the obese subjects, was associated with having a poor outcome on all scales (test for linearity, all  $p < 0.01$ ), except for role emotional in men and mental health in women. Elevated hsCRP showed more affected scores on scales within the dimension of physical health, than within the dimension of mental health. A higher percentage of obese male and female subjects with T2D had a worse score on all scales of physical health compared to those without T2D. Only the score on social functioning was affected by T2D ( $p < 0.01$ ).

**Conclusion:** Obese individuals had a lower HRQL compared to normal weight individuals, even in the absence of MetS, T2D or inflammation. Having T2D, a BMI  $\geq 40$  kg/m<sup>2</sup> or hsCRP >10 mg/L was associated with clinically relevant decreased physical health. MetS, T2D, increasing BMI and low-grade inflammation were all associated with poorer outcome of scales in the domain of physical health rather than in the mental health domain.

### 1032

**Day napping and risk of type 2 diabetes: a dose-response meta-analysis**

T. Yamada, K. Hara, N. Shojima, H. Hosoe, T. Kadowaki; Department of Diabetes and Metabolic Diseases, University of Tokyo, Japan.

**Background and aims:** A nap is a short period of sleep, typically during daylight hours, and the habit of napping is widely prevalent around the world. Daytime naps are usually brief, but can range from a few minutes to a few hours. The frequency varies from taking an occasional nap to planned rest periods several times daily for habitual nappers. Some individuals take a nap because they are excessively sleepy during the daytime as a result of a sleep disorder. We performed a meta-analysis of evidence on the association between napping and the risk of type 2 diabetes and attempted to quantify the potential dose-response relation.

**Materials and methods:** We searched Medline, the Cochrane Library, Web of Science, and Science Direct for articles published up to March 2014 using the keywords nap (siesta) and diabetes. We also searched the references of

the original studies that we identified. Observational studies reporting risk estimates for type 2 diabetes were assessed. To ascertain the validity of the eligible studies, the quality of each report was appraised with reference to the STROBE statement. In addition, the Newcastle-Ottawa Scale for assessing the quality of prospective cohort studies in meta-analyses was used to quantify the validity of each study. The adjusted relative risk and 95% confidence interval were calculated with the random effect model. Dose-response relations were evaluated using data from different nap categories in each study. Two authors independently confirmed the eligibility of the studies and collated the data. Any discrepancies were resolved through discussion. Sex was employed as an independent category for comparison. Publication bias was evaluated by the funnel plot, Begg test, and Egger test.

**Results:** Among 1,035 potential studies, 225,717 Asian and Western subjects stratified into 5 categories were identified. The analyses performed in each study were well adjusted for several confounders for diabetes. Pooled analysis revealed that a longer nap time ( $\geq 60$  min/day) significantly increased the risk of type 2 diabetes (relative risk 1.46 (1.23–1.74,  $p < 0.001$ )), while shorter nap time ( $< 60$  min/day) did not (0.95 (0.75–1.21,  $p = 0.68$ )). Meta-analysis showed a significant non-linear dose-response relation between nap time and the risk of diabetes ( $P$  for non-linearity  $< 0.01$ ) (Figure 1), with no effect of nap time up to about 40 minutes/day followed by a sharp increase in the risk of diabetes at longer times. Publication bias was not significant.

**Conclusion:** There was a J-curve relation between nap time and the risk of type 2 diabetes, with longer nap times being associated with an increased risk.

### 1033

#### Longterm impact of childhood onset type 1 diabetes: social insertion, quality of life, sexuality

H. Mellerio<sup>1</sup>, S. Guilmin-Crépon<sup>1</sup>, P. Jacquin<sup>2</sup>, C. Alberti<sup>1</sup>, C. Levy-Marchal<sup>3</sup>;

<sup>1</sup>Inserm, ECEVE U1123 et CIC-EC 1426, <sup>2</sup>Assistance Publique-Hôpitaux de Paris, Hôpital R. Debré, Médecine de l'adolescent,

<sup>3</sup>Inserm, CIC-EC, CIC 1426, Paris, France.

**Background and aims:** Little is known about the long-term social outcome of diabetic children. This study aimed to describe socio-professional life, quality of life (QOL) and sexuality at adult age of children and adolescents with type 1 diabetes (T1D).

**Materials and methods:** Of 721 adults with childhood-onset T1D identified in the nationwide French Register of Incidence of Diabetes, 388 (53.8%; age =  $28.5 \pm 3.1$  yrs; age at diagnosis of diabetes =  $11.5 \pm 2.5$  yrs; duration of diabetes =  $17.0 \pm 2.7$  yrs) responded to a questionnaire (198 items). Data were compared to French general population (FGP) using indirect standardized ratios (SIR) matched for age, gender, period +/- educational level and familial life, or Z-scores adjusted for age, gender and period. Linear regression was used to investigate correlates of Physical (PCS) and Mental (MCS) SF36 Composite Scores.

**Results:** Educational level was similar to FGP (68.6%  $\geq$  high school degree; SIR = 1.06 (CI95%: 0.93; 1.20)), whereas school delay in first year of primary school was lower (5.3%, SIR = 0.49 (0.30; 0.75)). Unemployment was increased in women (15.3%, SIR = 1.50 (1.0; 2.1)) but not in men (8.6%, SIR = 0.96 (0.51; 1.57)). Professional occupation and employment contract patterns were close to what was expected. Adults with T1D were less likely

to be homeowner (25.7%, SIR = 0.72 (0.57; 0.89)). Frequency of daily alcohol consumption was higher than in FGP (SIR: men = 3.34 (2.38; 4.54); women = 6.53 (4.57; 12.99)); 7.2% (12/166) of men consumed more than recommended (2 glasses per day), 5.0% (11/220) of women (1 glass per day). Familial life pattern was not different from FGP and among those who planned to have children, 72.2% (125/173) had one or more biological child. Overall, 7.1% were very dissatisfied with sexual life (SIR = 1.90 (1.18; 2.75)). Sexual problems prevalence was higher in women (SIR: dysorgasmia = 1.91 (1.21; 2.88); decrease/loss of desire = 2.11 (1.35; 3.08)), but similar in men; Social discrimination was more frequent (SIR = 5.64 (4.64; 6.62)). PCS and MCS were respectively moderately (mean =  $52.0 \pm 7.5$ ; mean Z-score =  $-0.2$  (CI95%:  $-0.3$ ;  $-0.1$ )) and substantially altered (mean =  $42.1 \pm 12.4$ ; mean Z-score =  $-0.7$  ( $-0.8$ ;  $-0.6$ )). Fatigue and abandoning sport were associated with lower PCS and MCS; educational level and presence of diabetes complication were also predictive of worse PCS, and sexual dissatisfaction and negative feelings related to transition pediatric/adult care were predictive of lower MCS. Participants with at least one vascular complication (n = 136) had preserved social outcomes but decreased PCS (mean =  $50.0 \pm 8.3$ ; mean Z-score =  $-0.5$  ( $-0.7$ ;  $-0.3$ )) and MCS (mean =  $40.3 \pm 12.3$ ; mean Z-score =  $-0.9$  ( $-1.1$ ;  $-0.7$ )).

**Conclusion:** Young adults with T1D have a satisfying social well-being but alteration of MCS, frequent dissatisfaction with sexuality and uncommon alcohol consumption suggest the high impact of disease on morale, especially in women. Improving the screening of sexual problems and alcohol consumption, as well as optimize the psychological support of patients to cope with the T1D burden must be high priorities for health caregivers.

### 1034

#### Spectrum of diabetes research does not reflect patients' scientific preferences

S. Arnolds<sup>1</sup>, S. Heckermann<sup>1</sup>, P.T. Sawicki<sup>2</sup>;

<sup>1</sup>Profil Institut für Stoffwechselforschung GmbH, Neuss,

<sup>2</sup>Institute for Health Economics and Clinical Epidemiology, Medical Faculty of the University of Cologne, Germany.

**Background and aims:** Involvement of patients and their relatives in planning of research has been proposed to increase the patient orientated relevance of scientific investigations. Here we compare the proportions of research topics patients would like to see and the trend in the distribution of research categories of accepted EASD abstracts during the last four years.

**Materials and methods:** We evaluated the spectrum of diabetes research as published during the EASD meetings 2010 - 2013 and compared them with the results of a survey in 918 lay people (652 patients with diabetes, 205 relatives, 61 others concerned) interested in diabetes research, who had described their research preferences in diabetes. To obtain a fairly unselected sample of an interested lay group a questionnaire was published in a popular weekly news magazine inviting patients with diabetes and their relatives to state which area of research was of top priority to them. Nine research categories had been defined by consensus by four scientifically active diabetologists, and their completeness had been checked by testing whether all EASD abstracts published 2008 were covered by a defined scientific field. For this 4-year evaluation two reviewers (SA and PTS) independently assigned each EASD abstract to one of the nine research categories and also classified them according to a commercial sponsorship as indicated in the abstract EASD booklet. The 4-year period was analyzed in terms of changes or trends observed in the proportions of EASD research topics and the results were compared with patients' preferences.

**Results:** "Development, pathophysiology and prevention of diabetes" was the primary category of scientific interest for 25% of patients, 19% preferred "transplantation and cell therapy" and 16% "blood glucose measurement, devices and artificial pancreas". During the 4 years of EASD abstract investigation 50% or more of total research activities was constantly dedicated to "development, pathophysiology and prevention of diabetes", less than 2% to "transplantation and cell therapy" and 2.8% to 4.3% to "blood glucose measurement, devices and artificial pancreas". The average proportion of EASD research related to "blood-glucose lowering therapy without insulin" and "insulin therapy" more or less corresponded with the proportion of research patients would like to see (12.0% vs. 12.5%, and 6.9% vs. 4.7%, respectively). The majority of this research, however, was commercially funded. In total, non-commercial research was not closer correlated to patients' preferences compared to commercial research.

**Conclusion:** The distribution of diabetes research topics over the last four years as measured by the distribution of accepted EASD abstracts does not reflect what patients with diabetes and their relatives want to have investigated.

Better patient involvement and a reassessment of non-commercial funding strategies might help create more valuable research at least from patients' point of view.

## 1035

### Glycaemic perception and other factors influencing adherence to self-monitoring blood glucose in patients with type 1 or type 2 diabetes

M. Jansà Morató<sup>1</sup>, M. Vidal Flor<sup>1</sup>, M. Galindo Rubio<sup>2</sup>,  
M. Penalba Martínez<sup>3</sup>, L. Corredoira González<sup>4</sup>;

<sup>1</sup>Servicio de Endocrinología y Nutrición, Unidad de Diabetes, Hospital Clínic i Provincial de Barcelona, <sup>2</sup>Servicio de Endocrinología y Nutrición, Hospital Clínico de San Carlos de Madrid, <sup>3</sup>Servicio de Endocrinología y Nutrición, Hospital Universitari i Politècnic La Fe de Valencia, <sup>4</sup>Departamento de Estadística, BioClever 2005 S.L., Barcelona, Spain.

**Background and aims:** Self-monitoring blood glucose is an important tool to achieve good glycaemic control. However, many patients measure their glucose concentrations less often than recommended. This study was conducted to assess the factors associated with adherence to self-monitoring blood glucose in patients with diabetes mellitus treated with insulin.

**Materials and methods:** In this observational, prospective and multicenter study in patients with type 1 or type 2 diabetes treated with insulin as per usual clinical practice, socio-demographic and clinical characteristics were collected at the baseline visit. Glycemic perception was assessed through 4 monthly telephone calls asking patients about their perceived glycemic levels and then comparing these perceptions with their real values from the glucometer. A patient was considered adherent if the minimum number of glucose measurements established by the Spanish Society of Diabetes was carried out. To assess factors associated with adherence to self-monitoring blood glucose, a multivariate logistic regression were performed.

**Results:** A total of 2.700 patients were recruited, of whom 2.029 (75%) were considered valid for the analysis. With an age range of 18 to 80 years, the mean duration of the disease was 16.5±10.5 years and 30% of patients had type 1 diabetes. The majority of patients (81%) had an unsatisfactory glycaemic control (baseline HbA1c ≥7%), which was significantly associated with an incorrect glycaemic perception. Only 17% of patients had a correct glycaemic perception. More than half of the patients (54%) were adherent to the self-monitoring according to the SED rules (95%CI: 52%, 56%), this being 51% in patients with type 1 diabetes. In patients with an age range of 18 to 44 years, the recommendation of >21 measurements/week (OR: 0.031; 95%CI: 0.015, 0.062) and alcohol consumption (OR: 0.452; 95%CI: 0.254, 0.805) were associated to low adherence. In patients with an age range of 45 to 64 years, an increase in the number of insulin injections/day was associated to a higher adherence (OR: 1.296; 95%CI: 1.073, 1.566), while the recommendation of >21 measurements/week (OR: 0.070; 95%CI: 0.048, 0.104) and the belief that it was possible to know their glucose levels without the glucometer (OR: 0.925; 95%CI: 0.877, 0.976) were associated to low adherence. In patients over 65 years, the recommendation of >21 measurements/week (OR: 0.112; 95%CI: 0.076, 0.163), obtaining the test strips from the health centre vs from the pharmacy (OR: 0.554; 95%CI: 0.378, 0.812) and discouragement in cases of off-target HbA1c levels (OR: 0.488; 95%CI: 0.337, 0.706) were associated to low adherence.

**Conclusion:** Adherence to self-monitoring blood glucose in patients with diabetes varies depending on age and on being recommended >21 measurements/week as a common factor associated with low adherence in all age groups. Other variables associated with poor adherence by age group are: alcohol intake in young patients, confidence in glycaemic perception in middle age and lack of motivation for poor control in older people.

## 1036

### The relation between illness perception, diabetes distress and depression in type 2 diabetes patients: pilot study in a Romanian sample

A.S. Mocan<sup>1,2</sup>, S.S. Iancu<sup>1</sup>, I.A. Vereşiu<sup>1</sup>, D.E. Dumitraş<sup>3</sup>, S. Puşcaşu<sup>2</sup>,  
C.M. Mureşanu<sup>3</sup>, A.G. Şerban<sup>2</sup>, L.A. Pop<sup>3</sup>, A.S. Băban<sup>2</sup>;

<sup>1</sup>Diabetes, Nutrition and Metabolic Diseases Department, Emergency Clinical County Hospital, <sup>2</sup>Psychology and Educational Sciences Faculty, Babes -Bolyai University, <sup>3</sup>Department of Economic Sciences, University of Agricultural Science and Veterinary Medicine, Cluj-Napoca, Romania.

**Background and aims:** Depression has a major negative effect on diabetes outcome. Illness perception and diabetes distress may contribute to emotion-

al and somatic depressive symptoms. Our aim was to investigate the relationship between illness perception, diabetes distress and depression.

**Materials and methods:** 204 type 2 diabetes patients were included in the study. Revised Illness Perception Questionnaire (IPQ-R) and Diabetes Distress Scale (DDS) were used to investigate illness burden. Beck Depression Inventory was used for depression. Linear regression analysis was used to evaluate the association between the five components of IPQ-R (illness identity, causes, timeline, consequences and cure-control), respectively four components of DDS (emotional burden, physician-related distress, regimen-related distress and diabetes-related interpersonal distress) and emotional and somatic symptoms of depression.

**Results:** Mean age of the participants was 64.61 years (range 32-81 years) and the mean HbA1c 7.43% (SD=1.46%). Depressive symptoms were found in 43.1% of patients of them 22.1% had subclinical depression. In depressive group, HbA1c was associated with somatic depressive symptoms ( $r = .262$ ,  $p < 0.05$ ). Emotional diabetes distress was identified as a mediator between illness perception identity and somatic depression: first and second mediation linear regression  $R^2 = .174$ ,  $p < .005$ ,  $R^2 = .239$ ,  $p < .005$ , Sobel test  $z$ -score = 2.853,  $p = 0.0043$ . Emotional diabetes distress was also identified as a mediator between perception of illness consequences and somatic depression: first and second mediation linear regression  $R^2 = .172$ ,  $p < .005$ ,  $R^2 = .217$ ,  $p < .005$ , Sobel test  $z$ -score = 3.170,  $p = 0.0015$ . Finally emotional diabetes distress was identified as a mediator between emotional representation of illness and somatic depression: first and second mediation linear regression  $R^2 = .236$ ,  $p < .005$ , second mediation linear regression  $R^2 = .216$ ,  $p < .005$ , Sobel test  $z$ -score = 3.1621,  $p = 0.0015$ .

**Conclusion:** Diabetes distress represents a mediator between illness perception and depression symptoms. Diabetes symptoms, perception of the illness severity and feelings of diabetes' complication inevitability having a significant effect on the mental representation of future life with diabetes. In return diabetes patients tend to be irritable, restless, with insomnia and fatigue. The results are important for clinical practice and may help these patients with cognitive restructuring concerning both illness perception and diabetes impact. A possible explanation for these findings may be the emotional and cognitive dysfunctional coping strategies in these patients.

## 1037

### Depression influences on cardiometabolic profile responses to a lifestyle intervention in at-risk Brazilians

A. Cezaretto<sup>1</sup>, M. Pakseresh<sup>2</sup>, F. Kolahdooz<sup>2</sup>, S. Sharma<sup>2</sup>,  
B. Almeida-Pititto<sup>1</sup>, C.R. Barros<sup>1</sup>, S.R.G. Ferreira<sup>1</sup>;

<sup>1</sup>Nutrition, University of Sao Paulo, Brazil,

<sup>2</sup>Endocrinology, University of Alberta, Edmonton, Canada.

**Background and aims:** Cardiometabolic diseases and depression are relevant public health problems that are commonly associated. Benefits of lifestyle interventions on improving cardiometabolic profile are well documented. Low adherence to a healthy lifestyle may be partially explained by the association with psychological disorders, such as depression. Aims: To evaluate whether depression modifies the impact of a lifestyle intervention on cardiometabolic profile responses in an at-risk sample of the Brazilian population.

**Materials and methods:** 129 individuals at risk of cardiometabolic diseases recruited from Brazilian public health care services (66% women, 56.2±11.6 yrs, BMI 30.3±5.4 kg/m<sup>2</sup>). Participants were allocated to one of two 18-month interventions on diet and physical activity. Socio-demographic and clinical data were obtained. Depressive symptoms were assessed by the Beck Depression Inventory and score ≥12 diagnosed depression. Changes in each of the five metabolic syndrome components (body adiposity: ≥5% decreased waist circumference and/or BMI; plasma glucose: ≥10% decreased fasting and/or post-load glycemia; blood pressure: ≥ 10% decreased mean blood pressure; HDL-cholesterol: ≥10% increased HDL; and triglycerides: ≥10% decreased triglycerides) were used to define responses to the intervention and improvement on cardiometabolic profile. Multiple logistic regression models were employed (by each gender) in order to analyze influence of depression in each of 6 cardiometabolic profile outcomes. All models were adjusted for age, physical activity and type of intervention. Inflammatory markers were added into the models as possible mediators of relationship between depression and cardiometabolic outcomes. Likelihood ratio test was employed to compare the results of a logistic regression model with interaction term and a logistic regression model without interaction term.

**Results:** Approximately 42% of individuals had depressive symptoms. Depressed participants had a higher BMI, cholesterol and diastolic blood pressure, and had a lower level of the quality of life and physical activity compared

to non-depressed individuals. Depressed women after 18 months of intervention were less likely to have an improvement in their plasma glucose (OR: 0.32; 95%CI: 0.12; 0.87) and blood pressure (OR: 0.29; 95%CI: 0.10; 0.94) compared to non-depressed women. Depression had no effect on the impact of intervention on body adiposity and lipid profile. Inclusion of inflammatory markers into the models did not influence the association of depression and improvement in cardiometabolic profile. Comparing models including or not the interaction variable (depression\*interdisciplinary intervention) no difference in results was found.

**Conclusion:** Depression at baseline of a lifestyle intervention may predict a lower chance of improving long-term cardiometabolic profile particularly among women. This raises the necessity of increase health professionals awareness and public health policy makers' attention to depressed people at high cardiometabolic risk. We suggest a focus on screening and management of depression as part of the intervention programs for lifestyle changes in at-risk individuals.

*Clinical Trial Registration Number: RBR #65N292*

## 1038

### The impact of hyperglycaemia and obesity on hospitalisation costs and clinical outcome in general surgery patients

L. Buehler<sup>1</sup>, M. Fayfman<sup>1</sup>, A.-S. Alexopoulos<sup>1</sup>, L. Zhao<sup>2</sup>, F. Farrokh<sup>1</sup>, J. Weaver<sup>3</sup>, D. Smiley<sup>3</sup>, F. Pasquel<sup>1</sup>, G. Umpierrez<sup>1</sup>;

<sup>1</sup>Medicine-Division of Endocrinology, Emory University,

<sup>2</sup>Biostatistics, Rollins School of Public Health,

<sup>3</sup>Information Technology, Emory University, Atlanta, USA.

**Background and aims:** The association between inpatient hyperglycemia and poor outcome in surgical patients is well established. It is not known if obesity increases rates of complications in surgical patients with and without hyperglycemia and diabetes.

**Materials and methods:** We analyzed the effects of obesity and hyperglycemia on hospitalization costs and clinical outcome in patients, with and without diabetes (DM), who underwent gastrointestinal, hepato-biliary and pancreatic surgery. Inpatient hyperglycemia was defined as BG  $\geq 7.8$  mmol/L. Overweight was defined by body mass index (BMI) between 25–30 kg/m<sup>2</sup> and obesity as a BMI  $>30$  kg/m<sup>2</sup>. Hospital cost was calculated using cost-charge ratios from Centers for Medicare & Medicaid Services. Hospital complications included a composite of major cardiovascular events, pneumonia, bacteremia, acute kidney injury, respiratory failure, and death.

**Results:** Among 2366 surgery patients, hyperglycemia was present in 1799 patients (76%) of whom 506 (28%) had history of DM and 1293 (72%) had no DM before surgery. Compared to patients with normoglycemia, those with DM and non-DM with hyperglycemia had higher number of hospital complications (5% vs. 21% vs. 20%,  $p<0.0001$ ), longer hospital stay (5 days vs. 9 days vs. 9 days,  $p<0.0001$ ), more readmissions within 30 days (10% vs. 18% vs. 17%,  $p<0.0001$ ), and higher hospitalization costs (\$20,212 vs. \$78,690 vs. \$72,550,  $p<0.0001$ ). Multivariate analysis adjusted for age, gender, BMI and type of surgery (laparotomy/open surgery) revealed that hyperglycemia in DM and non-DM patients was associated with a ~4-fold increased risk of complications compared to patients with normoglycemia [OR 4.4 (95% CI: 2.8,7.0) and 4.0 (2.6,6.1)]. In contrast, compared to normal-weight subjects (BMI 18.5–25 kg/m<sup>2</sup>), the presence of overweight status and obesity was not associated with increased risk of complications (17.3% vs. 15.7% vs. 16.1%,  $p=0.77$ ), or hospitalization costs (\$58,313 vs. \$58,173 vs. \$66,644,  $p=0.41$ ). Open surgery was associated with higher rates of complications (19.2% vs. 8.9%,  $p<0.0001$ ) and higher hospitalization costs (\$67,191 vs. \$43,767,  $p<0.0001$ ) compared to laparoscopic surgery; however, there were no differences in mortality, hospitalization costs or type of surgery among normal weight, overweight and obese (all,  $p=NS$ ).

**Conclusion:** Perioperative hyperglycemia but not increasing BMI, in patients with and without diabetes undergoing gastrointestinal surgery, was associated with a higher number of complications and hospitalization costs.

## 1039

### Seasonal fluctuations in nutrition variability in Europe: are patients with symptoms of a metabolic syndrome different?

A. Dzien<sup>1</sup>, C. Dzien-Bischinger<sup>1</sup>, C. Dzien<sup>1</sup>, H. Winner<sup>2</sup>, E. Theurl<sup>3</sup>;

<sup>1</sup>Medical Center Hentschelhof, Innsbruck,

<sup>2</sup>Department of Economics and Social Science, University of Salzburg,

<sup>3</sup>Department of Public Economics, University of Innsbruck, Austria.

**Background and aims:** A lower nutrition variability seems to be related with an increased risk for metabolic and cardiovascular disorders. Seasonal changes in the availability of certain food items might influence food variability also in the high income countries of central Europe. We were interested in the possible dependency of nutrition variability over 4 seasons in an Austrian population especially with respect to differences between healthy people and patients with symptoms of a metabolic syndrome, including type 2 diabetes, hypertension and obesity (Body mass index, BMI,  $\geq 30$  kg/m<sup>2</sup>).

**Materials and methods:** For this purpose we have evaluated data from 3354 individuals (mean age 45.5 $\pm$ 18.9 years; mean BMI 24.3 $\pm$ 4.4 kg/m<sup>2</sup>) attending a medical outdoor center in an urban area between January 2006 and May 2013. Because of repeated controls during the evaluation period data from 4457 observations in healthy people and 352 in the 85 patients with symptoms of a metabolic syndrome were available. To obtain information on their "normal" nutrition behaviour, patients were requested to complete a semi-quantitative food frequency questionnaire including 51 different food items. Frequencies of consumption of food items were reported on a scale between 1 (seldom or never) and 6 (more than once daily). Based on this sample, we defined dietary diversity as the total number of different food items consumed during one week.

**Results:** Overall, nutrition variability was lower in patients with symptoms of a metabolic syndrome compared to the healthy control group. While nutrition variability revealed no significant seasonal dependency in the healthy group, low variability values were found in patients with symptoms of a metabolic syndrome during spring and fall.

**Conclusion:** The food variability seems to be lower in patients with a metabolic syndrome compared to a healthy control group. Regarding a possible seasonal influence the food variability revealed a decrease in the fall period. This lower food variability could be due to strict dietary recommendations, but also to rigid food behaviour, which becomes obvious when fresh local fruit and vegetables are available in autumn. Dietary cancelling should include the recommendation for food variability.

## PS 087 Individual perception of diabetes

#### Somatic symptoms in Chinese patients with type 2 diabetes: frequency, risk factors, and the relation to quality of life

Y. Zhang<sup>1</sup>, A. Luk<sup>1</sup>, W. Yang<sup>2</sup>, W. Jia<sup>3</sup>, W. Li<sup>4</sup>, L. Ji<sup>5</sup>, X. Guo<sup>6</sup>, A. Kong<sup>1</sup>, R. Ozaki<sup>1</sup>, R. Yeung<sup>1</sup>, N. Sartorius<sup>7</sup>, Y.-K. Wing<sup>8</sup>, J. Weng<sup>9</sup>, J. Chan<sup>1</sup>, China Diabetes and Depression Study Group;

<sup>1</sup>Department of Medicine and Therapeutics, The Chinese University of Hong Kong, Shatin, <sup>2</sup>Department of Endocrinology, China-Japan Friendship Hospital, Beijing, <sup>3</sup>Department of Endocrinology, Shanghai 6th Hospital, <sup>4</sup>Department of Endocrinology, Peking Union Medical College Hospital, Beijing, <sup>5</sup>Department of Endocrinology, Peking University People's Hospital, <sup>6</sup>Department of Endocrinology, Peking University First Hospital, Beijing, China, <sup>7</sup>Association for the Improvement of Mental Health Programmes, Geneva, Switzerland, <sup>8</sup>Department of Psychiatry, The Chinese University of Hong Kong, <sup>9</sup>Department of Endocrinology, The Third Affiliated Hospital, Sun Yat-sen University, Guangzhou, China.

**Background and aims:** Somatic symptoms are common in patients with chronic diseases which may reflect underlying emotional distress. We investigated the burden of somatic symptoms, risk factors and its associations with psychological health and quality of life in Chinese patients with type 2 diabetes.

**Materials and methods:** 2401 patients aged 18-75 years attending hospital-based clinics in 4 cities in China underwent detailed clinical-psychological assessment during a 12-month period in 2011-2012. Somatic symptom burden was measured using the 28-item Somatic Symptom Inventory (SSI); emotional distress was measured using the 21-item Depression, Anxiety Stress Scale (DASS); quality of life was measured using the Euroqol-5D.

**Results:** In this cross-sectional analysis, the mean (SD) age of the study cohort was 56.4 (10.6) years (46.6% women). Somatic symptoms were highly prevalent with a mean SSI score of 41.4 (15.1), and 14 of the 28 symptoms were reported by more than 30% of patients. Overall, 71.5% of patients reported at least one pain symptom, and 51.9% reported at least one gastrointestinal symptom. The most frequent reported symptom was trouble with vision (55.9%), followed by joint pain (44.9%), fatigue (44.8%), and muscles soreness (42.7%). In multivariate linear regression, after controlling for study sites, somatic symptom severity (adjusted  $R^2=0.483$ ;  $P<0.001$ ) was independently associated with women ( $\beta=0.088$ ,  $P<0.001$ ), long duration of diabetes ( $\beta=0.049$ ,  $P=0.008$ ), frequent hypoglycemia during the past 3 months ( $\beta=0.075$ ,  $P<0.001$ ), history of cardiovascular disease ( $\beta=0.045$ ,  $P=0.006$ ), sensory neuropathy ( $\beta=0.088$ ,  $P<0.001$ ), and emotional distress ( $\beta=0.623$ ,  $P<0.001$ ). Using stepwise linear regression, age ( $\beta=-0.053$ ,  $P=0.026$ ), women ( $\beta=-0.07$ ,  $P=0.001$ ), obesity ( $\beta=-0.066$ ,  $P=0.002$ ), frequent hypoglycemia in past 3 months ( $\beta=-0.063$ ,  $P=0.003$ ), sensory neuropathy ( $\beta=-0.049$ ,  $P=0.025$ ), and emotional distress ( $\beta=-0.216$ ,  $P<0.001$ ) were independently associated with poor quality of life. After inclusion of somatic symptom severity ( $\beta=-0.257$ ,  $P<0.001$ ), sensory neuropathy became non-significant ( $\beta=-0.026$ ,  $P=0.217$ ).

**Conclusion:** Somatic symptom burden is high in Chinese patients with type 2 diabetes which may reflect underlying emotional distress, suboptimal glycaemic control and sensory neuropathy.

### 1041

#### The Diabetes Self-Management Questionnaire (DSMQ) can detect inadequate self-care behaviour and help identify patients at risk of a negative diabetes prognosis

A. Schmitt, N. Hermanns, B. Kulzer, A. Reimer, S. Schall, T. Haak; Research Institute of the Diabetes Academy Mergentheim, German Diabetes Center Mergentheim, Bad Mergentheim, Germany.

**Background and aims:** Existing psychometric instruments to assess diabetes self-management often reveal weak or inconsistent associations with 'hard data' such as medical outcomes and HbA1c. To fill this gap, the Diabetes Self-Management Questionnaire (DSMQ) was developed, focussing on self-care

activities which directly impact medical diabetes outcomes. This study evaluates the questionnaire's practical utility in detecting high-risk patients at a tertiary diabetes centre.

**Materials and methods:** 226 people with diabetes (age  $43 \pm 15$  y; 55% female; BMI  $29 \pm 7$ ; 70% type 1 diabetes; illness duration  $15 \pm 10$  y; 92% treated with insulin; HbA1c  $8.9 \pm 1.6\%$ ) were assessed with the DSMQ and further questionnaires regarding diabetes acceptance (AADQ), coping with illness (FQCI), treatment satisfaction (DTSQ), diabetes distress (PAID), and depressive symptoms (CES-D); additional data (demographic variables, self-monitoring of blood glucose, HbA1c, and long-term complications) were gained from electronic patient records. People were then categorized by a median split of the DSMQ total score into groups performing 'adequate' ( $n = 107$ ) versus 'inadequate' diabetes self-care ( $n = 119$ ); the groups were compared regarding relevant outcomes using multivariate ANOVA (subsequently presented data are  $M \pm SD$ , F statistic, and effect size Cohen's d).

**Results:** After adjusting for sex, age, BMI, diabetes type, diabetes duration, and type of treatment, people performing 'inadequate self-care' compared to those with 'adequate self-care' showed stronger diabetes non-acceptance ( $31 \pm 8$  vs.  $22 \pm 6$ ,  $F = 90.5$ ,  $d = 1.24$ ), less active coping with diabetes ( $2.7 \pm 0.9$  vs.  $3.4 \pm 0.8$ ,  $F = 18.1$ ,  $d = 0.82$ ), lower diabetes treatment satisfaction ( $20 \pm 7$  vs.  $24 \pm 6$ ,  $F = 21.3$ ,  $d = 0.60$ ), higher diabetes distress ( $43 \pm 21$  vs.  $33 \pm 19$ ,  $F = 17.0$ ,  $d = 0.85$ ), and more depressive symptoms ( $24 \pm 11$  vs.  $20 \pm 11$ ,  $F = 4.8$ ,  $d = 0.36$ ). Moreover, they performed fewer blood glucose self-tests ( $3.3 \pm 3.5$  vs.  $5.6 \pm 2.4$  times per day,  $F = 24.7$ ,  $d = 0.74$ ), consulted their diabetologist less often ( $1.9 \pm 1.8$  vs.  $2.6 \pm 2.3$  times per half-year,  $F = 6.6$ ,  $d = 0.34$ ), had a higher HbA1c value ( $9.5 \pm 1.5$  vs.  $8.2 \pm 1.4\%$ ,  $F = 34.6$ ,  $d = 0.87$ ), and showed a higher prevalence of retinopathy (28% vs. 14%,  $F = 6.0$ ,  $d = 0.35$ ).

**Conclusion:** The DSMQ yields excellent distinction between people with diabetes performing adequate versus insufficient diabetes self-care, thus enabling detection of people at high risk of a negative diabetes prognosis. The 16-item questionnaire is an efficient tool which may be used for screening and diagnostic purposes or clinical diabetes research.

#### What drives patients? A cross-sectional survey of the effects and fear of hypoglycaemia on individuals, workplace, and patients' continued eligibility to drive

M. Bagger<sup>1</sup>, M. Dømggaard<sup>1</sup>, N.A. Rhee<sup>2</sup>, C.M. Burton<sup>3</sup>, B. Thorsteinnsson<sup>4</sup>;

<sup>1</sup>Research & Knowledge, Danish Diabetes Association, Odense,

<sup>2</sup>Clinical, Medical and Regulatory Affairs, Novo Nordisk Scandinavia

AB, Copenhagen, <sup>3</sup>Point Of Care Medical Consulting, Copenhagen,

<sup>4</sup>Department of Cardiology, Nephrology and Endocrinology, Nordsjællands Hospital, Hillerød, Denmark.

**Background and aims:** The aim of this study was to investigate the effect of hypoglycaemia and fear of hypoglycaemia on the individual and society.

**Materials and methods:** An anonymous cross-sectional survey of Danish Diabetes Association members was conducted to investigate individual and societal consequences of hypoglycaemia.

**Results:** A total of 3,117 of 9,951 invited individuals with type 1 (32.2%) or type 2 diabetes (67.8%) completed the survey. The calculated incidence rates of self-reported severe hypoglycaemia was 2.9, 0.6 and 0.1 events per patient year (ppy) in patients with type 1 diabetes, insulin using type 2 diabetes and non-insulin using type 2 diabetes, respectively; and incidence rates of self-reported mild hypoglycaemia were 99.0, 23.2 and 10.9 events ppy, respectively. Self-care strategies to avoid hypoglycaemia include maintaining higher blood glucose levels (45.7%) and reducing physical activity (15.7%). Few people take sick leave as a result of hypoglycaemia, but prolonged mental recovery  $\geq 4$  hours following an episode of mild or severe hypoglycaemia was reported by 8.7% and 31.0%, respectively. 9.3% of patients holding a valid driver license reported having 1 or more episodes of severe hypoglycaemia in the last year. Patients considering under-reporting of hypoglycaemia to maintain their driver license were more likely to have experienced severe hypoglycaemia (Odds Ratio [OR] 3.03, 95% CI 2.42-3.79,  $p<0.0001$ ).

**Conclusion:** A high proportion of Insulin treated patients experience hypoglycaemia resulting in fear of hypoglycaemia and changes in self-care behaviour that may compromise glycaemic control. Many patients with a history of severe hypoglycaemia consider under-reporting hypoglycaemic events through concern over retaining their driver license.

**Perception of type 1 diabetes management by adolescents, parents and healthcare professionals: divergence of opinions influences metabolic and psychological outcomes**S. Schmit<sup>1</sup>, J. Jacobs<sup>1</sup>, J.-P. Bourguignon<sup>2</sup>, M. Fichelle<sup>3</sup>, S. Jellimann<sup>4</sup>, O. Ziegler<sup>5</sup>, C. De Beaufort<sup>3</sup>;<sup>1</sup>Centre for Health Studies, CRP-Sante, Luxembourg, <sup>2</sup>Adolescent Health Centre, CHU de Liège, Belgium, <sup>3</sup>Department of Paediatric Endocrinology and Diabetology, Centre Hospitalier de Luxembourg, Luxembourg,<sup>4</sup>Clinical Infantile and Genetic Medicine, CHRU de Nancy - Hôpital d'Enfants, <sup>5</sup>Department of Diabetology, Metabolic Diseases and Nutrition, CHRU de Nancy - Hôpital Brabois Adultes, France.

**Background and aims:** It is a major challenge for adolescents with type 1 diabetes to manage their disease, due to physical changes and psychosocial factors that characterise this period of transition. Although parents play an important role in supporting their children, responsibility is shifting. This may enhance conflicts between parents and adolescents, creating an important barrier to efficient metabolic control as well as to quality of life. Physicians and nurses represent another party supporting and influencing the youth's self-management. This study aims at comparing the perception of these different parties of several aspects of diabetes management and at identifying the influence of the convergence or divergence of these opinions on metabolic outcomes and the youth's well-being.

**Materials and methods:** Adolescents between 13 and 17 years visiting the outpatient clinic in 3 regions, as well as their parent(s), paediatric diabetologist and diabetes nurse filled out questionnaires containing questions on the adolescent's metabolic targets, treatment, well-being, quality of life, self-management and perception of self-management. Clinical data concerning blood glucose measurements, insulin regimen, episodes of severe hypoglycaemia and diabetic ketoacidosis and Hb1Ac level were collected via a Clinical Record Form. Answers of the 4 parties were compared to see whether convergent answers are related to metabolic control, well-being and quality of life. The study was approved by the three IRB's and Informed consent was obtained from all participants.

**Results:** The sum of distances between answers of the 4 parties on HbA1c targets and on well-being was correlated to HbA1c outcomes ( $R = 0.448$ ,  $p < 0.001$ ;  $R = 0.232$ ,  $p = 0.036$ ). The sum of distances between opinions on HbA1c aims, on hyperglycaemia management and on fear from hypoglycaemia were inversely correlated to the youth's self-management score ( $R = -0.378$ ,  $p < 0.001$ ;  $R = -0.349$ ;  $p = 0.001$ ;  $R = -0.295$ ,  $p = 0.003$ ).

**Conclusion:** These results confirm the importance of harmony between the different protagonists of the youth's type 1 diabetes management. The themes that seem to be most important are Hb1Ac targets, perception of the adolescent's well-being and perceptions of hyper- and hypoglycaemia management. Communication between protagonists proves to be extremely important in adolescent diabetes management, since the difficulty of this management may be related to the level of harmony between adolescents, parents and healthcare teams. These findings are an important element to be taken into account in the conception of patient education programmes.

## 1044

**The impact of glycaemic variability on quality of life in adults with type 1 diabetes**M. Reddy<sup>1</sup>, R. Agha-Jaffar<sup>1</sup>, P. Herrero<sup>2</sup>, P. Georgiou<sup>2</sup>, M. El-Sharkawy<sup>2</sup>, P. Pesl<sup>2</sup>, N. Jugnee<sup>1</sup>, H. Thomson<sup>1</sup>, C. Toumazou<sup>2</sup>, D. Johnston<sup>1</sup>, N. Oliver<sup>1</sup>;<sup>1</sup>Division of Diabetes, Endocrinology and Metabolism,<sup>2</sup>Centre for Bio-Inspired Technology, Institute of Biomedical Engineering, Imperial College London, UK.

**Background and aims:** We aimed to assess whether glycaemic variability (GV) has an impact on quality of life (QOL) in adults with established type 1 diabetes mellitus (T1DM) on either multiple daily injections (MDI) of insulin or continuous subcutaneous insulin infusion (CSII). There is evidence suggesting that GV reduces QOL in people with type 2 diabetes mellitus (T2DM), but this has not been fully explored in T1DM.

**Materials and methods:** Subjects wore a retrospective continuous glucose monitor (CGM) for 5-6 days and completed the diabetes quality of life questionnaire (DQOL). GV measures (SD, CONGA, LI, JINDEX, LBG, HBGI, GRADE, MODD, MAGE, ADRR, MVALUE, MAG) were calculated using the EasyGV version 9.0 software. A linear regression analysis was then per-

formed to assess whether there was a correlation between GV and measures of QOL.

**Results:** 57 adult subjects with T1DM (51% male, 65% on CSII, 35% on MDI, mean (SD) age 41 (13) years, duration of diabetes 21 (12) years, HbA1c 7.9 (1.1) %, body mass index 25.2 (4.0) kg/m<sup>2</sup>,) were included in the analysis. No significant associations between GV measures and DQOL scores (Table 1) were demonstrated. The GV was significantly higher for those subjects on MDI compared to the CSII group ( $p$ -value  $< 0.05$  for all GV measures), but no significant difference in QOL between the two treatment modality groups was observed.

**Conclusion:** Treatment with CSII is associated with lower GV compared to MDI. Interestingly, the outcomes from our study suggest that increased glycaemic variability does not impact overall quality of life in adults with T1DM, irrespective of whether they are on MDI or CSII.

| GV measures | DQOL Total score All subjects (n=57) |         | DQOL Total score MDI subjects (n=20) |         | DQOL Total score CSII subjects (n=37) |         |

**The relationship between negative emotions and quality of life in high risk patients with type 2 diabetes in Hong Kong**Y. Junmei<sup>1</sup>, R. Yeung<sup>1,2</sup>, A. Luk<sup>1,3</sup>, R. Wong<sup>3</sup>, A. Kong<sup>1,3</sup>, R. Ozaki<sup>1,3</sup>, R.C.W. Ma<sup>1,3</sup>, W. So<sup>1,3</sup>, J.C.N. Chan<sup>1,2</sup>;<sup>1</sup>Department of Medicine and Therapeutics, Chinese University of Hong Kong, <sup>2</sup>Asia Diabetes Foundation, Prince of Wales Hospital,<sup>3</sup>Diabetes and Endocrine Centre, Prince of Wales Hospital, Hong Kong.

**Background and aims:** To measure the rate of negative emotions among Chinese type 2 diabetic patients with high cardio-metabolic risk, and the relationship between negative emotions and quality of life in Chinese patients with type 2 diabetes in Hong Kong.

**Materials and methods:** A consecutive cohort of patients with type 2 diabetes, aged 18-75 years, referred to our hospital for comprehensive diabetes complication screening with high cardio-metabolic risk from 4 March to 30 December 2013 were recruited. High cardio-metabolic risk was defined as poor glycaemic control (HbA1c  $\geq 8\%$ ), obesity (body mass index [BMI]  $\geq 27.5$  kg/m<sup>2</sup>), central obesity (waist circumference  $\geq 90$ cm in men or  $\geq 80$ cm in women), and/or chronic kidney disease (GFR  $< 60$ ml/min/1.73m<sup>2</sup>). Clinical characteristics, self-care behaviors, and psychological measures were documented. Specifically, three types of negative emotions (depression, anxiety, and stress) were measured by the 21-item Depression, Anxiety, and Stress Scale (DASS-21). Quality of life was assessed by the 5-item Euroqol for health related quality of life (EQ-5D) and the Brief version of World Health Organization Quality Of Life (WHOQOL-BREF).

**Results:** Among 370 eligible patients, 303(82%) completed the assessments and 10 patients were excluded because they failed to complete  $> 20\%$  of the

WHOQOL-BREF. Among the remaining 293 patients (age [mean±SD]: 59.1±9.6 years, 52.2% male), 67% of patients had at least one negative emotion, and 22% had significant levels of all three negative emotions. 50% of patients had moderate/ severe depressive symptoms, 43% had moderate/severe anxiety symptoms, and 22% had moderate/severe levels of stress. Compared with patients with no/mild depression, patients who had moderate/ severe depression were younger (57.7±9.4 vs 60.3±9.7 years,  $p=0.024$ ), had shorter diabetes duration (10.8±7.6 vs 12.8±8.2 years,  $p=0.030$ ), used less insulin (38.8% vs 50.3,  $p=0.049$ ) and exercised less frequently (43.3% vs 56%,  $p=0.030$ ). They also had worse health related quality of life (EQ-5D: median[IQR] 0.85[0.75,1] vs 1[0.8,1],  $p=0.004$ ), worse quality of life in all 4 domains of the WHOQOL-BREF: physical health (13.0±2.2 vs 15.3±2.1,  $p<0.001$ ), psychological health (12.7±2.5 vs 14.6±2.5,  $p<0.001$ ), social relationships (13.2±2.7 vs 14.7±2.5,  $p<0.001$ ), and environment (12.9±2.8 vs 14.2±2.5,  $p<0.001$ ). Similar results were found after stratifying patients by having anxiety or stress.

**Conclusion:** Patients with high cardio-metabolic risk were more likely to have significant levels of depressive and anxiety symptoms, and associated with worse health and non-health related quality of life.

## 1046

### Evaluation of cognitive functions and daily living activities of elderly diabetic patients under intensive insulin therapy

Ü. Karabulut<sup>1</sup>, O. Basat<sup>1</sup>, S. Uçak<sup>2</sup>;

<sup>1</sup>Sisli Etfal Training and Research Hospital, Department of Family Medicine,

<sup>2</sup>Umraniyeli Training and Research Hospital, Department of Internal Medicine, Istanbul, Turkey.

**Background and aims:** Elderly population is a sensitive group. Insulin therapy needs strict compliance because of severe complications due to treatment. Cognitive functions and functionality may have an effect on the outcomes in this group. Our aim was to evaluate the cognitive functions and daily living activities of elderly diabetic patients who are under the basal-bolus intensive insulin therapy regimen. Our aim was to evaluate the cognitive functions and daily living activities of elderly diabetic patients who are under the basal-bolus intensive insulin therapy regimen.

**Materials and methods:** Our single centre, cross sectional study included 108 patients admitted to our Family Medicine outpatient clinic between February–June 2013, who are over 65 years of age and under intensive insulin therapy. Patients with established cognitive disorders, severe micro and macrovascular complications associated with diabetes mellitus were excluded from the study. Turkish validated versions of Mini Mental State Examination (MMSE) for cognitive functions, activities of daily living (ADL) and instrumental activities of daily living (IADL) scales were used to evaluate cognitive functions and daily living activities. MMSE score of  $\leq 22$  was considered as impaired cognitive functions. IADL scores vary between 0 and 17, higher score means patients are less dependent on somebody. ADL scores vary between 0–27, higher score means patients are more dependent on somebody. Fasting glucose and HbA1c levels were measured and history of mild and severe hypoglycemia were recorded. For group comparisons chi square and Student's T-tests were performed,  $p<0.05$  was regarded as statistically significant.

**Results:** MMSE revealed 24 patients (22.2%) with impairment of cognitive functions. Fasting plasma glucose levels were 184.96±76.92 and main HbA1c levels were 9.06±2.02% in patients with impaired cognitive functions and fasting plasma glucose levels were 177.98±58.0 and main HbA1c levels were 8.64±1.33% in patients with normal cognitive functions ( $p>0.05$ ). Number of severe hypoglycemic episodes was significantly higher in patients with impaired cognitive functions. 26.9% of patients with impaired cognitive functions reported at least one episode of severe hypoglycemia in the last 3 months whereas only 6.1% of patients with normal cognitive functions reported severe hypoglycemia. IADL and ADL scores of patients with impaired cognitive functions and normal cognitive functions were statistically significant. (IADL scores 11.04±4.89 vs 15.30±2.53 and ADL scores 8.96±3.26 vs 2.85±0.8,  $p: 0.000$ ). Impaired cognitive functions were in relation with more hypoglycemic episodes and lower functionality.

**Conclusion:** Due to complexity of intensive insulin therapy regimen, cognitive functions and functionality of elderly diabetics should be carefully examined before deciding on intensive insulin therapy. In addition to that elderly diabetics under intensive insulin therapy should be evaluated closely by the physician.

## 1047

### Stress: an important comorbidity of the metabolic syndrome

M.M. Singh<sup>1</sup>, K. Usman<sup>1</sup>, A.K. Vaish<sup>1</sup>, A. Nischal<sup>2</sup>, W. Ali<sup>3</sup>;

<sup>1</sup>Internal Medicine, King George's Medical University,

<sup>2</sup>Psychiatry, King George's Medical University,

<sup>3</sup>Pathology, King George's Medical University, Lucknow, India.

**Background and aims:** It has become increasingly evident that psychological status affects all medical conditions, hence researchers have focused on these psychological status' roles especially on non communicable disease with almost unknown origin. The relationship of psychological distress with chronic metabolic disease such as diabetes mellitus, insulin resistance and dyslipidemia has been established. There are some evidences that have shown relations of lower physical well being and social function as indicators of Quality of life to Metabolic Syndrome. With this background, the present study was undertaken to investigate association of depression, anxiety, psychological distress and quality of life with metabolic syndrome in a sample of Indian population as a population with high prevalence of Metabolic Syndrome. Present study was undertaken with the aims of assessing levels of stress (Anxiety / Depressive symptoms) and Quality of Life in patients of Metabolic Syndrome and comparing it with healthy controls.

**Materials and methods:** A hospital based cross sectional case-control study was conducted in 200 patients attending medicine clinics and wards. They were analyzed separately as cases and controls based on the International Diabetes Federation Criteria for Metabolic Syndrome. Subjects who were a known case of any Psychiatric illness, having history of any major Psycho-social stressor in the past three months, suffering from any major medical or surgical illness or those patients who were on medications affecting emotion and mood were excluded from the study. Levels of stress were assessed using: General Health Questionnaire - 12 items, Hospital Anxiety and Depression Scale, Hamilton Rating Scale for Depression and Hamilton Rating Scale for Anxiety. Quality of life was assessed using World Health Organization Quality of life - BREF Version. Levels of stress and Quality of life in cases were subsequently compared with age, sex and social status matched healthy controls.

**Results:** A significant proportion of cases of metabolic syndrome reported psychological distress as evaluated by General Health Questionnaire. A significant proportion of cases of metabolic syndrome suffer from anxiety and depressive disorder as evaluated by Hospital Anxiety Depression Scale. Severity of anxiety as evaluated by Hamilton Anxiety Rating Scale is not associated with metabolic syndrome. Severity of depression as evaluated by Hamilton Depression Rating Scale is associated with metabolic syndrome. Cases of metabolic syndrome reported lower Quality of life scores thereby signifying poor quality of life in all the four domains as compared to controls, viz., Domain 1 (Physical health), Domain 2 (Psychological), Domain 3 (Social relationships) and Domain 4 (Environment) but the difference was statistically insignificant for the Domain 1.

**Conclusion:** This study proves the higher prevalence of depression as compared to anxiety and impaired quality of life in cases of metabolic syndrome. Although it suggest that psychological stress may have a causal role in etiology of metabolic syndrome yet there is a hen and egg dilemma that which comes first psychological stress or metabolic syndrome pointing out need for further studies to examine the effect of stress reduction techniques in reducing insulin resistance and improving the metabolic syndrome as a whole.

## 1048

### Diabetes and work: a national register based cohort study on the potential influence of socioeconomic group, age, gender and ethnicity

K. Poulsen, B. Cleal, I. Willaing;

Steno Center for Health Promotion, Steno Diabetes Center, Gentofte, Denmark.

**Background and aims:** In countries with ageing populations it is anticipated that people will have to remain active in the labour market for longer and thus retire later in life. It is important, therefore, to address potential problems that might accrue from this significant social change. A number of studies have previously shown the impact of diabetes mellitus on, sickness absence, presenteeism and disability retirement among the workforce, yet the extent to which diabetes mellitus impacts on the working age population and the nature of its distribution within this group has not been comprehensively delineated. The aim of this study was to examine the impact and demographic distribution of incident diabetes mellitus on the working age population.

**Materials and methods:** The Danish National Diabetes Register was linked with socioeconomic and population registers covering the entire population. Twelve year diabetes incidence was analysed using multivariate Cox regression for 2,161,700 people aged 30-59 years at baseline.

**Results:** 93.2 % were of Danish origin, 3.6 % of non-Danish Western origin and 3.3 % of Non-western origin. 12 year incidence of diabetes was, respectively, 5.8%, 7.9 % and 11.4 %. Occupational activity was stratified by five main socioeconomic categories which are derived from the International Standard for the Classification of Occupations: professionals, managers, technicians, workers skilled at basic level and unskilled workers. Professionals were used as reference. The results of the survival analysis are shown in the table with 99 % confidence intervals.

**Conclusion:** Diabetes incidence increases with age, male gender, occupations with low socioeconomic status and among people of Non-western origin. The results indicate that undifferentiated upward adjustment of the retirement age has the potential to cause a marked increase in employees with diabetes, especially among already vulnerable groups. The social and economic implications are unknown and need to be subject of future research.

Hazard Ratios of 12 year diabetes incidence related to gender, age, socio-occupational group and country of origin among the total Danish population aged 30-59 year in 1999 (N=2,161,700)

|   | N         | Diabetes (%)   | RR   | 99% CI        |
|---|-----------|----------------|------|---------------|
| Female                                  | 1,082,883 | 56,483 (5.22)  | 1.00 | -             |

| Non-western origin                      | 79,064    | 7,945 (11.34)  | 2.15 | (2.08 - 2.21) |

## 1049

### Relative rates of disability retirement among employees in Denmark with and without diabetes: a prospective analysis with 10 year follow-up

B. Cleal<sup>1</sup>, K. Poulsen<sup>1</sup>, H. Hannerz<sup>2</sup>, L. Andersen<sup>2</sup>;

<sup>1</sup>Steno Health Promotion Center, Steno Diabetes Center, <sup>2</sup>National Research Center for the Working Environment, Copenhagen, Denmark.

**Background and aims:** Work and the workplace have been allocated a pivotal role in the future of health promotion, with economic and social stability predicated, in many accounts, on the assumption that more people will be fit, able and willing to work for longer. In this light, it is important to determine what socio-demographic trends might challenge this vision of future prosperity. Our ambition in this study was to estimate the proportion of disability retirements, among employees with diabetes, which could be attributed to socioeconomic status. This perspective was considered important since both incident diabetes and work-disability are marked by a social gradient. Obtaining more detailed and nuanced information on the relationship between diabetes and disability retirement is, therefore, undertaken in order to inform efforts to reduce disability retirement among people with diabetes.

**Materials and methods:** Using four national population registries, including the Danish National Diabetes Registry, we identified all employees in Denmark aged 20-59 years old at baseline (January 2001). These individuals were stratified according to their presence/absence in the diabetes registry and their socioeconomic status, and subsequently followed in our national registries until 31 December 2010.

**Results:** 29,210 people with diabetes and 1,950,962 people without diabetes were included in the analysis. The follow-up yielded 3,163 cases of disability retirement among people with diabetes and 64,262 cases among people without diabetes. With Professionals without diabetes as reference, the results indicate heightened levels of risk according to both presence of diabetes and socioeconomic status. The compound risk of being a person with diabetes and working in an occupation identified as having low socioeconomic status is clearly revealed in the 11.62 rate ratio for people with diabetes in elementary occupations.

**Conclusion:** The results show liability for early retirement among people with diabetes is especially acute for employees in lower socio-economic groups. The relative risks revealed in our study are especially concerning for the fact that there is evidence to suggest levels of social inequality in prevalent T2DM are on the increase. If current trends continue, therefore, there will, both proportionally and numerically, be more individuals with diabetes with

a relatively high risk of disability retirement. Targeting primary, secondary and tertiary prevention to the groups that need it most thus seems an essential strategy in attempts to prolong the working lives of individuals.

| Socioeconomic Status  | Diabetes | N         | Cases  | RR    | 95% CI          |
|---|----------|-----------|--------|-------|-----------------|
| Legislators, senior officials and managers                  | No       | 65,823    | 926    | 0.92  | (0.86 - 0.99)   |
|   | Yes      | 1,032     | 67     | 3.19  | (2.49 - 4.10)   |
| Professionals   | No       | 286,401   | 4,724  | 1.00  | -               |
|   | Yes      | 3,630     | 228    | 3.52  | (3.08 - 4.02)   |
| Technicians and associate professionals                     | No       | 377,340   | 8,486  | 1.43  | (1.38 - 1.48)   |
|   | Yes      | 5,206     | 382    | 4.18  | (3.77 - 4.64)   |
| Workers in occupations that require skills at a basic level | No       | 1,005,542 | 36,040 | 2.69  | (2.61 - 2.78)   |
|   | Yes      | 14,632    | 1,653  | 7.02  | (6.63 - 7.42)   |
| Workers in elementary occupations                           | No       | 225,856   | 14,086 | 4.58  | (4.43 - 4.73)   |
|   | Yes      | 4,710     | 838    | 11.62 | (10.89 - 12.51) |

Rate ratios (RR) with 95 % confidence interval (CI) for disability retirement in Denmark 2001 - 2010 among employees with and without diabetes at baseline.

#### Early evaluation of the ANAIS (Alimentación Normal Con Ajuste De Insulina) programme, a Spanish version of DAFNE

R. Sánchez Hernández<sup>1,2</sup>, Y. López Plasencia<sup>1,2</sup>, D. Alvarado Martel<sup>1,2</sup>, J. Rodríguez Cordero<sup>1</sup>, A. Jiménez Ortega<sup>1</sup>, A. Carrillo Domínguez<sup>1</sup>, F. Nóvoa Mogollón<sup>1,2</sup>, A. Wägner<sup>1,2</sup>;

<sup>1</sup>Endocrinology and Nutrition, Hospital Insular de Gran Canaria,

<sup>2</sup>Instituto Universitario de Investigaciones Biomédicas y Sanitarias, Universidad de Las Palmas de Gran Canaria, Spain.

**Background and aims:** The DAFNE (Dose adjustment for normal eating) programme promotes a flexible diet and has led to a reduction in clinical admissions and improved quality of life (QoL) in type 1 diabetes (T1D). ANAIS is a translation and adaptation of DAFNE to Spanish cultural and dietary patterns. Our aim was to evaluate the programme, using both clinical and patient-centred variables.

**Materials and methods:** This randomized, controlled, parallel group trial included patients with >2 years of T1D, age >18 years and HbA1c 7–12%. Participants were randomized (2:1 ratio) to participate immediately in a 5-day outpatient course (immediate ANAIS) or to do so after one year (delayed ANAIS). The primary endpoint was glycaemic control (HbA1c), measured 3, 6 and 12 months after the programme. We also evaluated the number of hypoglycemic episodes, weight, insulin dose, diabetes-related QoL (EsDQOL), treatment satisfaction (DTSQ), fear of hypoglycemia (MH-15), anxiety (STAI), depression (BDI), diet flexibility (open question) and achievement of self-defined goals (scale from -2 (much less than expected) to +2 (much more than expected)). Comparisons were made (Student's t, Wilcoxon's test and chi-square).

**Results:** So far, 80 patients (48 immediate ANAIS) have been included, 45% men, aged 34.6 (SD 11.35) years, diabetes duration 12.5 [range 3–47] years, with a BMI: 24.9 (3.9) kg/m<sup>2</sup> and a daily insulin dose of 0.75 (0.24) UI/Kg. In the intervention group, there was a 0.2–0.3% non-significant reduction in HbA1c at 3, 6 and 12, less hypoglycaemia at 6 months (2 [0–16] vs 1 [0–8]/week, p=0.045), and a trend towards a reduction in long acting insulin dose at 12 months (31.08 UI (12.5) vs 28.92 UI (12.6), p=0.08). No changes in weight were seen. Quality of life improved at 3 (96.7+/-19.9 vs 82.4+/-22.4 points, p<0.0005), 6 (87.1+/-22.7; p<0.0005) and 12 months (87.1+/-19.2; p=0.002). Treatment satisfaction increased at 3 (25.9+/-5.7 vs 28.2 (3.2) points, p=0.019), 6 (30.8 (4.6), p<0.0005) and 12 months 30.4 (7.7) p=0.024). Reduction in the fear of hypoglycaemia at 3 months (27.8 (9.3) vs 24.7 (8.5) p=0.045). Reduction in anxiety-trait at 1 year. No changes in depression. On average, the patients achieved their primary goal somewhat more than expected (1 point [(-1)+2]). Before ANAIS, 25.5% considered their diet to be restricted. At 3 months, no patient had that opinion. In the control group, there were no significant changes in HbA1c or hypoglycaemia, but a weight increase was observed (baseline BMI: 24.85 kg/m<sup>2</sup> (4.57), 25.27 (4.69) at 3 and 25.07 (4.05) at 6 months, p<0.005) and total insulin dose increased at 12 months (0.80 UI/kg (0.27) vs 0.87 (0.3), p=0.039). QoL and fear for hypoglycaemia improved, but there was no change in treatment satisfaction or depression. Initially 38.7% considered their diet to be restricted and at 6 months, 31.3% still thought so.

**Conclusion:** So far, after the inclusion of a half of the patients, ANAIS has led to positive results in hypoglycemic events, weight and insulin dose, as well as in several measures of patient satisfaction, anxiety and depression and self-defined goal achievement.

#### A new metric for objective evaluation of daily glucose profiles to obtain personalised recommendations for an individually sufficient diabetes care

E. Salzsieder<sup>1</sup>, P. Heinke<sup>1</sup>, L. Vogt<sup>2</sup>, P. Augstein<sup>1</sup>;

<sup>1</sup>Institute of Diabetes, Karlsburg,

<sup>2</sup>Diabetes Service Center Karlsburg, Germany.

**Background and aims:** Structured glucose monitoring (CGM or SMBG) is an indispensable precondition for sufficient diabetes care and management. However, an objective and practicable tool for objective evaluation of measured glucose profiles to draw helpful, therapeutically relevant conclusions

from the measured glucose profiles is missing. It was the aim of our study to develop and to verify an objective evaluation tool for measured glucose profiles that might be able to bridge this existing gap in diabetes care and management.

**Materials and methods:** 1495 registered glucose profiles provided the database for this study. First, a factor analysis was performed to identify factors with major impact on the measured profiles. For each factor one parameter was selected and used for the development of a metric which can be used for automated, i.e. objective evaluation of the measured glucose profiles on the one hand and which provides recommendations for an improved diabetes management on the other.

**Results:** This study resulted in a Q-Score, which can be used for objective evaluation of glucose profiles, for automated identifying of potentials of improvement, and for providing recommendations for applying these potentials in practical diabetes care by predicting the expected outcome. To verify the Q-Score two diabetes specialists (DS) diagnosed independently 729 glucose profiles. The results were analysed for the inter-individual variation. There was a high correlation between the Q-Score and the results of both DS. The Q-Score was then tested for categorisation of glucose profiles. 729 profiles were categorised by one DS in very good, good, satisfactory, borderline, and not satisfactory and compared with the result obtained from the evaluation by applying the Q-Score. The Q-Score was significantly correlated with the results obtained from the evaluation of the DS.

**Conclusion:** The Q-Score combines all essential quality parameters to describe glucose profiles in only one parameter. The Q-Score is independent of subjective opinions and can be used therefore for automated evaluation of glucose profiles and to draw conclusions to generate patient related helpful recommendations for improving personalized diabetes care and management. The Q-Score has the high potential to become a practical tool in diabetes diagnosis and therapy.

### 1052

#### An innovative use of the ambulatory glucose profile to reveal the glycaemic effect of food

L.K. Lyons, K.D. Kulkarni;

Scientific Affairs, Abbott Diabetes Care, Alameda, USA.

**Background and aims:** The Ambulatory Glucose Profile (AGP) has been proposed as a standard reporting system for continuous glucose monitoring (CGM). The AGP reveals the progression from pre- to post-prandial periods, which may aid in refining nutrition & insulin therapy. Our aim was to explore the use of AGP to determine pre- and post-prandial identifiers and corresponding interventions.

**Materials and methods:** AGP reports were evaluated from an intervention group of 53 subjects in a prospective, 9-site, 100-day study in the UK. Subjects were 18–82 years old, with type 1 or 2 diabetes, had HbA1c of 7.5–12.0%, and were managed by multiple daily injections of insulin. CGM (alarms turned off) was used by the intervention group. AGP reports similar to Figure 1 were evaluated using >14 days of CGM data.

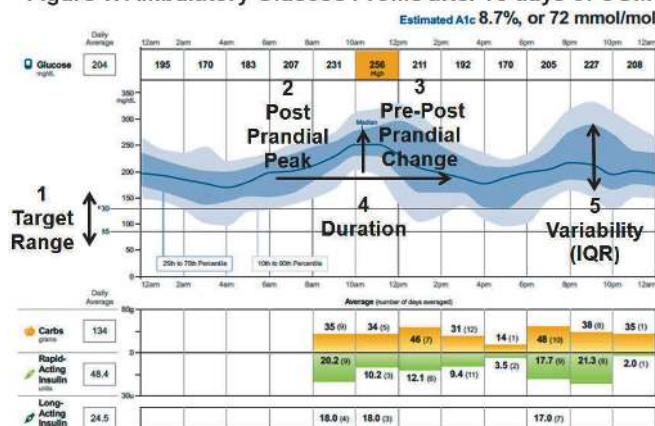

**Results:** Five key metrics were identified to aid in prandial assessment and decision making (Figure 1). 1) Target Range identifies whether the pre-prandial and post-prandial median glucose levels are within target. If pre-prandial glucose is outside of target, consider assessing basal insulin and pre-prandial events or snacks; whereas, if the post-prandial glucose is outside target, consider assessing carbohydrate (carb) portions, insulin to carb ratio, and insulin timing. 2) Post-Prandial Peak is the highest point on the median curve typically occurring 1–3 hours after the start of the meal. Peak times may differ depending on meal composition. Peak time can aid in planning the timing of prandial insulin. Ideally the insulin action peak should match the post-prandial peak. 3) Prandial Glucose Change (pre-prandial - peak = change), reflects the balance of prandial insulin dose and carb. For excessive change, carbs may need to be decreased or the prandial insulin increased. 4) Duration of the Post-Prandial Curve is the amount of time after a meal to reach pre-prandial glucose levels. Longer durations can indicate high fat or high protein meals, gastroparesis, or inadequate prandial insulin coverage. The amount and timing of prandial insulin can be adjusted to lessen the duration of post-prandial rise. If post-prandial glucose does not return to baseline within the typical 3–5 hours and the next pre-prandial glucose starts at a higher level, an adjustment of basal and bolus insulin doses may be required. 5) Mealtime Glucose Variability is represented as the difference between the 25th–75th percentile curves or the interquartile range (IQR) after a meal. If carb type or amount varies on different days, the AGP may show greater variability or a wider IQR. Because AGP combines glucose profiles from multiple days,

evaluate the sources of variability such as food-insulin balance and the timing of meals across days. Decreasing variability or IQR may reduce the risk of hypo or hyperglycemia.

**Conclusion:** Analysis of AGP prandial periods can reveal the glycemic effect of food and insulin. AGPs can refine nutrition and insulin therapy relative to type and amount of carb, amount of dietary fat and protein, timing and amount of prandial insulin, and meal times.

### Perioperative diabetes regulation and Protocol Compliance: the PC study

J. Hermanides<sup>1</sup>, J.A.W. Polderman<sup>1</sup>, F.A. de Groot<sup>1</sup>, F. Holleman<sup>2</sup>, B. Preckel<sup>1</sup>;

<sup>1</sup>Anesthesiology,

<sup>2</sup>Internal Medicine, Academic Medical Centre, Amsterdam, Netherlands.

**Background and aims:** Peri-operative diabetes regulation differs between hospitals. Compliance with regard to peri-operative glucose regulation protocols is notoriously low and evidence with regard to efficacy is lacking. There are, however, convincing studies demonstrating that improving post-operative diabetes control decreases complications. We therefore investigated whether implementing a modified and stricter peri-operative diabetes protocol improved compliance and peri-operative glucose regulation.

**Materials and methods:** We performed a prospective observational cohort study from March 2013 through July 2013, comparing compliance and glucose regulation following protocol A (conventional protocol) with protocol B (strict protocol). Protocol A prescribed a Glucose-Insulin-Potassium infusion, with 8 IU of insulin. Protocol B prescribed a Glucose-Insulin infusion, with 1/8 IU of the normal daily insulin dose. A pre-defined treatment algorithm to treat hyperglycaemia, glucose > 10 mmol/l, was added. In May 2013, we switched from protocol A to protocol B. Analyses were performed with the Mann Whitney U test and multivariate regression analyses.

**Results:** In total, 192 patients were included in protocol A and 183 in protocol B, mean age was 64 years and 54% was female, 10,4% of patients (n=20) had diabetes type 1, 86,5% (n=166) type 2, 3,1% (n=6) other. There were no differences between the patient characteristics in protocol A and B. The median compliance (IQR) was 67% (57-83) for Protocol A and 71% (57-83) for Protocol B,  $p=0.04$ . Differences between peri-operative glucose values are shown in graph 1. Adjusted for age, gender, ASA status, DM type, emergency procedures, fasting glucose and compliance, protocol B (red line) improved the proportion of patients that reached the target of < 10 mmol/l (OR 0.36, 95% CI 0.19-0.70,  $p < 0.01$ ) before discharge to the ward.

**Conclusion:** Implementing a stricter peri-operative diabetes protocol only slightly improved compliance, but significantly and relevantly improved post-operative glucose control before discharge from the recovery.

## 1054

### The burden of “serial non-adherence” in type 2 diabetic patients

C. Frois<sup>1</sup>, K. Dea<sup>1</sup>, D. Ling<sup>1</sup>, J. Dunn<sup>2</sup>, M. Baron<sup>3</sup>;

<sup>1</sup>Analysis Group, Inc., Boston, <sup>2</sup>VRx Pharmacy Services, Salt Lake City,

<sup>3</sup>Intarcia Therapeutics, Inc., Boston, USA.

**Background and aims:** Although medication adherence is recognized as a key concern for the treatment of Type 2 diabetes patients, there has been limited assessment of the scope of “serial non-adherence,” i.e. non-adherence to current diabetes regimen following non-adherence to prior therapies (diabetes or non-diabetes related), its predictability, and impact on patient/healthcare burden. The aim of this research was to characterize the healthcare burden associated with non-adherence with second-line anti-diabetic medication and to identify its key predictors, including the role of serial non-adherence.

**Materials and methods:** A retrospective cohort study was conducted using the Truven Health MarketScan® US Commercial health insurance database for the period 2008-2012. Patients were identified as first-line metformin users by requiring no prior anti-diabetic drug history going back at least 12-months before the date of the first metformin prescription. Patients in this group who subsequently initiated second-line (post-metformin) therapy were identified and selected for study. Diabetic regimen adherence was measured using the proportion of days covered (PDC), calculated as the total number of non-overlapping days of supply of any antidiabetic medication one year following the initiation of second-line therapy divided by 365 days. Adherence for selected non-diabetic medications, including lipid-lowering drugs and anti-hypertensives, was measured in a similar way during the baseline period. Non-adherence was defined as PDC<80%. Logistic regression models were constructed to identify predictors of adherence to second-line anti-diabetic therapy.

**Results:** Among the 46,789 patients who initiated second-line anti-diabetic therapy with at least 12 months of follow-up, 58% were non-adherent to anti-diabetic therapy during the first year after initiating second-line therapy. Among these patients, non-adherence to first-line metformin was very common (80% of patients) as was non-adherence to earlier non-diabetic medication (53% of those with non-diabetic prescriptions), with serial non-adherence accounting for over a quarter of overall non-adherence. Regression analysis showed that serial non-adherence was associated with a 4.67 times greater risk of non-adherence to second-line therapy ( $p < 0.0001$ ). Non-adherent patients were significantly (20% and 53%) more likely than adherent patients to experience any and severe hypoglycemia events, respectively ( $p < 0.001$  for both). After accounting for other confounding factors, non-adherent patients had average annual medical costs \$2,432 higher than adherent patients, which included \$1,678 higher annual inpatient costs during the first year following initiation of second-line therapy ( $p < 0.0001$  for both).

**Conclusion:** This study showed that more than half (58%) of patients initiating second-line anti-diabetic therapy are not adherent to therapy, with serial non-adherence (i.e., non-adherence to earlier diabetic and non-diabetic therapy) associated with much greater risk of non-adherence (OR=4.67). Second-line non-adherence is associated with higher risk of hypoglycemia and with higher healthcare costs. Since prior non-adherence is observable and appears highly predictive of later non-adherence, intervention strategies that target serial non-adherence may be particularly effective in improving the care of these diabetes patients.

## 1055

### Do type 2 diabetes patients achieve therapeutic goals with medication adherence?

A.B. Garcia, E. Lopez Gonzalez, S. Milrad, A. Luongo, S. Houssay, M.L. Ruiz, FRADYC II Group; Hypertension Committee, Argentinean Diabetes Society, Buenos Aires, Argentina.

**Background and aims:** In developed countries, adherence to drug treatment in chronic diseases hovers around 50 %. Improving adherence is key to effectively address the treatment of people with diabetes. Objectives: To determine the percentage of medication adherence and its relationship to the achievement of A1c, blood pressure and lipids goals in people with T2DM. To assess which factors are associated with lower medication adherence.

**Materials and methods:** A study was conducted in 31 medical centers specialized in diabetes in Argentina (12/ 2010- 05/2011), with a clinical and laboratory evaluation. The Morisky-Green test was used to assess adherence and WHO -5 for well-being and depression. Were taken as therapeutic targets A1c < 7 % , blood pressure < 140/90 mmHg and LDLcholesterol < 100mg/dl. (ADA ). Statistics : Chi2, multiple logistic regression.

**Results:** 1,491 people were included; mean age 64.1 ± 11.3 years, duration of DM2 : 9.8 ± 7.8 years, 46.7 % female, BMI 31.4 ± 6. kg/m<sup>2</sup> and A1C 7.2% ± 1.4. The mean WHO -5 test was 63.4 ± 22.1% with 39.2 % having values suggestive of depression. Adherence criteria was observed in 55% of the People. Factors that correlated with lower adherence to drug treatment by multiple logistic regression were: age under 65 years ( OR: 1.36 , CI 1.08 to 1.72, p < 0.009 ), symptoms of depression WHO - 5 (OR : 1.59 , CI :1.01 -2, 59, p < 0.04 ), lower WHO -5 well-being (OR 1.02, CI :1.02 -1.04, p < 0.04 ), sedentary lifestyle (OR : 1.38 , CI 1.07 to 1.73, p < 0.01), fewer diabetologist visits in a year ( OR: 1.37, CI 1.07 to 1.72 , p < 0.01) and not having health insurance ( p < 0.008 ). In those who met adherence criteria 39.4% ( p < 0.001 ) achieved A1c < 7%, 69.4 % BP targets ( p < 0.048 ) and LDL- c 47.9 % ( p < 0.001 ); having 25.6% achieved the three goals, 39.8 % two and 9.52% none.

**Conclusion:** In this sample of individuals with type 2 diabetes we found the frequency of medication adherence being 55 % and that 25.6 % of them achieved the three standard goals significantly. Predictors of lower adherence were age, symptoms of depression, lower welfare, sedentary lifestyle, diabetologist number of visits / year and not having health insurance.

## 1056

### Regular exercise improves metabolic control and reduces chronic complications in patients with type 2 diabetes

J. Tang<sup>1</sup>, X. Li<sup>2</sup>, Y. Yang<sup>1</sup>, L. Yuan<sup>3</sup>, J. Han<sup>1</sup>, C. Ju<sup>1</sup>, L. Shen<sup>4</sup>, Q. Lou<sup>5</sup>, F. Zhao<sup>6</sup>, Z. Sun<sup>1</sup>, X. Guo<sup>4</sup>;

<sup>1</sup>Zhongda Hospital, Institute of Diabetes, Southeast University, Nanjing,

<sup>2</sup>Institute of Public Health, Southeast University, Nanjing,

<sup>3</sup>West China Hospital, Institute of Diabetes, Sichuan University, Chengdu,

<sup>4</sup>Peking University First Hospital, Institute of Diabetes, Peking University,

<sup>5</sup>Sir Run Run Shaw Hospital, Institute of Diabetes, Zhejiang,

<sup>6</sup>China-Japan Friendship Hospital, Institute of Diabetes, Beijing, China.

**Background and aims:** To investigate the current situation of exercise in patients with type 2 diabetes and the effect of different levels of exercise on metabolic control and chronic complications.

**Materials and methods:** A total of 5961 patients with type 2 diabetes from 50 centers in China were included in this nationwide, multicenter, cross-sectional survey. Patients were divided into three groups according their compliance to exercise: full, partial and poor compliance. Data were analyzed using analysis of variance and Chi-square methods.

**Results:** According to the questionnaire feedback, the patients (percentages) of full, partial and poor compliance groups were 2096(35.17%), 2398(40.23%) and 1466 (24.60%), respectively. There were significant differences in glucose and lipid level among three groups. Fasting blood glucose (7.70±2.83 vs 8.17±2.91 vs 8.55±3.47, P<0.05), 2h postprandial blood glucose (10.80±4.23 vs 11.71±4.38 vs 12.16±4.75, P<0.05), HbA1c (7.96±2.12 vs 8.31±2.23 vs 8.70±2.32, P<0.05 ), total cholesterol (4.75±1.33 vs 4.90±1.51 vs 4.82±1.36, P<0.05), triglycerides (1.90±1.60 vs 2.09±1.72 vs 2.25±2.00, P<0.05), body mass index (24.12±3.73 vs 24.61±4.04 vs 24.80±4.68, P<0.05), systolic blood pressure (129.26±16.32 vs 129.97±16.71 vs 131.86±17.80, P<0.05), diastolic blood pressure (78.03±9.89 vs 79.24±10.38 vs 79.83±10.81, P<0.05) of patients in the full compliance group were signifi-

cantly lower than those of partial and poor compliance group. The targeted rate of HbA1c (43.83% vs 27.98%,  $\chi^2=59.444$ , P<0.05) in the full compliance group was higher than the poor compliance group. The morbidity of diabetic peripheral vascular disease (12.51% vs 15.96%,  $\chi^2=8.580$ , P<0.05), diabetic nephropathy (12.56% vs 18.69%,  $\chi^2=25.547$ , P<0.05), diabetic peripheral neuropathy (24.50% vs 29.33%,  $\chi^2=10.715$ , P<0.05), diabetic retinopathy (28.84% vs 33.63%,  $\chi^2=9.629$ , P<0.05) and diabetic foot (4.11% vs 9.14%,  $\chi^2=47.724$ , P<0.05) of patients in the full compliance group were less than poor compliance group. For patients using insulin therapy, the incidence of hypoglycemia (45.25% vs 39.11%,  $\chi^2=9.549$ , P<0.05) in the full compliance group was higher than the poor compliance group.

**Conclusion:** Regular exercise can improve glycemic, lipids, blood pressure, weight control and reduce morbidity of diabetic complications of patients with type 2 diabetes.

### Pedometer-based walking intervention and resting blood pressure in type 2 diabetes: a meta-analysis of randomised controlled studies

X. Cai, S. Qiu, C. Ju, Z. Sun;

Department of Endocrinology, Zhongda Hospital, Institute of Diabetes, Medical School, Nanjing, China.

**Background and aims:** Pedometer-based walking intervention, which is associated with improved physical activity and reduced body weight, has become popular among patients with type 2 diabetes (T2D). However, its effectiveness in resting blood pressure (systolic and diastolic) control has been poorly recorded. The aim of this meta-analysis of randomized controlled trials (RCTs) was to evaluate the association of pedometer-based walking intervention with resting blood pressure in T2D patients.

**Materials and methods:** PubMed, Web of Science and the Cochrane Library were searched from January 1994 to December 2013, using the following key words: pedometer\*, accelerometer\*, step counter, blood pressure, diabetes. RCTs in the English language were eligible for inclusion if they had utilized an intervention (lasting at least 8 weeks) using pedometer as a motivational tool to increase walking or walking speed in T2D patients, with more than 5 participants and reported changes in resting blood pressure. The summary estimates were made by a random-effects model.

**Results:** Of the 179 articles retrieved, 10 RCTs were included. Pedometer-based walking intervention was associated with a decreased resting systolic blood pressure by -1.13 mmHg (10 RCTs, 1020 participants; 95% confidence interval (CI): -2.79 to 0.52 mmHg), and a decreased resting diastolic blood pressure by -1.49 mmHg (9 RCTs, 928 participants; 95% confidence interval (CI): -4.04 to 1.05 mmHg) in T2D patients. However, both results were not statistically significant (P = 0.18 and P = 0.25, respectively). Univariate meta-regression analyses showed that neither intervention duration nor diary use was associated with a significant changes in resting systolic blood pressure (P = 0.687 and P = 0.890, respectively) or diastolic blood pressure (P = 0.957 and P = 0.131, respectively). No significant publication bias was detected by Begg's test or Egger's test in meta-analysis of resting systolic blood pressure (P = 0.371 and P = 0.218, respectively), or diastolic blood pressure (P = 0.917 and P = 0.879, respectively).

**Conclusion:** Current evidence regarding the effects of pedometer-based walking intervention in decreasing resting blood pressure remains insufficient in T2D patients. More well designed RCTs with guidelines for reporting data and details about the anti-hypertensive drugs use are needed.

## PS 089 Met and unmet needs in diabetes care

**Does clinical inertia vary by personalised HbA<sub>1c</sub> goal? A study of predictors and prevalence of clinical inertia in a US managed care setting**  
J. Lin<sup>1</sup>, S. Zhou<sup>2</sup>, W. Wei<sup>3</sup>, C. Pan<sup>3</sup>, M. Lingohr-Smith<sup>1</sup>, P. Levin<sup>4</sup>,  
<sup>1</sup>Novosys Health, Flemington, <sup>2</sup>Sanofi US, Inc., Bridgewater, <sup>3</sup>Pro-Unlimited, Inc., Boca Raton, <sup>4</sup>Model Clinical Research, Baltimore, USA.

**Background and aims:** Clinical inertia (CI) in type 2 diabetes mellitus (T2DM) care is defined as a failure to intensify treatment in patients with inadequate glycaemic control. There is a gap in understanding patterns of CI, particularly when considering the recent move towards personalized glycaemic targets rather than the standardized HbA<sub>1c</sub> goal of < 7.0%. This study applied 3 different definitions of CI to a T2DM cohort from a large US managed care database to investigate the prevalence and predictors of CI. The 3 definitions of CI were based on different HbA<sub>1c</sub> goals: (1) HbA<sub>1c</sub> < 7.0%; (2) a modified target defined by Ismail-Beigi; and (3) Healthcare Effectiveness Data and Information Set (HEDIS) HbA<sub>1c</sub> targets.

**Materials and methods:** Eligible adult T2DM patients were identified from the Optum Impact National Managed Care Database™ (IHCIS) between January 1, 2008–December 31, 2012. The index date was defined as the date of the first above target HbA<sub>1c</sub> (the trigger HbA<sub>1c</sub>) during the study period. Patients were required to have continuous health plan coverage for 6 months prior to index (baseline period) and for 6 months after index (response period). CI was defined as patients not receiving treatment intensification, defined as adding another oral antidiabetes drug (OAD), or initiating insulin or a glucagon-like peptide-1 receptor agonist within the response period. Predictors of CI were identified from the baseline period and evaluated by multiple logistic regression.

**Results:** The prevalence of CI was the highest for Definition 1, although the differences between the definitions were not substantial; 72.8%, 70.4%, and 70.6% for Definitions 1, 2, and 3, respectively. Common predictors of CI included higher age, higher baseline OAD usage, and a more recent index year, indicating a higher risk of CI over time (Table). Patients at a lower risk of CI included those with certain comorbidities, increased baseline non-diabetes medication use, an endocrinologist visit, and a higher index HbA<sub>1c</sub> value. Differences between the predictors were also observed between the 3 definitions. Patients with baseline neuropathy, retinopathy, and a Charlson Comorbidity Index of 2-3 were less likely to experience CI according to Definition 1 only. Baseline myocardial infarction was identified as a predictor of CI for Definition 1 only.

**Conclusion:** These data suggest that the prevalence of CI in a US managed care setting was high and increased over the study period. The prevalence and predictors of CI were generally similar across all 3 study populations with different HbA<sub>1c</sub> targets; however, there were some significant differences, particularly in the comorbidity-related predictors identified for Definition 1. This study provides some insights into clinical patterns of CI that could aid targeting of relevant T2DM subpopulations for improvement.

| Predictors  | Definition 1                             | Definition 2                            | Definition 3                     |

**Table. Predictors of CI During the 6-Month Response Period Based on 3 Target HbA<sub>1c</sub> Definitions**  
All data are odds ratio (Wald 95% confidence limits). Odds ratio indicates risk of clinical inertia; a ratio > 1 suggests an increased risk whereas a ratio < 1 suggests these patients were less likely to experience clinical inertia. Healthcare plan type, region, additional comorbidities, co-medications, hypoglycaemia, and hospitalization data were also included in the analysis, but are not shown in the table. Patient cohorts were not mutually exclusive.  
\*p < 0.05; \*\*p < 0.01; and \*\*\*p < 0.001.

**Association of metabolic control and chronic complications with self-care behavior in Chinese type 2 diabetic patients: a nationwide, multi-centre, cross-sectional survey**

Y. Yang<sup>1</sup>, Z. Sun<sup>1</sup>, X. Guo<sup>2</sup>, L. Yuan<sup>3</sup>;

<sup>1</sup>Department of Endocrinology, Medical School, Zhongda Hospital, Institute of Diabetes, Southeast University, Nanjing, <sup>2</sup>Department of Endocrinology, Peking University First Hospital, Beijing, <sup>3</sup>Department of Endocrinology, Medical School, West China Hospital, Sichuan University, Chengdu, China.

**Background and aims:** The purpose of this survey was to study the association of metabolic control and complications, with attitudes towards diabetes and self-care behavior in type 2 diabetic patients in China.

**Materials and methods:** Adults with type 2 diabetes from 50 medical centers across China covered 29 administrative divisions were eligible. The third version of the Diabetes Attitude Scale (DAS-3) and summary of Diabetes Self-Care Activities (SDSCA) were utilized to assess attitude towards diabetes and self-care behavior, respectively. Adequate metabolic control (hemoglobin A1c < 7.0%, FPG < 7.2 mmol/L, 2hPPG 1.3 mmol/L in women, TC < 4.5 mmol/L, TG < 1.7 mmol/L) was defined as standards of medical care from the 2013 American Diabetes Association. The information of chronic complications was collected through primary interrogation and check.

**Results:** A total of 5961 respondents completed the questionnaires. As shown in table 1, patients with optimal glycemic control have higher scores of SDSCA in general diet (HbA<sub>1c</sub>, P < 0.001, FPG, P < 0.001), exercise (HbA<sub>1c</sub>, P < 0.01), SMBG (HbA<sub>1c</sub>, P < 0.001), and medication adherence (HbA<sub>1c</sub>, P < 0.05, FPG, P < 0.01, 2hPPG, P < 0.001) than those with poor glycemic control. Patients with adequate lipid control have higher scores of SDSCA in general diet (TG, P < 0.01), SMBG (TG, P < 0.01, LDC, P < 0.001, TC, P < 0.05), and medication adherence (HDL, P < 0.001, TC, P < 0.05). People with targeted BMI (BMI ≤ 24 kg/m<sup>2</sup>) have higher scores of SDSCA in general diet (P < 0.01), special diet (P < 0.05), and but lower in medication adherence (P < 0.001). However, there was no significant difference on scores of attitude towards diabetes between patients with optimal and poor metabolic control. On the other hand, the score of SDSCA in general diet (P < 0.01), exercise (P < 0.01), SMBG (P < 0.01), and medication adherence (P < 0.001) of patients without chronic complications including macroangiopathy, microangiopathy, neuropathy were significantly higher than those of patients with chronic complications. Meanwhile, showed less positive attitude on psychosocial impact of diabetes (P < 0.05).

**Conclusion:** These data demonstrated that metabolic control and diabetic complications was directly associated with self-care behavior but not attitude. It suggests that the diabetes educators in China should pay more efforts on diabetes skill training towards self-care behavior for patients.

**Table 1 Association of behavior with metabolic control and complications**

### Identifying consistent inconsistency in network meta-analyses: an illustration in type 2 diabetes

D.A. Scott, N. Hawkins;

Health Economics & Epidemiology, ICON Clinical Research UK Ltd, Oxford, UK.

**Background and aims:** Network meta-analyses (NMA) combine direct and indirect evidence across a connected network of trial comparisons to provide estimates of comparative efficacy for multiple treatments. They have been embraced by reimbursement agencies and recommended by health technology assessment bodies. A key concern is the comparability of treatment effect estimates from different trials. Where there is both indirect and direct evidence for one or more comparisons ('loops' in the network) it is possible to evaluate empirically the 'consistency' of the network. Inconsistencies between direct and indirect estimates may be alleviated by adjusting for trial differences using regression analysis or by excluding studies. However, as the networks of trial evidence become more complex, and potentially include multiple 'loops' it becomes more difficult to interpret evidence regarding 'inconsistency'.

**Materials and methods:** A variety of alternative methods have been proposed to examine inconsistency including (i) node-splitting whereby the difference between the direct and indirect evidence is calculated (where possible) for each comparison in the network, (ii) comparisons of the NMA to an 'inconsistency' model where the effect estimates for each treatment com-

parison in the network is allowed to be independent, (iii) a method which looks at inconsistencies between alternative study designs, (iv) plotting residual deviance for individual trial arms within the NMA, and (v) plotting mixed predictive p-values against a uniform distribution. We compare the implementation and interpretation of these methods using a previously published NMA in type 2 diabetes. In this analysis HbA1c was compared across six treatments (two GLP-1s at different administrations, placebo, and insulin glargine) in a network of 22 studies with multiple 'loops'. As in the original study, a random effect model controlling for baseline HbA1c was performed.

**Results:** The methods agreed in showing the presence of inconsistency with the network. For example, the inconsistency model showed an improved fit (DIC -62.35) compared to the consistency model (DIC -60.25). The node splitting method identified two treatment arcs as being inconsistent, liraglutide 1.8mg vs placebo and liraglutide 1.8mg vs exenatide QW. However, the methods varied in their ability to provide an overall 'test' of inconsistency across the network and their ability to identify which parts of the network contain inconsistencies. We highlight that none of the methods alone can identify individual studies as being the cause of inconsistencies and argue that we need to consider the whole structure of the network and the characteristics of the studies (in terms of treatments, subjects, and design) within the network.

**Conclusion:** Meta-analysis and decision makers often seek similarity across the network. However, we argue that we may be more confident generalising from treatment effects estimated from a well-connected and heterogeneous network if the estimates within the network prove to be consistent.

### A patient centered approach on newly-arrived persons to a diabetes clinic

A.C. Paiva, M.J. Afonso, R.T. Ribeiro, L. Serrabulho, J. Susano, J.F. Raposo; APDP - Diabetes Portugal (Education and Research Centre - APDP/ERC), Lisbon, Portugal.

**Background and aims:** It's recognized that person-centred therapeutic education and group education with active methodologies promote experiences sharing, conviviality and stimulates learning among participants. The clinic introduced two structured programs for self-management education (DSME) addressed to newly-arrived patients covering a wide range of Diabetes Care in an integrated way. It's a comprehensive program of patient-centred care designed to increase autonomy, promote better adherence to treatment, and thus better metabolic control. We aim to perceive the programme's practical feasibility and people's adherence.

**Materials and methods:** Programme 1: lasts for 04:30h; -During this period the person performs several tests: blood samples, EKG and retinography. A nurse performs a foot screening with risk assessment and foot care education. Then the person participates in two group sessions: a session with nurse guidance addressing pathophysiology of diabetes, relating the various important aspects in treatment and self-control, as well as doubts clarification and a final session about healthy eating, its importance for the metabolic control and lipid profile, and role of exercise in controlling diabetes (guided by a dietician/nutritionist). The average time between the program and the 1st medical consultation at the clinic is 4 weeks. Programme 2: lasts for 3 months, divided in three group education sessions before the diabetes individual medical consultation (med). Sessions are guided by a facilitator using an IDF approved education tool, which provides an interactive verbal and visual learning experience, allowing groups engagement in an open and meaningful debate about diabetes. Sessions are divided by themes: the 1st (S1) leads to a reflection on their role in disease's self-management, the 2nd (S2) covers general concepts for healthy eating, and the 3rd (S3) is a physical activity session with a gym teacher. Patients are selected based on their age (50-80 y) and HbA1c (< 10%), they are invited to attend programme 1 or 2 according to their convenience.

**Results:** Programme 1: A sample of 300 people (February to September 2013) with 60.4±10.3 years of age, an initial mean HbA1c of 8.7±1.5% and BMI mean of 28.2±4.6kg/m<sup>2</sup> were analysed. No consistent changes were observed in terms of BMI or HbA1c in this group between the session and the medical consultation. Programme 2: We analysed a sample of 231 people (same period of time), with 68.3±8.8 years of age and an initial mean HbA1c of 9.1±0.7% and BMI mean of 35.3±3.2 kg/m<sup>2</sup>. The drop-out rate was 10.8% at session 2 and 82% at session 3. No consistent changes were observed in BMI between the various groups. In terms of HbA1c it was observed a tendency of decrease between S1 and medical consultation directly related to the number of sessions attended (ΔA1c - Session 1: -0.27%; Session 2: -0.59 %; Session3: -0.85 %)

**Conclusion:** It's well known that active methods are a fundamental tool in group training. Here, the consistent decrease in HbA1c (programme 2) achieved independently of weight loss, hints to the impact of sharing solutions among peers by boosting diabetes acceptance, well-being and development of autonomy with DSME. The longer duration of this program also enables a slower integration of knowledge and skills in the daily life. However, the high drop-out before the exercise session advises us to consider alterations on program implementation, further encouraging patients participation.

### Relation between quality of care indicators of diabetes and prediction of hospitalisation and mortality for heart failure

L. Policardo, G. Seghieri, P. Francesconi;  
Agenzia Regionale Sanità, Florence, Italy.

**Background and aims:** Heart failure (HF) is a major complication of diabetes especially as a consequence of ischemic heart disease. With the aim of evaluating whether a panel of quality of care indicators, as suggested by current guidelines, are related to the risk of hospitalization or subsequent mortality for HF, this study has retrospectively followed up, along a period of eight years (from 2005 to 2012) a cohort of diabetic patients living in Tuscany, a region of centre of Italy.

**Materials and methods:** The database used for this investigation was obtained from linking three datasets: the first concerning all hospital discharges with main diagnosis of heart failure (ICD-9-CM 402 to 428) from all Tuscan hospitals over the period 2005 to 2012, the second was the general population registry of all inhabitants of Tuscany and the third a dataset containing the registry of all known diabetic patients from Tuscany. This latter gave information about whether patients did perform annual assessment of HbA1c, eye examination, serum lipids, creatinine and microalbuminuria. In addition, from this dataset it was possible to evaluate whether patients were given at least 2 annual drug prescription of ACE-inhibitors (ACEI), aspirin (ASA) or lipid-lowering drugs (LIPID).

**Results:** On a total of 95,205 diabetic patients (47,762 males and 47,443 females), followed up over eight years, we counted 4,494 hospitalizations for HF (2,131 in males and 2,363 in females). After using a Cox proportional hazard model, the hazard ratio (HR) of hospitalization for HF, adjusted for age and Charlson co-morbidity index was inversely related with the annual execution of HbA1c, microalbuminuria or of lipid profile both in men (HR:0.923;0.896-0.952(95%CI), 0.972;0.949-0.995 and 0.895;0.870-0.920), and in women (HR:0.908;0.883-0.934, 0.968;0.945-0.991 and 0.900;0.878-0.923). The annual evaluation of serum creatinine, was on the contrary a positive predictor of risk (HR:1.306;1.260-1.353 in males and 1.359;1.315-1.405 in females). Annual eye examination was associated with a decrease in the risk of hospitalization for HF only among females (HR:0.957;0.937-0.977 among women and HR:0.986;0.964-1.008 among men). Finally, the composite indicator including the prescription for at least five years of ASA, ACEI and LIPID was significantly related with an augmented risk of HF-related hospitalization in both males (HR:1.285;1.130-1.456) and females (HR: 1.192;1.028-1.375). After HF hospitalizations 997 all-cause deaths were recorded and, by using a Cox model adjusting for age, sex and Charlson index, the survival after HF-hospitalization was significantly predicted by a low Charlson index (HR:0.928;0.864-0.996) and, again, by a lower number of annual evaluations of serum creatinine (0.935;0.886-0.985). No other indicator was significantly correlated with the prediction of post-hospitalization fatal events

**Conclusion:** In this cohort of Tuscan diabetic patients, over a eight-year period the annual execution of HbA1c, microalbuminuria, lipid profile and eye examination were inversely related with the risk of hospitalization for HF. Prescription of ACEI, ASA and lipid-lowering drugs was, on the contrary, associated with a significant increase in predicted hospitalization risk. Finally, post-hospitalization mortality risk was predicted by a higher Charlson index and by a higher rate of annual serum creatinine evaluations.

### Quality of care in type 1 diabetes in Italy: focus on gender differences

Rossi<sup>13</sup>;  
<sup>1</sup>Dept. of Int. Medicine, E.Franchini Hospital, Montecchio, Reggio Emilia, <sup>2</sup>University of Messina, <sup>3</sup>University of Perugia, <sup>4</sup>Hospital of Prato, <sup>5</sup>Cardarelli Hospital, Campobasso, <sup>6</sup>University of Naples, <sup>7</sup>Hospital of Sacile (PN), Sacile (PN), <sup>8</sup>Hospital Monaldi, Naples, <sup>9</sup>Hospital Brotzu, <sup>10</sup>Sapienza University, Roma, <sup>11</sup>S.Pertini Hospital, Roma, Italy, <sup>12</sup>Idibaps, Barcellona, Spain, <sup>13</sup>Mario Negri Sud, Santa Maria Imbaro (CH), Italy.

**Background and aims:** We evaluated the quality of care according to gender in type 1 diabetes (T1D) in 300 diabetes outpatient clinics participating to "The Annali AMD" initiative. The Italian Association of Diabetologists (AMD) identified a set of quality indicators used for benchmarking activities since 2006, including process and intermediate outcome measures, as well as indicators of treatment intensity/appropriateness. A quality of care summary score (Q score), based on a combination of process and outcome indicators (range 0-40), was also calculated.

**Materials and methods:** We report here clinical data of 28,802 T1D patients (54.5% men; 45.5% women), collected during 2011 and extracted from electronic medical records.

**Results:** Both men and women received similar evaluation for process indicators (HbA1c, Lipids, BP, microalbuminuria, foot and eye examination), whereas the outcome indicators and treatment intensity/appropriateness differed according to gender (Table). No gender differences as to age (F: 45±16 years; M: 45±17) and diabetes duration (F: 19±13 years; M: 18±13) were noted. Men were more often smokers than women (31.8% vs. 22.7%) and showed a higher BMI (25±4 vs. 24±4 kg/m<sup>2</sup>), but F showed higher prevalence of BMI lt 18 or gt 35. T1D women showed poorer metabolic control and more often did not receive lipid-lowering agents in spite of high LDL-cholesterol levels than men, while men had poorer blood pressure control, and higher percentage of micro/macroalbuminuria. However, the overall quality of care, as estimated by Q score, was similar in both genders. Regarding the therapeutic approach (MDI vs CSII), the percentage of women treated with CSII was higher than men (19,6% vs. 13.8%); women were slightly younger (42.2±16.9 vs 45.1±16.9) for the same duration of disease (18.3±12.5 vs 18.1±13.2). A greater proportion of subjects treated with CSII reached the HbA1c level below 7.0% but women experienced more difficulties in achieving the HbA1c goal even if treated with CSII (HbA1c < 7.0%: 25.1% F vs 31.2% M).

**Conclusion:** Despite a similar quality of care, T1D women still show a poorer metabolic control, with any type of treatment, and were less intensively treated for LDL-C, while men show a worse cardiovascular profile in terms of blood pressure, microalbuminuria, BMI and smoking habits.

| Indicators of intermediate outcome                      | F (%) | M (%) | p       |
|---|-------|-------|---------|
| HbA1c ≤ 7.0% (≤ 53 mmol/mol)                            | 20.4  | 25.6  | <0.0001 |
| LDL-C <100 mg/dl  | 41.5  | 41.4  | 0.91    |
| BP ≤ 130/80 mmHg  | 69.5  | 61.5  | <0.0001 |
| Presence of micro/macroalbuminuria                      | 24.7  | 30.2  | <0.0001 |
| Indicators of treatment appropriateness                 |       |       |         |
| No lipid-lowering agents despite LDL-c ≥ 130 mg/dl      | 71.1  | 68.2  | 0.04    |
| No antihypertensive treatments despite BP ≥ 140/90 mmHg | 47.4  | 49.8  | 0.06    |
| No ACE-I and/or ARBs despite micro/macroalbuminuria     | 8.9   | 8.7   | 0.58    |
| Overall quality of care                                 |       |       |         |
| Q score <15   | 7.6   | 7.5   | 0.68    |
| Q score >25   | 41.5  | 40.6  | 0.15    |

## 1064

### A global study of unmet need for glycaemic control and predictor factors among patients with type 2 diabetes mellitus

D. Raccach<sup>1</sup>, E. Chou<sup>2</sup>, S. Colagiuri<sup>3</sup>, Z. Gaàl<sup>4</sup>, F. Lavallo<sup>5</sup>, A. Mkrtumyan<sup>6</sup>, E. Nikonova<sup>7</sup>, N. Tentolouris<sup>8</sup>, J. Vidal<sup>9</sup>, M. Davies<sup>10</sup>;

<sup>1</sup>Department of Diabetology, University Hospital Sainte-Marguerite, Marseille, France, <sup>2</sup>Sanofi R&D, Bridgewater, USA, <sup>3</sup>Boden Institute, University of Sydney, <sup>4</sup>Josa Andras Teaching Hospital Department of Medicine, Nyíregyháza, Hungary, <sup>5</sup>Hospital Universitario, Facultad de Medicina UANL, Monterrey, Mexico, <sup>6</sup>Moscow State Medical and Stomatological University named after Evdokimov, Moscow, Russian Federation, <sup>7</sup>Global Medical Affairs, Diabetes Division, Sanofi, Bridgewater, USA, <sup>8</sup>University of Athens Medical School, Greece, <sup>9</sup>Endocrinology and Nutrition Department, Hospital Clinic, Barcelona, Spain, <sup>10</sup>Diabetes Research Centre, University of Leicester, UK.

**Background and aims:** Information on the efficacy of various treatments for type 2 diabetes mellitus (T2DM) in achieving glycaemic control is available globally from a number of different sources. This study utilized data from randomized controlled trials (RCTs), clinical trial registries (CTRs) and electronic medical records (EMRs) to identify unmet need for improved prandial glycaemic control in patients with T2DM following initiation of basal insulin therapy in Europe (EU), Asia Pacific (APAC), the US, and Latin America (LATAM).

**Materials and methods:** Different levels of evidence were used as available for each country/region, including RCTs (EU, LATAM, and APAC), CTRs (CREDIT 4-y, 9 countries mainly EU; ALOHA 0.5-y, Japan; Asia-FINE, 11 Asian countries), and EMRs (Germany IMS-DA, UK THIN, and US GE). We evaluated hyperglycaemia status by categorizing as 'well controlled' (defined as endpoint fasting plasma glucose [FPG] at target [defined as FPG <130 or 140 mg/dL; cut-off depending on country-specific recommendations] and HbA<sub>1c</sub> at target [defined as HbA<sub>1c</sub> <7%]), 'residual hyperglycaemia' (FPG at target but not HbA<sub>1c</sub>) or 'uncontrolled' (both FPG and HbA<sub>1c</sub> above target). Logistic regression analysis was used to identify predictor factors from the RCT dataset.

**Results:** Analysis of RCT data showed that ~43–54% of patients with T2DM globally had residual hyperglycaemia (Table), and rates across CTRs (CREDIT 31%, Asia-FINE 34.9%, and ALOHA 36%), and EMR (26% [Germany], 36% [UK], and 25% [US]) datasets were similar. A comparison across the EU showed consistent residual hyperglycaemia between CTR and EMR databases. Significant predictor factors were identified from RCT data, including baseline HbA<sub>1c</sub> (all countries/regions except Brazil), baseline FPG (UK and Japan), and duration of diabetes (Brazil).

**Conclusion:** The higher proportion of patients with residual hyperglycaemia in the RCTs may be due to the selected population in RCTs. However, irrespective of intrinsic source differences between the datasets, 25–54% of patients with T2DM globally had residual hyperglycaemia despite meeting FPG goals, indicating an unmet need for additional prandial glycaemic control.

**Table:** Glycaemic control in randomized clinical trials by region.

| Region        | N   | Controlled <sup>a</sup> | Residual hyperglycaemia <sup>b</sup> | Uncontrolled <sup>c</sup> | Missing data |
|---------------|-----|-------------------------|--------------------------------------|---------------------------|--------------|
| Europe        | 954 | 28.0%                   | 54.4%                                | 16.9%                     | 0.7%         |
| Latin America | 417 | 26.9%                   | 52.0%                                | 20.9%                     | 0.2%         |
| Asia-Pacific  | 787 | 16.9%                   | 42.7%                                | 38.1%                     | 2.3%         |

<sup>a</sup>Defined as both HbA<sub>1c</sub> and FPG at target; <sup>b</sup>Defined as HbA<sub>1c</sub> above target despite FPG at target; <sup>c</sup>Defined as neither HbA<sub>1c</sub> or FPG at target.

## 1065

### Metabolic outcome data from a type 2 diabetes clinic in Denmark between 2001–2012

N. Safai, R.S. Terkildsen, U. Trustrup, M. Glindorf, M. Ridderstråle; Steno Diabetes Center, Gentofte, Denmark.

**Background and aims:** Multifactorial interventions offered patients with type 2 diabetes (T2D), lead to substantial reduction in morbidity and mortality. Subsequent the Steno-2 study, a clinic providing referred T2D patients with dysregulated diabetes, complications or poor compliance, was opened at a specialized Diabetes Center (DC). Patients undergo a six to nine month treatment programme consisting of lifestyle education and motivation, and individually tailored pluri-pharmacy targeting hyperglycaemia, hypertension,

dyslipidaemia, and microalbuminuria. Our aim here was to find out the impact of this programme on short term metabolic outcomes and compare attainment of metabolic goals for patients in the general population to those of DC.

**Materials and methods:** Annual data from all patients with T2D referred to the type 2 clinic between Jan 1<sup>st</sup> 2001 and Jan 1<sup>st</sup> 2013 were extracted from the electronic medical records as part of quality of care assurance. In accordance with the national plan for diabetes care, the majority of patients (72%) were referred back to their general practitioner (GP) after being treated at the type 2 clinic. The remainder was retained at DC due to their level of disease complexity. Data up to nine months at type 2 clinic were followed. For comparison we used data from the Danish Adult Diabetes Database (DVDD) from 2012. Non-parametric statistic analysis was used throughout.

**Results:** We included a total of 4,143 patients (male 59%), with 489 (12%) patients going through more than one treatment programme. Mean age was 60 ± 12 years (mean ± SD) and mean duration of diabetes was 6.8 ± 6.6 years. DVDD contains data from 12,501 patients (male 56%) with T2D followed by GPs; mean age 68 ± 11 years, and mean duration of diabetes 6.5 years. The mean HbA<sub>1c</sub> in patients with T2D followed by GPs was 48 mmol/mol (DCCT HbA<sub>1c</sub> 6.5%), while that of referred patients was 67 ± 20 mmol/mol (8.3%) and decreased to 55 ± 14 mmol/mol (7.2%) by the end of programme (p75 mmol/mol); 32% at baseline and 9% after completion of the programme. The well-regulated group (HbA<sub>1c</sub> <53 mmol/mol) increased from 25% to 52% of all after 9 months (p<.0001). Mean body mass index (BMI) also decreased significantly, most notable from 2010; mean BMI from 31.3 ± 6.5 kg/m<sup>2</sup> to 30.9 ± 6.2 kg/m<sup>2</sup>. This decrease was most prominent in those who were obese (BMI >30 kg/m<sup>2</sup>) at baseline, as well as in females (p<.0001 for both). Mean systolic and diastolic BP levels decreased from 143 ± 21/82 ± 12 mmHg at baseline to 137 ± 19/80 ± 10 mmHg (p<.0001). The percentage of patients below target pressure (<140/<90 mmHg) went from 45% at baseline to 70% after the programme (Figure). LDL-cholesterol decreased from 2.6 ± 1.0 mmol/L to 2.2 ± 0.9 mmol/L (p<.0001); 52% of patients on target (LDL-cholesterol <2.6 mmol/L) at baseline and 84% after finishing the programme.

**Conclusion:** Our data show that the patients referred from GPs to a specialized DC are of appropriate complexity or dysregulated and that their metabolic control can be improved to near average GP level.

**Trends over 8 years in quality of care provided by Italian diabetes clinics to elderly patients with type 2 diabetes**

R. Candido<sup>1</sup>, M.C. Rossi<sup>2</sup>, M.A. Pellegrini<sup>3</sup>, G. Felace<sup>4</sup>, M. Boemi<sup>5</sup>, M. Scardapane<sup>2</sup>, A. Nicolucci<sup>2</sup>, P. Di Bartolo<sup>6</sup>, C. Giorda<sup>7</sup>;

<sup>1</sup>Diabetic Centre, A.S.S. 1 Triestina, <sup>2</sup>Department of Clinical Pharmacology and Epidemiology, Consorzio Mario Negri Sud, S. Maria Imbaro (CH),

<sup>3</sup>Diabetes and Metabolism Unit, AOU Santa Maria della Misericordia, Udine, <sup>4</sup>Diabetes and Metabolism Unit, O.C. di Spilimbergo, Spilimbergo (UD), <sup>5</sup>Diabetes Unit, Department of Medicine, INRCA-IRCCS, Ancona,

<sup>6</sup>Diabetes Unit, A.Usl della Romagna, Ravenna,

<sup>7</sup>Diabetes and Metabolism Unit, ASL TO<sup>5</sup>, Chieri (TO), Italy.

**Background and aims:** The prevalence of diabetes in people over 75 years approaches 30%, while at least 25% of all patients attending Italian outpatients diabetes clinics are older than 75 years. Clinicians who manage older people with diabetes require special skills to provide high-quality care. In the context of a continuous quality improvement initiative promoted in Italy by Associazione Medici Diabetologi (AMD Annals initiative), we evaluated the trends over 8 years in the quality of care provided by diabetes clinics to elderly patients (i.e. > 75 years).

**Materials and methods:** Overall, 300 diabetes clinics (about half of all clinics in Italy), all using electronic medical record systems, extracted data relative to the years 2004–2011. The proportion of patients with at least one value registered during each year (process measures), the percentage of patients reaching specific favorable or unfavorable targets (intermediate outcome measures), and rates of use of drugs were evaluated. In addition, a quality of care summary score (Q score) was calculated. The Q score, ranging between 0 and 40, is based on process and outcome indicators (HbA1c, blood pressure, LDL-cholesterol, microalbuminuria) and is closely related to long-term outcomes in diabetic patients.

**Results:** Over the years, there was an increase in the percentage of patients aged > 75 years (19.9% in 2004 vs. 27.2% in 2011) and in the prevalence of male patients (42% in 2004 vs. 46% in 2011). As compared to 2004 we observed after 8 years a slight increase in the mean age (79.9±3.8 vs. 80.5±4.1) and in the duration of diabetes (13.8±10.5 vs. 14.2±10.9). Table 1 shows quality of care indicators.

**Conclusion:** Care provided by diabetes clinics to elderly patients shows a significant improvement over the years. Elderly patients are more frequently monitored for blood pressure, lipid profile and microalbuminuria, show better intermediate outcomes and are less often treated with sulphonylureas. In addition we observe a better global quality of care with a significant increase in the Q score through the years.

**Comparing the use of patient level data to an average patient profile within a type 2 diabetes simulation model**

P. McEwan<sup>1,2</sup>, H. Bennett<sup>2</sup>, T. Ward<sup>2</sup>, K. Bergenheim<sup>3</sup>;

<sup>1</sup>Swansea Centre for Health Economics, Cardiff, <sup>2</sup>Health Economics and Outcomes Research Ltd, Monmouth, UK, <sup>3</sup>Global Health Economics and Outcomes Research, AstraZeneca, Molndal, Sweden.

**Background and aims:** To accommodate patient heterogeneity and complex treatment pathways, type 2 diabetes models employ simulation techniques beyond the basic Markov process. Yet averages are commonly relied upon

when defining patient populations and treatment effects; in turn clinicians may struggle to relate the results of such modelling to the full spectrum of patients they see in practice. This study investigates the value of fully modelling between patient variation by comparing patient and cohort level model inputs within a published simulation model, based on the UKPDS68 outcomes equations.

**Materials and methods:** Anonymised UK patient data was obtained from The Health Improvement Network (THIN) describing 2,251 patients initiating dual therapy. Simulations were initialised by applying either the average patient profile to the cohort, or by individually replicating each patient's profile, followed by the collation of model outputs over all replications. The impact of utilising patient level baseline and treatment effect data was compared to the average patient profile through evaluation of total costs, benefits and complication rates, predicted over a medium-term horizon of 20 years.

**Results:** On average patients were aged 63.36 (±11.14) at baseline, with the following risk factor profile; HbA1c 8.39 (±1.23) %, total cholesterol 4.18 (±0.92) mmol/L, systolic blood pressure 135.07 (±14.76) mmHg and weight 89.85 (±19.01) kg. The mean treatment effect on HbA1c was a reduction of 1.01 (±1.23) %. Over 20 years, fewer macrovascular and microvascular events (-82/1,000 patients) and higher all-cause mortality (+17/1,000 patients) were predicted when using patient level data inputs compared to the average patient profile. Differences in the simulated frequency and timing of deaths were driven primarily by variation in baseline age and led to fewer estimated life-years (-0.66), quality adjusted life-years (QALYs) (-0.59) and costs (-£551) per patient. Patients estimated to have both lower costs and higher QALYs than those associated with the average patient profile were younger, with higher HbA1c and cholesterol and lower blood pressure at baseline.

**Conclusion:** Modelling results differ depending on the use of patient level or average cohort model inputs. Patient level data may provide insight into the type of patients in whom therapy is likely to be most beneficial. Furthermore, it enables the accurate simulation of correlations between patient characteristics and treatment effect, which are rarely accounted for as part of a standard probabilistic sensitivity analysis.

**Is there an evidence base for the clinical features used to differentiate type 1 from type 2 diabetes? A systematic review of the literature**

B.M. Shields<sup>1</sup>, J.L. Peters<sup>2</sup>, C. Cooper<sup>2</sup>, J. Lowe<sup>2</sup>, B. Knight<sup>1</sup>, R. Powell<sup>1</sup>, C.J. Hyde<sup>2</sup>, A.T. Hattersley<sup>1</sup>;

<sup>1</sup>NIHR Exeter Clinical Research Facility, University of Exeter Medical School, <sup>2</sup>Peninsula Technology Assessment Group, University of Exeter Medical School, <sup>3</sup>Research Design Service, Royal Devon and Exeter NHS Foundation Trust, Exeter, UK.

**Background and aims:** Clinicians predominantly use clinical features to differentiate Type 1 from Type 2 diabetes but no guidelines quote an evidence base for which features are the most discriminatory. Whilst Type 1 patients are thinner, diagnosed younger, and rapidly go onto insulin, the best cut offs of these criteria are not provided. Misclassification of diabetes is widespread (7–15% of cases) and will result in patients receiving the wrong treatment. The key difference between Type 1 and Type 2, that determines treatment, is that patients with Type 1 diabetes develop absolute insulin deficiency. We aimed to systematically review the literature to identify which clinical criteria could be used to discriminate Type 1 and Type 2 diabetes, using insulin deficiency as a gold standard.

**Materials and methods:** The search strategy took the form of: (terms for diabetes) AND (terms for C-Peptide). 14 databases including MEDLINE and EMBASE were searched. All diagnostic accuracy studies, published since 1979, using clinical criteria to predict insulin deficiency (defined by C-peptide concentrations) were included. There was no restriction on race, age, language, or country of origin. Data synthesis was largely descriptive.

**Results:** 10,917 abstracts were screened, and 231 full texts reviewed. 10 references were identified for final inclusion. Studies varied by age, race, year, and proportion of participants who were C-peptide negative, prohibiting formal meta-analysis. Consistent predictors across studies were age at diagnosis (the most discriminatory feature; mean ranking of predictors by discriminatory ability within studies=1.4), insulin treatment/time to insulin (mean rank=1.7), and BMI (mean rank=2.6). Discriminatory cutoffs were age at diagnosis 30–40 years, time to insulin 1–2 years, and BMI 27–28kg/m<sup>2</sup> (>66% sensitivity and specificity for all). BMI added little over age at diagnosis and/or time to insulin (<1% improvement in classification).

**Conclusion:** Studies of the accuracy of clinical criteria to define Type 1 diabetes are surprisingly few given the importance for treatment of patients. Despite finding only 10 studies, and considerable heterogeneity between studies, age at diagnosis (35 years) and time to insulin treatment(1.5 years) were consistently the most discriminatory. BMI, despite being widely used in clinical practice, adds little to these 2 criteria.

**Background and aims:** Among non-critically ill patients, there are detrimental effects of hypoglycemia during hospital stay. Hospitalization-associated hypoglycemic events may occur in patients with diabetes mellitus that are prone to develop it. We studied the association between admission hypoalbuminemia and the risk of hospitalization-associated hypoglycemia, among patients admitted to internal medicine departments.

**Materials and methods:** In this retrospective analysis of electronic medical records, we included all 2599 patients with diabetes mellitus and documented admission albumin levels (Mean age 71.7±13.0 years, 48.4% males, 65.9% of all patients with diabetes), admitted to internal medicine departments during 2009. All glucose measurements were computerized using an institutional glucometer. Patients were categorized into 4 groups according to hospitalization-associated hypoglycemia (yes/no) and admission albumin levels below 3.5 g/dL (yes/no).

**Results:** Patients with hypo-albuminemia had higher rates of hypoglycemia and severe hypoglycemia during the admission despite similar HbA1c and average glucose control during the admission. Only creatinine (OR 1.237, 95% CI 1.098-1.392, p<0.001) and albumin levels (OR 0.417, 95% CI 0.342-0.509, p<0.001) affected the risk for hypoglycemia. In addition, Patients with hospitalization-associated hypoglycemia combined with admission hypoalbuminemia had the lowest survival rates (hospital and 1-year), compared to the other groups (OR 7.419, 95% CI 5.255-10.473 respectively, p<0.001). Patients with hypoglycemia but with normal albumin levels had a similar survival curve compared to diabetes patients without hypoglycemia nor hypoalbuminemia.

**Conclusion:** Low albumin levels upon admission are associated with increased risk for hypoglycemia during hospitalization. The occurrence of hypoglycemia among patients with low albumin levels is associated with reduced 1-year survival compared to both diabetes patients with hypoalbuminemic but without hypoglycemia, as well as diabetes patients without hypoglycemia and normal albumin levels.

**Real-world treatment switching patterns in patients (pts) with type 2 diabetes mellitus (T2DM) on basal insulin (INS)**

J. Kapustin<sup>1</sup>, J.E. Anderson<sup>2</sup>, T. Reid<sup>3</sup>, A. Rhinehart<sup>4</sup>, S. Brunton<sup>5</sup>, J. Stewart<sup>6</sup>, W. Zhou<sup>6</sup>, T. Dex<sup>7</sup>, M. Kazemi<sup>7</sup>, A. Vljajic<sup>7</sup>, M. Dalal<sup>7</sup>;

<sup>1</sup>University of Maryland School of Nursing, Baltimore, <sup>2</sup>The Frist Clinic, Nashville, <sup>3</sup>Mercy Diabetes Center, Janesville, <sup>4</sup>Johnston Memorial Diabetes Care Center, Abingdon, <sup>5</sup>Primary Care Education Consortium, Charlotte, USA, <sup>6</sup>Sanofi Canada, Laval, Canada, <sup>7</sup>Sanofi US, Bridgewater, USA.

**Background and aims:** Increasing treatment options have empowered but also complicated disease management. We explored transitions from INS to other therapies in a real-world setting.

**Materials and methods:** We analyzed data from Diabetes FORWARD, a practice-based research network focused on T2DM pts and their providers across the US (September 2012-December 2013). Pts aged ≥ 18 years, diagnosed with T2DM and with a start date for INS ≤ 12 months (mo) before enrolment were eligible. Based on prescription data from electronic medical records, pts were stratified by treatment switches at 3, 6, and 9 mo as those who: remain on INS; switch to oral antidiabetes drugs (OADs); switch to a glucagon-like peptide-1 receptor agonist (GLP-1) ± INS; or switch to other insulin (85-90% added prandial insulin to INS). As in any observational study, not all pts contributed data at each time point; therefore, 3, 6 and 9 mo groups were defined.

**Results:** 300 pts were eligible. At 3 mo, 81% of pts remained on INS, decreasing to 65% at 6 mo and 56% at 9 mo; proportions of pts switching to other therapies increased. At baseline (BL) there were no differences in age, gender, race/ethnicity, education level, or number of OADs between groups. Pts remaining on INS or switching to other insulin had more Medicare coverage. In the GLP-1 group, more pts had private health insurance, although numbers are small (Table). At all time points, pts transitioning to OADs reported worse general health than those remaining on INS; those transitioning to other insulin reported the worst general health (Table). There were no differences in BL HbA1c between groups, although BL HbA1c was numerically highest for pts switching to other insulin (Table). HbA1c decreased in all groups except for pts transitioning to other insulin which increased. Greatest reductions in HbA1c were seen in the OAD and GLP-1 groups (Table). Pts switching to GLP-1 or other insulin had higher BL weight; those in the 6 and 9 mo OAD groups had the lowest weight. Greatest weight loss was observed in the GLP-1 group (data not shown).

**Conclusion:** Patterns observed here suggest that, in the practice setting, pts with T2DM transitioning from INS to OADs report worse health, have a lower weight, and relatively good glycaemic control. However, those transitioning to GLP-1 report good health, higher weight, and better glycaemic control. Pts transitioning to other insulin report poorer health, higher weight, and the worst glycaemic control. Medicare beneficiaries had the least access to GLP-1 suggesting insurance influences provider decisions. Other reasons for switching therapy may be intolerance to, or ineffectiveness of, previous therapy and disease progression.

| Characteristic                          | INS                       | Switch to OAD(s)       | Switch to GLP-1 + INS | Switch to other insulin | p-Value              |                     |

**Overtreatment in elderly patients  $\geq 75$  years with type 2 diabetes and renal disease**A. Penforis<sup>1</sup>, J.-F. Blicke<sup>2</sup>, B. Fiquet<sup>3</sup>, S. Dejager<sup>3</sup>;<sup>1</sup>Jean Minjoz Hospital, Besançon, <sup>2</sup>Strasbourg University Hospital,<sup>3</sup>Novartis Pharma SAS, Rueil Malmaison, France.

**Background and aims:** Few data exist regarding management of patients (pts) with type 2 diabetes mellitus (T2DM) over 75 years (y), who frequently have renal impairment (RI). This real-life study aimed to assess the treatment of T2DM in elderly patients with chronic kidney disease (CKD), a uniquely fragile population that poses specific challenges.

**Materials and methods:** Observational cross-sectional study: 3704 pts with T2DM were recruited by 968 physicians in France. Data from 980 diabetic pts  $\geq 75$  y with CKD are presented in this sub-analysis.

**Results:** Mean age was 81 y (range 75–101), 56% were male, with BMI 28.5 kg/m<sup>2</sup>, while mean estimated glomerular filtration rate (eGFR) was 43 mL/min/1.73m<sup>2</sup>. 20% of patients had severe RI (eGFR <30mL/min/1.73m<sup>2</sup>; mean 22.5) and 71% had moderate RI (eGFR 30–60 mL/min/1.73m<sup>2</sup>; mean 43.7). 38% had seen a nephrologist. Mean HbA1c was 7.4% (60% had HbA1c <7.5% and 36% <7%). They had long-standing T2DM (15.4 y), often complicated (macrovascular complications 49%, heart failure 20%, retinopathy 20%). Respectively, 96% and 78% had hypertension and dyslipidemia, almost all treated. They received a mean of 5.5 concomitant therapies for cardiovascular risk management. Antidiabetic therapy was oral-based for 51% of pts (40, 46 and 13% as single, dual or triple-drug therapy) and insulin-based for 49% (combined with  $\geq 1$  oral antidiabetic [OAD] in 59%). Treatment included metformin (47%), SU (26%), glinide (19%),  $\alpha$ -glucosidase inhibitor (6%), DPP-4 inhibitor (31%) or insulin (49%). The type of agents differed across renal function (RF) strata: there was less use of metformin (70, 49 and 29% of pts, respectively, in normal RF, moderate or severe RI), SU (28, 28 and 19%) and DPP-4 inhibitors (38, 33 and 20%) and more use of glinides (11, 19 and 22%) and insulin (37, 46 and 65%) with declining RF. Metformin daily dose remained high (mean 1.9 g/d; >2 g/d for 25%) across all degrees of RI. Metformin was stopped/reduced at the end of the visit in only 25% of the metformin-treated pts overall and 40% of those with severe RI. 60% (n=579) of these older pts with overt RI and multiple comorbidities (nearly half with macrovascular disease) had an HbA1c level <7.5% (mean 6.7%) while being still quite intensively treated (Figure). Only ¼ were receiving oral monotherapy and 69% were receiving insulin secretagogues and/or insulin.

**Conclusion:** In clinical practice, most elderly T2DM pts with CKD appeared to be over-treated, putting them at high risk for severe hypoglycaemia. RI was insufficiently taken into account when adjusting anti-diabetics; at odds with current guidelines, 30% and 19% of elderly pts with severe RI were receiving metformin and SU, respectively.

**Patient-reported outcomes and costs associated with insulin and non-insulin therapies for type 2 diabetes in five European countries**S. Nuho<sup>1</sup>, J. Vietri<sup>2</sup>, G. Isherwood<sup>3</sup>, M. Worbes-Cerezo<sup>4</sup>;<sup>1</sup>Janssen-Cilag A/S, Birkerød, Denmark, <sup>2</sup>Kantar Health, Milan, Italy,<sup>3</sup>Kantar Health, Epsom, <sup>4</sup>Janssen Cilag Limited, High Wycombe, UK.

**Background and aims:** The progressive nature of type 2 diabetes (T2D) often requires escalation of therapy for glycemic control and to protect against complications, but the consequences of different management strategies on patient well-being are not well documented. This study was conducted to describe patient outcomes by medication regimen.

**Materials and methods:** Data came from the 2013 5EU National Health and Wellness Survey, representative of adults in France, Germany, Italy, Spain, and UK in terms of age and gender. Respondents were categorized into four groups by use of antihyperglycemic medications: 1 non-insulin medication, 2 non-insulin medications,  $\geq 3$  non-insulin medications, and therapy including insulin. Outcome measures included the SF-36v2, Work Productivity & Activity Impairment questionnaire, and 6-month self-reported healthcare use. Indirect costs were estimated using work impairment and wage statistics, and direct medical costs estimated using reported medical visits and unit costs. Groups were compared using ANOVA with pairwise t-tests and chi-square test for continuous and categorical variables, respectively.

**Results:** Of 2,894 respondents included in the final sample, 68% were male and 32% were employed. Respondents using insulin had the lowest average scores for mental health component summary (44.9) by >2 points, physical component summary (40.9) by 3.8 points, and SF-6D health utility (0.63) by 0.05 points. Twice as many respondents using insulin (24%) reported  $\geq 2$  hypoglycemic events requiring assistance per year as non-insulin users (5.6–11.9%). The average rating of activity impairment was 1.3 times as high in insulin users (46.5%) as in non-insulin users (32.0–34.2%), with similar increases in ratings of work impairment among the employed subsample using insulin (32.4%) vs other employed respondents (21.3–24.9%). Healthcare use was most frequent in respondents using insulin, with a mean 11 total provider visits vs 8 during the same period for other groups. Emergency visits (mean 0.4) and hospitalizations (mean 0.3) were also most frequent among insulin users. Estimated annual indirect costs were higher in the insulin group than in non-insulin mono- and dual-therapy patients, while estimated direct costs were higher among insulin users than any other group (Table). All presented differences  $p < 0.05$ .

**Conclusion:** T2D patients using insulin experience greater burden in health-related quality of life, impairment to work and activities, and use more healthcare than patients managed without insulin. Therapies that delay insulin initiation may potentially offer better quality of life and work productivity to patients and provide savings to the healthcare system, though confounds such as duration of diabetes may have affected results. Further research comparing insulin-based and non-insulin management strategies is required.

| Annual costs     | Non-insulin therapies |         |              |         |                           |         | Insulin therapies |         |

**Randomised trial of a type 2 diabetes community case worker intervention reduces hospitalisations and emergency visits over 3 years in a collaborative care model**R.O. Yeung<sup>1</sup>, Y. Zhang<sup>1</sup>, A.O. Luk<sup>1</sup>, Y. Cheung<sup>2</sup>, R. Ozaki<sup>1</sup>, H. Chung<sup>1</sup>, J.C.N. Chan<sup>1</sup>, W. So<sup>1</sup>;<sup>1</sup>Medicine, Chinese University of Hong Kong,<sup>2</sup>Ma On Shan Family Medicine Clinic, Hong Kong.

**Background and aims:** Collaborative care between family medicine doctors and specialists with periodic review at a diabetes centre reduced major clinical outcomes and mortality compared to management by family doctors alone. Further, increased contact time with support staff who promoted self-management and reduced negative emotions has improved metabolic control and reduced acute health care utilization. We hypothesized that provision of a community care worker (CCW) in the setting of collaborative care further improves metabolic control and reduces acute health utilization in patients with type 2 diabetes.

**Materials and methods:** In a collaborative care model, patients with type 2 diabetes attending a community-based family medicine clinic underwent annual comprehensive assessment (CA) at a specialist diabetes centre for risk stratification with personalized report and decision support using the web-based Joint Asia Diabetes Evaluation portal and were randomized to either additional support by a trained CCW (JADE+CCW) or JADE alone (JADE). Guided by the personalized report, the CCW counselled patients after the medical consultation to reinforce treatment adherence, self-care, and provide emotional support. Using intention-to-treat analysis, primary outcome was change in glycemic control after 3 years. Secondary outcomes included cardiometabolic control (changes in blood pressure and LDL-C), as well as acute health care utilization as measured by number of hospitalizations, total length of stay (TLOS), and number of emergency visits over 3 years. Metabolic control was measured at CAs. Hong Kong's public health care system services the majority of the population, so utilization measures were retrieved from the Health Authority database that captured all visits to public medical institutions within 3 years of enrolment. Negative binomial regression was used to ascertain the incident rate ratio (IRR) of hospitalization and emergency visits between groups, as well as rate ratio (RR) of TLOS.

**Results:** Of 661 patients recruited, 332 were randomized to JADE and 329 to JADE+CCW. At entry, 46% were male, with mean±SD age of 60.3±10.9 years, diabetes duration of 6.8±6.0 years, and HbA1c of 6.8±1.1%. The median number of CAs was 4 in both groups over 3 years, and those in the intervention group saw the CCW 12.2±4.3 times. After 3 years, HbA1c deteriorated in both groups (JADE 0.44% (95%CI 0.32- 0.55%) and 0.48% (95%CI 0.37- 0.70) in JADE+CCW (P=0.635 between groups)), whereas LDL-C improved in both groups. Systolic blood pressure improved in JADE+CCW from baseline (133.1 to 129.5mmHg, P<0.001) but did not in JADE (131.8 to 131.4mmHg P=0.406). In JADE, 44% had ≥ 1 hospitalization with a mean TLOS of 7.1±23.1 days and 50% had ≥ 1 emergency visit. The respective figures in JADE+CCW were 35%, 3.3±11.2 days and 43%. After adjusting for age, sex, diabetes duration, and risk level, the IRR (95% CI) in JADE+CCW was 0.77 (0.61-0.97) for hospitalization, 0.68(0.55-0.84) for emergency visits, and TLOS was 0.45(0.37-0.54) times as long compared to JADE.

**Conclusion:** The use of a trained CCW within a collaborative care setting reduced acute care utilization in patients with type 2 diabetes. These findings highlight the importance of using knowledge transfer and team-based management to make quality diabetes care more accessible and sustainable. Supported by: Asia Diabetes Foundation

## PS 091 Tailored diabetes care

## 1074

**Tailored support for type 2 diabetes patients with a first acute coronary event after discharge from hospital: results of a RCT in primary care**

M.J. Kasteleyn, R.C. Vos, G.E.H. Rutten, Diacourse Study Group; University Medical Center Utrecht (UMCU), Netherlands.

**Background and aims:** Type 2 diabetes mellitus (T2DM) patients with a recent acute coronary event (ACE) might experience decreased quality of life and increased distress. The first period after discharge is a critical time. We aimed to evaluate the effectiveness of a tailored supportive intervention on diabetes related distress, psychological well-being and clinical variables in T2DM patients and a recent first ACE.

**Materials and methods:** In this randomised controlled trial, the intervention group received a tailored supportive intervention based on the results of focus groups with patients and their partners. A diabetes nurse visited the T2DM patients at home within three weeks after discharge from hospital after a first ACE, and two weeks and two months later. From a list of ten topics, three were chosen by the patient and discussed with the patient and his/her partner, based on a protocol and with the use of a patient's handbook with assignments and homework. The attention control group received a consultation by telephone. Outcome variables were measured after discharge and five months later, using validated questionnaires: diabetes-related distress (PAID) well-being (WHO5), health status (EQ VAS), anxiety and depression (HADS). HbA1c, blood pressure and lipids were retrieved from the general practitioners' medical records. Differences between groups in change over time were analysed according to the intention-to-treat principle, using ANCOVA. The Holm-Bonferroni correction is used to adjust for multiplicity.

**Results:** Of the 201 randomised patients, 81 patients from the intervention group (age 65.8±9.3 yrs, 76.5% male) and 80 from the control group (age 65.6±9.4 yrs, 75% male) completed both baseline and follow-up questionnaires. All patients experienced low distress after discharge from hospital (8.7±11.8), which did not increase during the five months after discharge. Low levels of anxiety (4.1±3.8) and depression (3.7±3.5) were experienced at baseline and did not increase after five months. Baseline well-being (Intervention group: 60.6±27.4; control group: 58.2±25.5) and health status (Intervention group: 71.2±13.4 and control group: 68.8±16.2) were less favourable in both groups. A significant intervention effect was found for health status (effect size=0.35; p=0.007) and a trend was found for well-being (effect size=0.22; p=0.061). This corresponds to a small to moderate statistical and clinical difference in health status and in well-being between the two intervention and control group. From the patients in the intervention group (n=48) who received cardiac rehabilitation as well, 62% rated the intervention as having added value. Especially the individualised and timely character of the intervention was appraised.

**Conclusion:** This tailored intervention significantly improved the health status of T2DM patients shortly after discharge from hospital because of their first ACE. It did not influence the fortunately low levels of diabetes related distress, anxiety or depression in this group of patients.

Clinical Trial Registration Number: NCT01801631

Dutch Diabetes Research Foundation (no: 2009.70.)

## 1075

**Improvements of diabetic control in a diabetes day clinic compared to the classic out-patient approach**

V. Altabas, M. Strinović, J. Marinković, L. Ružman, G. Mirošević, M. Berković Cigrovski, D. Herman Mahečić, P. Sulentić, I. Kruljanc, M. Vrkljan;

Department of Endocrinology, Diabetes and Metabolic Diseases, UHC „Sestre milosrdnice“, Zagreb, Croatia.

**Background and aims:** Diabetic day clinics allow patient - focused, structured and extensive education, improving knowledge about the nature of diabetes, its complications, and therapy options. In a small group environment patients are able to ask questions, share their problems and hear other people's experiences. More frequent and precise pharmacological interventions are an additional benefit of diabetic day clinics. With acquisition of knowledge and skills necessary to control diabetes, a positive attitude of patients towards their illness develops, allowing better diabetes control on the long-term. The aim of this research is to show the superiority of a combined struc-

tured approach in diabetes day clinics in the treatment of adult patients with diabetes in comparison to periodical visits in out-patient clinics.

**Materials and methods:** A total of 280 adult diabetic patients participated in this study, 140 patients were treated in the diabetes day clinic, and 140 controls were treated as out-patients. There was no significant difference between groups considering age, sex, diabetes type, and diabetes duration at study start. The study group underwent structured theoretical and practical education about diabetic nutrition, weight control, physical activity, acute and chronic diabetic complications and pharmacological management. They received psychological assistance, and training in specific skills in the diabetes day clinic. The control group received standard care in the out-patient clinic. Routine biochemistry relevant to glycemic control (e.g. fasting and postprandial glycemia, HbA1c, lipidogram) was determined, and - if necessary - therapy was adjusted in all patients. BMI and routine biochemistry were repeated after 3 months. Statistical analysis was performed by using Student's t-test for numerical data, and chi-square test for qualitative data.

**Results:** In the study group, both fasting ( $10,68 \pm 3,89$  vs.  $8,34 \pm 2,49$  mmol/L,  $p < 0,0001$ ) and postprandial blood glucose ( $12,79 \pm 4,97$  vs.  $10,70 \pm 4,43$  mmol/L,  $p < 0,0001$ ) were significantly improved during treatment in the diabetes day clinic, consecutively there was a statistical significant reduction in HbA1c at the first control visit performed after three months ( $9,08 \pm 2,33$  vs.  $7,2 \pm 1,51$ ,  $p < 0,0001$ ), body mass index ( $30,33 \pm 5,80$  vs.  $30,11 \pm 5,33$  kg/m<sup>2</sup>,  $p = 0,0029$ ), and improved HDL cholesterol ( $1,21 \pm 0,36$  vs.  $1,33 \pm 0,36$  mmol/L,  $p = 0,0003$ ). In the control group, there was no statistical significant difference in controlled parameters noticed on control visits. Additionally, patients in the study group had significant lower values of fasting ( $8,34 \pm 2,49$  vs.  $8,92 \pm 3,03$  mmol/L,  $p = 0,03$ ), and a significant more profound drop in HbA1c levels ( $-1,84 \pm 0,15$  vs.  $+0,09 \pm 0,25$ ,  $p < 0,0001$ ) in comparison to controls after three months of follow up.

**Conclusion:** Diabetic day clinic provide a superior way to intervene in glyemic control, offering better chances for life style changes (reflected in a significant weight loss) and a better glycemic control.

## 1076

### Relation between perception of professional care provision and self-care activities in people with diabetes: Japanese DAWN2 subsample analysis

Y. Hayashino<sup>1</sup>, H. Ishii<sup>2</sup>;

<sup>1</sup>Tenri Hospital, Nara, <sup>2</sup>Nara Medical University, Kashihara, Japan.

**Background and aims:** It has not been studied whether the perception of people with diabetes (PWD) that they received care by a healthcare professional was associated with adherent self-care activities in PWD. The aim of this analysis was to investigate the association between the perception of PWD that they received diabetes care by a healthcare team and the diabetes self-care activities practiced by PWD and glycemic control using Japanese sub-sample data from the second Diabetes Attitudes, Wishes and Needs (DAWN2) study.

**Materials and methods:** The DAWN2 study was a multi-national questionnaire-based online survey of perceptions about healthcare provision for benchmarking and sharing of clinical practices to improve diabetes care in 17 countries. In Japan, a total of 508 PWD participated in the survey. PWD were asked whether they experienced healthcare provision (measuring HbA1c, blood pressure, lipid profile, etc.) during the past 12 months. Diabetes self-care activities were assessed using the Summary of Diabetes Self-Care Activities (SDSCA)-6 scores, representing the mean number of days that PWD performed specific self-care activities in the past 7 days. Statistical comparison was performed using the Mann-Whitney U test.

**Results:** The mean age of PWD was 54 years, and 57.9% were male. The mean duration of diabetes was 12.4 years and the mean HbA1c was 6.8%. With regard to healthcare provision, 91.3% of PWD recognized that they were provided with “measuring HbA1c level,” and 71.9% of PWD recognized that they were provided with “measuring weight.” In contrast, “examining feet” (15.7%) and “asking if having been anxious or depressed” were not frequently recognized (12.2%). PWD were more likely to practice “taking all diabetes medications exactly as previously agreed with a healthcare professional” (mean: 6.1 days) and “eating healthily” (4.1 days), and were less likely to practice “testing blood sugar” (2.6 days) and “checking feet” (1.4 days). PWD who recognized that they were provided healthcare provision, such as “examining feet” and “asking about the amount of physical activity,” showed a significant difference in the days of practicing the related self-care activity compared to PWD who didn't experience the healthcare provision. (“examining feet”: 2.0 days vs. 1.3 days, “asking about the amount of physical activity”: 4.2 days vs. 2.5 days.) PWD who experienced “examining feet” also showed a significant difference

in the days of practicing not only “checking feet” but also “eating healthily” and “testing blood sugar the number of times recommended by a health care provider” compared to those who didn't. HbA1c was significantly lower in the group who practiced 5 days or more of the following self-care activities: “eating healthily” and “being physically active” compared with the group who practiced less than 5 days of those self-care activities.

**Conclusion:** The findings of this analysis suggest that PWD who reported to have received sufficient healthcare provision practiced certain self-care activities more often, and that certain diabetes care provisions may have a favorable effect on all-around self-care activities. PWD who practice self-care activities more often may achieve better HbA1c as a treatment outcome.

### Shared decision making in type 2 diabetes using the Diabetes Medication Choice Decision Aid: preliminary results from a cluster-randomised trial

T. Karagiannis<sup>1</sup>, M.E. Branda<sup>2,3</sup>, A. Liakos<sup>1</sup>, E. Athanasiadou<sup>1</sup>, M. Mainou<sup>1</sup>, D.G. Goulis<sup>4</sup>, P. Boura<sup>1</sup>, V.M. Montori<sup>2,3</sup>, A. Tsapas<sup>1,5</sup>;

the Diabetes Medication Choice Cards Trial in Greece study group;

<sup>1</sup>Clinical Research and Evidence-Based Medicine Unit, Second Medical Department, Aristotle University, Thessaloniki, Greece, <sup>2</sup>Knowledge and Evaluation Research Unit, Mayo Clinic, Rochester, <sup>3</sup>Division of Health Care Policy and Research, Department of Health Sciences Research, Mayo Clinic, Rochester, USA, <sup>4</sup>Unit of Reproductive Endocrinology, First Department of Obstetrics and Gynaecology, Aristotle University, Thessaloniki, Greece, <sup>5</sup>Harris Manchester College, University of Oxford, UK.

**Background and aims:** Patient involvement in healthcare decisions is advocated in existing type 2 diabetes guidelines and can improve the quality of care. Decision aids (DAs) are tools that facilitate the shared decision making (SDM) process. In a cluster-randomised clinical trial we compared the efficacy of the Diabetes Medication Choice DA with usual care in patients with type 2 diabetes in Greece.

**Materials and methods:** Practices, matched by setting and level of care were randomly allocated to use of the DA or usual care to support decision making for choice of antidiabetic medications. Eligible patients required treatment intensification (HbA<sub>1c</sub> 7.5-10%) and had more than one available treatment options. The trial comprised an initial clinical encounter and two follow-up visits. Immediately after the initial encounter, we assessed the quality of the decision making process by a modified 13-item Decisional Conflict Scale, patient's knowledge about antidiabetic medications, and patient's and clinician's satisfaction.

**Results:** We enrolled five practices (N=101) to the DA arm and four practices (N=103) to the usual care arm, between May 2013 and February 2014. Patients' baseline characteristics were equally balanced between the two arms. Patients in the decision aid arm had better (lower), albeit not significantly, scores in overall decisional conflict (mean difference 7.0; 95% CI -8.1 to 22.2), and its subscales (Table). Knowledge transfer was high in both groups (mean difference 2.4%; 95% CI -16.0 to 20.7). Patients allocated to the DA and standard practice were equally satisfied. In most cases, physicians found the DA useful and reported that its use and integration in their clinical setting was easy. They also appeared willing to use a similar DA for patients with other chronic conditions.

**Conclusion:** Our results are similar to findings from trials that assessed the Diabetes Medication choice DA in US. Promoting patient-centered care through a DA for type 2 diabetes in Greece was positively accepted by clinicians and patients. Further research is needed to determine the DA's impact

on care experience and patient-oriented outcomes on populations with different background sets of values and preferences.

### Group-based self-management support leads to more adequate exercise behaviour in recently diagnosed type 2 diabetes patients

A.L. van Puffelen<sup>1</sup>, M. Rijken<sup>1</sup>, G. Nijpels<sup>2</sup>, G.E.H. Rutten<sup>3</sup>, F.G. Schellevis<sup>1,2</sup>; <sup>1</sup>NIVEL, the Netherlands Institute for Health Services Research, Utrecht, <sup>2</sup>Department of General Practice & Elderly Care Medicine, EMGO Institute for Health and Care Research, VU University Medical Center, Amsterdam, <sup>3</sup>Julius Center for Health Sciences and Primary Care, UMC Utrecht, Netherlands.

**Background and aims:** Adequate self-care behaviours and lifestyle changes are considered essential, though challenging elements in the management of type 2 diabetes mellitus (T2DM). Previous research indicated that illness perceptions of patients and partners are important precursors for health behaviours. In addition, interventions based on the Common-Sense Model of Self-Regulation (CSM) seem effective in enhancing health outcomes in various (chronic) conditions. We therefore developed a group-based self-management support programme for recently diagnosed T2DM patients (1-3 years post-diagnosis) and their partners, based on the CSM. In this study, we want to investigate the short and long-term effectiveness of this new course on self-care behaviours in T2DM.

**Materials and methods:** Randomised controlled trial with a pre-test (T0), post-test (T1) design and follow-up after six months (T2). T2DM patients were selected on the basis of medical records of participating general practices in different regions in the Netherlands and, after informed consent, randomly allocated to the intervention (four course sessions) or attention control (single information meeting) condition. Self-care was assessed with three items of the revised Summary of Diabetes Self-Care Activities (SDSCA) measure, assessing exercise, diet (both 0 - 7 days) and smoking (yes/no) during the past week. Exercise and diet were dichotomised into adequate ( $\geq 5$  days) and non-adequate behaviours. Effectiveness on self-care was established by logistic regression analyses adjusting for demographic characteristics (age, gender and educational level) and pre-test scores on self-care.

**Results:** A total of 167 patients participated in the study: 81 in the intervention and 86 in the control condition. 146 patients returned the T1 questionnaire (drop-out rate 13%). Participating patients had an average age of 64 years (SD = 10.10, 27 - 83 years) and 56% were male. At baseline, 43% of the patients reported adequate exercise, 77% adequate dietary and 82% non-smoking behaviours. Preliminary results showed a significantly higher proportion of self-reported exercise behaviours in the intervention group (47%) at T1 (OR = 2.42, CI = 1.07 - 5.50), compared to the control group (32%). No significant differences between the intervention and control group were found on (changes in) reported dietary (76% vs 72%) and non-smoking behaviours (87% vs 74%) at T1.

**Conclusion:** In the short term, a self-management support programme based on the CSM appears to be effective in enhancing adequate (self-reported) exercise behaviours in recently diagnosed T2DM patients. Results on long-term effectiveness of the course are currently investigated and will be presented during the conference.

## 1079

### Diabetes care process performance using the alphabet strategy compared to the national audit data: practice of evidence based medicine (POEM) 2013

J.D. Lee<sup>1</sup>, P. Saravanan<sup>2</sup>, V. Patel<sup>3</sup>;

<sup>1</sup>Diabetes Centre, George Eliot Hospital NHS Trust, Nuneaton,

<sup>2</sup>Metabolic & Vascular Health, <sup>3</sup>Education and Development, Warwick Medical School, Coventry, UK.

**Background and aims:** The Alphabet Strategy is a diabetes care checklist based on a mnemonic: A for advice with regard smoking cessation, ideal weight attainment, regular exercise; B for blood pressure; C for cholesterol profile and creatinine care; D for diabetes glycaemic control; E for yearly eye exam; F for regular year foot exam; and G for guardian drugs with regard to aspirin, ACE inhibitors, and statins. Such a management strategy has been demonstrated to be effective in ensuring performance of care processes and attainment of diabetes target parameters. We performed an audit of the notes of all patients with Type 2 diabetes attending the diabetes outpatient department using the Alphabet Strategy as an audit template to determine adherence to the checklist. We compared these results to the UK's recently published National Diabetes Audit 2011/12.

**Materials and methods:** The Diabetes Outpatient Clinic register was consulted for the names of patients currently attending the department. Relevant demographic and diabetes data were extracted from information attained at most recent clinic visit. Case notes, electronic letters and the computerised pathology reporting system were reviewed for outstanding care processes. Care performance within 15 months of the most recent clinic visit was registered as positive documentation. Data collection was performed over three months between October to end of December 2013. Statistical analysis was performed using chi-squared test.

**Results:** Data was available from 551 patients. Mean age of the whole cohort was 63 years. 18.7% of people were more than 74 years of age. Men comprised 59.2% of the study group, and as a group were of similar average age to females at 63 years. Compared to the NDA, POEM achieved better performance of care processes except for annual foot exam. For target process achievement, POEM achieved better control in total cholesterol and target blood pressure, but fared worse in glycaemic control.

**Conclusion:** The use of the Alphabet Strategy continues to help achieve performance of essential diabetes care processes.

| Care process recorded                 | Care process performed % of cohort |             | p value |
|---------------------------------------|------------------------------------|-------------|---------|
|                                       | POEM 2013                          | NDA 2011/12 |         |
| Smoking                               | 96.9                               | 85.9        | 0.002   |

## 1080

### Cost-effectiveness of centralised and partly centralised care compared to usual care for patients with type 2 diabetes

A.A.W. van der Heijden<sup>1</sup>, T.L. Feenstra<sup>2</sup>, M.C. de Bruijne<sup>1</sup>, C.A. Baan<sup>3</sup>,

G.A. Donker<sup>4</sup>, J.M. Dekker<sup>1</sup>, G. Nijpels<sup>1</sup>;

<sup>1</sup>The EMGO Institute for Health and Care Research, VU University Medical Center, Amsterdam, <sup>2</sup>UMC Groningen, <sup>3</sup>RIVM, Bilthoven,

<sup>4</sup>Nivel, Utrecht, Netherlands.

**Background and aims:** Due to an ever increasing number of type 2 diabetes patients, innovations to control the increasing health care use and costs are needed. Results of diabetes care programs on the costs or (cost-) effectiveness are heterogeneous. The aim of this study is to compare the cost-effectiveness of two diabetes care models with usual care for type 2 diabetes patients from the societal perspective.

**Materials and methods:** An economic evaluation was performed alongside a clinical trial. In two distinct regions of the Netherlands, two diabetes care models were implemented with different levels of centralized organizational structures. One of them was centralized care (CC) with a central organization and coordination of the care between all care providers and the use of a central database. Patients receive an annual extended diabetes assessment at the Diabetes Care Centre, in addition to the care by patients' general practitioner (GP). GPs receive feedback about their performance. Partly centralized care (PC) focuses on adherence to type 2 diabetes guidelines. An online clinical database is used to monitor mean values of risk factors. All assessments were performed in patient's GP practice. Usual care (UC) has a decentralized organisation structure and patients' GP is responsible for the diabetes care. Clinical outcome measure was risk of a coronary heart disease (CHD) calculated with the UKDPS risk engine. Cost-effectiveness analysis was performed from the societal perspective comparing patients receiving CC (n=313), PC (n=293) and UC (n=485) during one year of follow-up. Missing costs and effects data were imputed using multiple imputation. Differences in costs, effects and cost-effectiveness between the diabetes care groups were analysed using bootstrapping techniques.

**Results:** Differences in changes in CHD risk over 12 months of follow-up between the three groups were statistically insignificant and clinically irrelevant. Compared to UC, health care costs during the follow-up period were lower in CC (-1300 (95% CI: -2300 to -570)) and PC (-960 (95% CI: -1890 to -100)). Costs from the societal perspective showed the same trend, although not statistically significant.

**Conclusion:** Clinical outcomes did not differ between the different care models. Lower health care costs were observed in (partly) centralized care compared to usual care, mainly due to substitution of secondary health care use by primary health care use. This suggests that centralizing the diabetes care results in equal outcomes at lower health care costs.

### The effectiveness of the Diabetes Shared Care Program for diabetes-related avoidable hospitalisations in Taiwan: a nationwide population-based study

E. Kornelius<sup>1,2</sup>, C.-N. Huang<sup>1,2</sup>, J.-Y. Chiou<sup>3</sup>, Y.-S. Yang<sup>1,2</sup>, Y.-L. Lu<sup>1,2</sup>, C.-H. Peng<sup>4</sup>

<sup>1</sup>Department of Endocrinology and Metabolism, Chung Shan Medical University Hospital, Taichung, <sup>2</sup>Institute of Medicine of Chung-Shan Medical University, <sup>3</sup>School of Health Policy and Management, Institute of Medicine of Chung-Shan Medical University, <sup>4</sup>Institute of Biotechnology, Hungkuang University, Taichung, Taiwan.

**Background and aims:** The Diabetes Shared Care Program was implemented in 2001 by Taiwan's Ministry of Health and Welfare to improve the quality of diabetes care. The efficacy of this program is unknown and we aimed to evaluate whether Diabetes Shared Care Program participants had lower frequency of avoidable hospitalizations in Taiwan.

**Materials and methods:** We collected nationally representative data from Taiwan's National Health Insurance Research Database. The dataset comprised 120,000 patients who were newly diagnosed with type 2 diabetes in 1999. The analysis included the patients' follow-up data until December 31, 2011. We designed a case-control study consisting of patients with avoidable hospitalizations as cases and selected two age-, gender-, and avoidable hospitalization duration-matched controls by risk-set sampling. We further compared the hypoglycemia risk between Diabetes Shared Care Program participants and non-participants. We used the conditional logistic regression to estimate the crude and adjusted odds ratio (OR).

**Results:** A total of 2,377 avoidable hospitalizations cases and 4,754 matched-controls were identified. After adjusting for potential confounders in the stratified analyses, Diabetes Shared Care Program participants had a significantly lower frequency of all diabetes-related avoidable hospitalizations (OR, 0.15; 95% CI 0.13-0.17). A similar trend was found for short-term complications (OR 0.13; 95% CI 0.08-0.20), long-term complications (OR 0.13; 95% CI 0.11-0.16), uncontrolled diabetes (OR 0.21; 95% CI 0.15-0.30), and lower-extremity amputations (OR 0.06; 95% CI 0.03-0.13).

**Conclusion:** The Diabetes Shared Care Program decreased the frequency of all diabetes-related avoidable hospitalizations in Taiwan.

## PS 092 Screening and risk factors for gestational diabetes mellitus

### 1082

#### Screening for gestational diabetes mellitus in resource constrained settings

V. Mohan<sup>1</sup>, R. Unnikrishnan<sup>1</sup>, B. Bhavadharini<sup>1</sup>, M. Mahalakshmi<sup>1</sup>, K. Maheswari<sup>1</sup>, G. Kalaiyarasi<sup>1</sup>, R. Uma<sup>2</sup>, R.M. Anjana<sup>1</sup>, M. Deepa<sup>1</sup>, B. Malanda<sup>3</sup>, A. Belton<sup>3</sup>, A. Kayal<sup>3</sup>;

<sup>1</sup>Diabetology, Madras Diabetes Research Foundation & Dr. Mohan's Diabetes Specialities Centre, <sup>2</sup>Gynaecology, Seethapathy Clinic, Chennai, India, <sup>3</sup>International Diabetes Federation, Brussels, Belgium.

**Background and aims:** The International Association of Diabetes in Pregnancy Study Groups (IADPSG) criteria for screening for gestational diabetes mellitus (GDM) requires 3 venous samples drawn in the fasting state. This is difficult in resource-poor settings for two reasons: women find it difficult to come to the clinic in the fasting state and also obtaining three blood samples is difficult due to limited resources. We therefore assessed the usefulness of a non-fasting capillary blood glucose (CBG) as a preliminary screening test to reduce the number of women who would need to be referred for a definite diagnostic test done in the fasting state.

**Materials and methods:** Pregnant women (n=1031) attending antenatal clinics in Tamil Nadu in Southern India underwent a CBG test 2 hours after a 75 g glucose load administered irrespective of time of last meal (non-fasting). Participants were requested to come back within the next 2 to 3 days for a fasting OGTT, and both IADPSG and WHO (1999) criteria were used for diagnosis of GDM. The optimal sensitivity and specificity of the non-fasting 2 hour CBG value to identify GDM diagnosed by IADPSG and the WHO (1999) criteria were determined.

**Results:** A non-fasting 2 hour CBG value of 126 mg/dl (6.9 mmol/l) had sensitivity and specificity of 64.6% and 63% respectively to identify GDM diagnosed by IADPSG criteria, but 40% of all pregnant women would need to be referred for the fasting OGTT. For the WHO 1999 criteria, the CBG cutpoint of 144 mg% (7.9 mmol/l) had a sensitivity and specificity of 87.9% and 86.9% respectively and only 19.1% of the women would have to be referred for the fasting OGTT.

**Conclusion:** A 2 step screening procedure for GDM using a non-fasting 2 hour CBG as the initial screening test and use of WHO (1999) criteria would help to minimize the number of women who would need to be referred for a diagnostic OGTT in the fasting state and thus make screening for GDM feasible in resource constrained countries.

### 1083

#### Gestational diabetes: what is the impact of the adoption of the criteria of IADPSG?

M. Bachaoui<sup>1</sup>, K. Benharrat<sup>1</sup>, A. Rahou<sup>1</sup>, L. Benali<sup>1</sup>, A. Ouslim<sup>2</sup>, F. Ayad<sup>1</sup>, S. Aribi<sup>1</sup>, M. Belhadji<sup>1</sup>;

<sup>1</sup>University Hospital Establishment (EHU), Internal Medicine-Diabetology, <sup>2</sup>University Hospital Center (CHU), Obstetrics and Gynecology, Oran, Algeria.

**Background and aims:** We have always performed a systematic screening for gestational diabetes (GDM). The recommendations made in 2010 by the International Association of Diabetes and Pregnancy Study Groups (IADPSG) give the possibility for each country to choose whether the screening should be universal or selective on the basis of risk factors assessment (adjusted according to the prevalence of diabetes in the population). We have chosen to continue systematic screening. The aim of our study was to assess the level of risk in our screened population, and the maternal-fetal morbidity associated with GDM depending on the presence or absence of risk factors

**Materials and methods:** We retrospectively analyzed the data of all pregnant women admitted in day-hospital in the service of our hospital between June 1, 2010 and December 31, 2012 for screening for GDM. We conducted a systematic screening between 24 and 28 weeks of gestation by OGTT with 75 g glucose (IADPSG criteria). We evaluated the frequency of risk-factors: Age  $\geq$  35 years, BMI  $\geq$  25 kg/m<sup>2</sup>, history of diabetes in first degree relatives, previous GDM or macrosomic child. We compared the incidence of maternal and

fetal complications between the group with risk-factors (RF +) and the group without risk-factors (RF -).

**Results:** Of 1680 women screened, 330 had a GDM, an estimated prevalence of 19.6%. Among them 52 (15.8%) showed no RF : average age 28.3 years, mean BMI 23.6 kg/m<sup>2</sup>; and 278 (84.2%) had at least one RF : 128 (46%) had age  $\geq$  35 years, 208 (74%) BMI  $\geq$  25 kg/m<sup>2</sup>, 139 (50%) a history of GDM, 70 (25%) a history of macrosomia and 35 (12%), family history of diabetes. The maternal-fetal prognosis of the group without RF compared to the one with RF only differs in macrosomia: 7.3% vs 15.6% ( $p < 0.05$ ), preeclampsia 0% vs 6.2% (NS), preterm ( $< 37$  weeks) 16.6% vs 13.2% (NS), cesarean 32.2% vs 37.6% ( $p = 0.44$ ), insulin 63% vs 49% ( $p = 0.19$ ).

**Conclusion:** Our population has a high prevalence of GDM. It is diagnosed in a non-negligible population without RF. There is no significant difference in the maternal-fetal morbidity between the groups with and without RF, so it seems appropriate to maintain a systematic screening.

## 1084

### National guidelines for gestational diabetes mellitus (GDM) screening in Italy: application and effectiveness

E. Lacaria<sup>1</sup>, C. Lencioni<sup>2</sup>, M. Romano<sup>1</sup>, P. Lemmi<sup>2</sup>, M. Rossi<sup>1</sup>, L. Russo<sup>2</sup>, S. Del Prato<sup>1</sup>, A. Bertolotto<sup>1</sup>, G. Di Cianni<sup>2</sup>;

<sup>1</sup>Department of Endocrinology and Metabolism, Section of Diabetes and Metabolic Diseases, University of Pisa, <sup>2</sup>Department of Diabetes and Metabolic Diseases, Hospital of Livorno ASL<sup>6</sup>, Italy.

**Background and aims:** Universal screening for GDM has been used in Italy for over 20 years; since 2012 the National Health Authority recommended GDM screening only for women with risk factors. According to these new Criteria, screening test (OGTT 75 g 2 hours) is recommended early in pregnancy (14-18 week) in women at high risk (HG: previous GDM; pre-pregnancy BMI  $\geq 30$  kg/m<sup>2</sup>, glucose value at 1st visit between 100-125 mg/d.) and later in pregnancy (24-28 week) in women at medium risk (MR: pre-pregnancy BMI  $\geq 25$  and  $< 30$  kg/m<sup>2</sup>, age  $\geq 35$  years, previous macrosomia; positive family history of diabetes), while women at low risk (LR: no risk factors) are excluded from screening. The aim of the present study was to evaluate whether the new national guidelines (NGL), are correctly applied and the effectiveness of GDM diagnosis according to risk factor profile.

**Materials and methods:** We collected a cohort of 2552 Caucasian pregnant women (age  $33 \pm 5$  years; family history of diabetes 18.2%; pre-pregnancy BMI  $22.8 \pm 4$  kg/m<sup>2</sup>) consecutively screened for GDM according to NGL. For each category we recorded timing of screening test and prevalence of GDM. Finally, we compared GDM prevalence in this cohort with that one recorded in a historical cohort (years 2001-2003) of 3950 women with universal screening, this population being comparable with the most recent one (age  $31 \pm 5$  yrs, family history of diabetes 18.1%; pre-pregnancy BMI  $22.5 \pm 3.7$  kg/m<sup>2</sup>).

**Results:** Out of 98 LR women (3.8% of total), 2 (1.6%) underwent OGTT at early stage and the remaining 96 (98.4%) in the late period. MR women (n 2193) accounted for 86% and a late screening was performed in almost all cases (98.4%). The remaining 10.2% (n 261) included HR women who underwent early screening in only 7% of cases with 93% of them screened in the late period. GDM was diagnosed in 279 cases with a prevalence of 10.9%, i.e. 25.3% higher than previously reported in our population (8.7%;  $P = 0.003$ ). Based on risk factory categories, GDM prevalence increased from 4.7% in LR, to 13.7% in MR women, and 29.8% in HR.

**Conclusion:** Our data show that the NGL recommendations are still poorly applied. Contrary to what recommended only a minority of HR women perform the screening test early in pregnancy, in spite of a 30% prevalence of GDM. Action has to be taken to improve application of new recommendations.

## 1085

### Experiences of the providing for pregnancies complicated with IADPSG criteria

A. Kun<sup>1</sup>, J. Tornoczky<sup>2</sup>, L. Muth<sup>3</sup>, Z. Kerényi<sup>4,5</sup>, A.G. Tabak<sup>6,7</sup>;

<sup>1</sup>Department Obstetrics and Gynecology, Tolna County Balassa Janos Hospital, Szekszard, Hungary, <sup>2</sup>Diabetes Care Outpatient Unit, <sup>3</sup>3rd Department Internal Medicine, Tolna County Balassa Janos Hospital, Szekszard, <sup>4</sup>Diabetology, Tóth Ilona Health Service, <sup>5</sup>National Centre for Diabetes Care, Semmelweis University, <sup>6</sup>1st. Department of Medicine, Semmelweis University, Budapest, Hungary, <sup>7</sup>Department of Epidemiology and Public Health, University College London, UK.

**Background and aims:** Based on the results of the HAPO study IADPSG recommended in 2010 new criteria for diagnosing gestational diabetes (GDM). To our knowledge the new criteria might significantly increase prevalence of GDM. The aim of our study was to determine the result of the care of our IADPSG-GDM patients.

**Materials and methods:** Continuing the universal screening between 15th January 2009 and 15th March 2013 in the West Hungarian Region (Szekszard district) a three-points 75 g OGTT (fasting, 60- and 120 min blood glucose values) were performed in 4658 pregnant women (age:  $29.64 \pm 5.55$  yrs; mean  $\pm$  SD). GDM was diagnosed using new IADPSG criteria, too.

**Results:** 388 (WHO, 9.08 %) and 699 (IADPSG, 15.00%) resp., GDM cases were found. Women in both GDM groups - compared to healthy counterparts - were older ( $31.40 \pm 5.19$  vs.  $29.51 \pm 5.47$  yrs [WHO];  $31.14 \pm 5.13$  vs.  $29.35 \pm 5.49$  yrs [IADPSG]);, had significantly higher systolic blood pressure ( $121.38 \pm 9.66$  vs.  $119.17 \pm 9.33$  mmHg; [WHO];  $121.62 \pm 9.61$  vs.  $118.92 \pm 9.26$  mmHg [IADPSG]);. All-risk-scores of both GDM groups were significantly higher than that in the healthy women. According to both criteria 254 women had GDM. Using IADPSG criteria 104 WHO-GDM cases were lost, 435 new cases were found. There was no difference in the frequency of Caesarean section between healthy women and both GDM groups. Analysing data of 4900 newborn babies (71 twin pairs) no differences in the frequency of intrauterine death and congenital malformations between any groups could be proven. Babies born to IADPSG-GDM mothers had a bigger mean birth weight than newborn babies of healthy women ( $3413 \pm 548$  vs.  $3327 \pm 505$  g) while no differences were found by babies of WHO-GDM mothers ( $3340 \pm 537$  vs.  $3340 \pm 511$  g). The authors formed within IADPSG-GDM group treated /n:289/ (diet or diet and insulin) and untreated /n:409/ subgroup. The date in treated subgroup of IADPSG-GDM were: age:  $32.02 \pm 4.76$  yrs, weight gain:  $10.28 \pm 5.54$  kg birth weight:  $3331 \pm 531$ . vs. the date in untreated subgroup of IADPSG-GDM were: age:  $30.52 \pm 5.30$  yrs. weight gain:  $13.18 \pm 5.43$  kg birth weight:  $3470 \pm 554$  kg.

**Conclusion:** Analysing results of a universal screening using IADPSG criteria frequency of GDM probably doubles. In IADPSG-GDM the adverses pregnancy outcomes be prevented by complex pregnancy care.

## 1086

### Age at menarche: a new risk factor for GDM?

E. Anastasiou, A. Papadimitriou, M. Zairi, A. Angelopoulou, V. Vasileiou, E. Zapanti, M. Alevisaki;

Diabetes Center, <sup>1</sup>st Endocrine Section, Alexandra Hospital, Athens, Greece.

**Background and aims:** Earlier age at menarche has been associated with increased risk of type 2 diabetes (DM2) and obesity. As DM2 shares several common risk factors with Gestational Diabetes Mellitus (GDM), the aim of this study was to examine whether there is an association between age at menarche and GDM risk in a large cohort of pregnant women.

**Materials and methods:** Over a period of 10 years, at a tertiary hospital, 5390 pregnant women without known DM underwent a 100g OGTT in the third trimester of pregnancy. For GDM diagnosis the Carpenter and Coustan criteria were applied. Age, pre-pregnancy BMI, family history of DM2, parity, education status, smoking and age at menarche were recorded. For statistical analysis  $\chi^2$ , t-test were used; odds ratios (OR-95%CI) were calculated and stepwise logistic regression model was applied.

**Results:** GDM (n=2452) women presented with lower age at menarche compared to Normal (n=2938) pregnant women ( $12.9 \pm 1.5$  vs  $13.1 \pm 1.6$  years,  $p < 0.001$ ). Women with age at menarche equal to or more than 12 years were found to have a reduced risk of GDM (OR = 0.84 [95%CI = 0.76-0.94], compared to those with age at menarche less than 12 years. They also had lower BMI ( $25.1 \pm 5.0$  vs  $26.4 \pm 5.9$  kg/m<sup>2</sup>,  $p < 0.001$ ). Further the prevalence of obesity (BMI  $> 30$  kg/m<sup>2</sup>) was significantly lower in this group (14.1% vs 21.7%,

$p < 0.001$ ). The odds ratio for a woman with menarche age  $< 12$  years to be obese was 1.7 [95%CI=1.5–1.9]. Additionally, the presence of a family history (FH) of DM2 was associated with earlier age at menarche ( $12.7 \pm 1.5$  vs  $13.2 \pm 1.6$  years,  $p < 0.001$ ). The OR for age at menarche  $< 12$  years to have FH of DM2 was 1.4 [95%CI = 1.2–1.5]. Subsequently, a stepwise logistic regression model was applied where GDM was a dependent variable, and independent predictors were: age at menarche  $< 12$ y, age  $> 25$ y, positive FH of DM2 and BMI  $> 30$  kg/m<sup>2</sup>. The age at menarche remained an independent predictor of GDM when age and FH of DM2 were included in the model, but lost its significance when BMI was added in the model.

**Conclusion:** We showed that early age at menarche increases the risk of GDM, a finding which has not been reported. This association may be explained by the effect of obesity on both conditions, namely early menarche and GDM.

## 1087

### Drinking alcohol before pregnancy induces the abnormal foetus development through oxidative stress-mediated metabolic disorders in maternal liver and pancreas

D.-Y. Lee, Y.-J. Lee, J.-Y. Kim, E.-A. Jeong, K.-J. Park, G.-H. Kim, W.-H. Kim;  
Korea National Institute of Health, Cheongwon-gun, Chungbuk, Republic of Korea.

**Background and aims:** Alcohol drinking during pregnancy poses serious health risks to the unborn child such as prematurity, low or high birthweight, fetal death and fetal alcohol syndrome. However, the effects of maternal ethanol consumption before pregnancy on the abnormal development of fetus and the association with the impaired glucose tolerance of mother are not fully understood.

**Materials and methods:** To this, the 6-week C57BL/6J female mice were fed with 5% ethanol-containing liquid diet for 2 weeks before pregnancy and examined the effects of ethanol pre-exposure on fetal development during a subsequent pregnancy.

**Results:** Here, we found that pregnancy or fertility rates were decreased in ethanol-fed mice, correlated with the delaying of eye formation and the formation of defective toe. Also, birth weight in postnatal 0 day (P0) of ethanol-fed mice was higher than those of pair-fed mice, but thereafter, in P14 and P21, growth retardation appeared in the child of ethanol-fed mice. The macrosomia phenomenon in ethanol-fed mice is strongly associated with the dysregulation of glucose metabolism and triglyceride accumulation in maternal liver during the pregnancy. Gut-derived serotonin (GDS) as well as hepatic inflammatory chemokines and cytokines are also markedly increased in ethanol-fed mice, subsequently followed by the alteration of glucose metabolism in the liver and pancreatic  $\beta$ -cells. Alcohol intake changed the expression of GDS-response receptors from Gs-GPCR to Gi or Gq-GPCR. The detrimental fetal development and impaired glucose metabolism by maternal pre-exposure to ethanol are strongly attenuated by the injection of 4-methyl-prazol, an inhibitor of CYP2E1.

**Conclusion:** Taken together, our results suggest that ethanol consumption before pregnancy is a major causing factor for the detrimental fetus development via maternal metabolic disorders, especially on the dysregulation of glucose or insulin metabolism in maternal liver and pancreatic  $\beta$ -cells.

### Adverse foetal outcomes in women at risk of gestational diabetes with normal OGTT: exploring the role of HbA<sub>1c</sub> in risk prediction

A.U. Nayak<sup>1</sup>, C.J. Duff<sup>2</sup>, R. Indusekhar<sup>1</sup>, L. Varadhan<sup>1</sup>;  
<sup>1</sup>Combined Antenatal Diabetes Clinic, <sup>2</sup>Clinical Biochemistry, University Hospital of North Staffordshire NHS Trust, Stoke on Trent, UK.

**Background and aims:** Screening for gestational diabetes (GDM) is currently based on performing oral glucose tolerance test (OGTT) in pregnant women with various risk factors such as high body mass index, ethnicity and previous macrosomia. Women who get diagnosed with GDM with a positive OGTT benefit from targeted antenatal care towards improving pregnancy outcomes. However pregnancy outcomes in those women at high risk for GDM but normal glucose tolerance at screening are not well documented. The aim of our study was to compare the fetal complication profile in women confirmed to have gestational diabetes (GDM) with women at risk of GDM

but normal OGTT and explore the potential utility of HbA<sub>1c</sub> in predicting such fetal outcomes.

**Materials and methods:** The records of 40,943 deliveries performed at the regional maternity hospital over a 7 year period (2006–2013) were identified and reviewed. Women with pre-existing diabetes (type 1 or type 2) were excluded ( $n=203$ , 0.5%). Based on active identification of risk factors for GDM, OGTT was performed at around 28 week gestation ( $n=8,542$ ). HbA<sub>1c</sub> was performed simultaneously with the OGTT in line with the hospital policy. Women were categorized into (1) Low risk (i.e. those not screened for GDM with OGTT/HbA<sub>1c</sub>) ( $n=32,198$ ), (2) High risk with negative OGTT and HbA<sub>1c</sub>  $< 42$  mmol/mol ( $n=7,420$ ), (3) High risk with negative OGTT and HbA<sub>1c</sub>  $\geq 42$  mmol/mol ( $n=157$ ) and (4) confirmed GDM ( $n=965$ ).

**Results:** Women in high risk category with normal OGTT, especially those with HbA<sub>1c</sub>  $\geq 42$ , had statistically significant ( $P < 0.001$ ) and worst fetal outcomes (table 1). On logistic regression, the risk of fetal macrosomia was significantly higher in category 2 [OR 1.95 (1.57–2.42),  $P < 0.001$ ] and category 3 [OR 3.7 (1.53–9.35),  $P=0.004$ ], whilst for women with GDM it was a similar risk to that for women in low risk category. The risk of preterm delivery and still birth was also significantly higher in category 3 [OR 1.63 (1.02–2.61),  $P=0.041$  and OR 4.87 (1.78–13.29),  $P=0.002$  respectively] compared to the low risk group. The GDM group interestingly fared very similar to the low risk group, which could be largely attributed to the active intervention and follow up provided once diagnoses is established.

**Conclusion:** Women with risk factors for GDM but a negative OGTT, appear to be a high risk cohort for adverse fetal outcomes especially fetal macrosomia. A small but significant sub-cohort of these high risk women (1.8%) with elevated HbA<sub>1c</sub> could be at a further risk of pre-term delivery and still birth. HbA<sub>1c</sub> could potentially help in risk stratification of high risk women with negative OGTT. Such women may need risk reduction intervention including diet and life style measures in line with what is already offered for GDM.

Table 1: Fetal macrosomia (Birth weight  $> 4500$ g), Pre-term delivery (Before 37 week gestation) and Still birth in women categorised into low risk (category 1), high risk (categories 2 and 3) and with GDM (category 4)

|  | Fetal macrosomia | Pre-term delivery | Still birth |
|--|------------------|-------------------|-------------|
| Low risk (category 1)  | 1.3%             | 8.2%              | 0.5%        |
| High risk with negative OGTT and HbA <sub>1c</sub> $< 42$ mmol/mol (category 2)    | 2.6%             | 6.6%              | 0.3%        |
| High risk with negative OGTT and HbA <sub>1c</sub> $\geq 42$ mmol/mol (category 3) | 4.9%             | 12.7%             | 2.5%        |
| GDM (category 4)   | 1.2%             | 9.4%              | 0.3%        |

## 1089

### Beta cell death is not increased in pregnant women with gestational diabetes mellitus

E.M. Akirav, L.M. Kenna, M.S. Radin;  
Biomedical Research, Winthrop University Hospital, Mineola, USA.

**Background and aims:** Gestational diabetes mellitus (GDM) affects approximately 7% of all pregnancies in the United States. Although it is believed that insulin resistance and reduced  $\beta$ -cell function are the underlying causes of GDM development, changes in  $\beta$ -cell mass during GDM remain largely unknown. We have previously developed a novel biomarker assay for the detection of  $\beta$ -cell death in type 1 diabetes by measuring the levels of  $\beta$ -cell derived demethylated insulin DNA in the blood. This study is designed to evaluate the levels of  $\beta$ -cell death in normal subjects and in patients with gestational diabetes mellitus.

**Materials and methods:** Serum samples from women with gestational diabetes mellitus (GDM) were compared with samples from women with normal pregnancy (PRG), women at postpartum (PP), and non-pregnant (NP) women. Samples were analyzed for  $\beta$ -cell derived DNA as a biomarker of  $\beta$ -cell death. Postprandial glucose, insulin and c-peptide levels were also measured.

**Results:** Women with GDM showed higher glucose levels when compared with PRG (PRG=105.9 $\pm$ 7.24 vs. GDM=201.7 $\pm$ 6.96 mg/dL,  $p < 0.0001$ ). Surprisingly,  $\beta$ -cell derived insulin DNA levels were lower in GDM when compared with PRG and NP groups (Demethylation index: PRG=0.19 $\pm$ 0.09, GDM=0.009 $\pm$ 0.0009, PP=1.06 $\pm$ 0.78, and NP=0.05 $\pm$ 0.047; GDM vs. PRG  $p=0.0175$  and GDM vs. NP  $p=0.0132$ ). This decrease in  $\beta$ -cell death was

associated with reduced insulin (PRG=18.69±2.22, GDM=4.05±2.34, PP=8.11±3.56, and NP=3.78±2.04 μU/mL; ANOVA  $p=0.0005$ , PRG vs. GDM  $p=0.01$ , PRG vs. PP  $p=0.05$ , PRG vs. NP  $p=0.01$ ) and c-peptide (PRG=3.36±0.64, GDM=0.24±0.10, PP=2.01±0.74, and NP=1.66±0.44 ng/mL; ANOVA  $p=0.0042$ , PRG vs. GDM  $p=0.01$ ) levels.

**Conclusion:** This study shows, for the first time, lower  $\beta$ -cell death in women with GDM, suggesting that  $\beta$ -cell death is not a main contributor to the development of GDM.

## 1090

### Genetic variants associated with type 2 diabetes and obesity better predict gestational diabetes than traditional risk factors

J. Hryniewicka<sup>1</sup>, M. Zbucka-Kretowska<sup>2</sup>, N. Wawrusiewicz-Kurylonek<sup>3</sup>, W. Bauer<sup>3,4</sup>, M. Szamatowicz<sup>1</sup>, B. Telejko<sup>3</sup>, M. Kuzmicki<sup>1</sup>, J. Szamatowicz<sup>1</sup>, M. Gorska<sup>3</sup>, A. Kretowski<sup>3,4</sup>,

<sup>1</sup>Department of Gynecology,

<sup>2</sup>Department of Reproduction and Gynecological Endocrinology,

<sup>3</sup>Department of Endocrinology, Diabetology and Internal Medicine,

<sup>4</sup>Centre for Clinical Research, Medical University of Białystok, Poland.

**Background and aims:** There is increasing evidence that gestational diabetes (GDM) shares genetic risk with type 2 diabetes (T2DM) and that 50 % of women with prior GDM develop T2DM in the next few years. Recent meta-analyses have shown that T2DM risk variants may be associated with GDM through different mechanisms, including impaired  $\beta$ -cell function (CDKAL1, IGF2BP2, KCNQ1, KCNJ11, MTNR1B), insulin resistance (TCF7L2), and abnormal glucose utilization (GCK). So, in the present study we evaluated the risk of GDM development associated with genetic variants increasing the susceptibility for obesity and T2DM.

**Materials and methods:** Four hundred and seventy four pregnant women, including 103 diagnosed as having GDM according to the JADPSG criteria and 371 controls with normal glucose tolerance, were genotyped for 65 SNPs, identified in genome wide-associated studies as risk variants for T2DM and obesity.

**Results:** On the basis of genotype case-control differences we found an association between GDM and four obesity gene variants (BAT2 [rs2260000] - OR=2.07 [1.05-4.1],  $p=0.03$ ; MTCH2 [rs10838738] - OR=1.97 [1.002-3.88],  $p=0.045$ ; FAIM2 [rs7138803] - OR=1.95 [1.15-3.34],  $p=0.012$ ; CRY2 [rs11605924] - OR=0.56 [0.34-0.92],  $p=0.021$ ), and three T2DM risk variants (TCF7L2 [rs7901695] - OR=1.67 [1.16-2.4],  $p=0.03$ ; SLC30A8 [rs11558471] - OR=1.67 [1.16-2.4],  $p=0.007$ ; CDKAL1 [rs10946398] - OR=1.62 [1.02-2.56],  $p=0.036$ ). In logistic regression model comprising all studied SNPs, adjusted for relevant clinical data, GDM was significantly predicted by BMI before index pregnancy (OR=1.15 [1.07-1.23],  $p=5.2 \times 10^{-5}$ ) and 4 studied SNPs: CDKAL1 (rs10946398) - OR=1.67 (1.02-2.1),  $p=0.04$ ; GCK (rs4607517) - OR=2.64 (1.31-5.3),  $p=0.007$ ; ADRA2A (rs10885122) - OR=2.88 (1.36-6.1),  $p=0.003$  and KCTD15 (rs29941) - OR=2.17 (1.2-3.9),  $p=0.007$ .

**Conclusion:** Our results suggest that genetic variants associated with T2DM and obesity better predict GDM than the patient's age, the history of previous births and BMI before pregnancy. The mechanisms related to GDM risk seem complex and comprise the effect of numerous genes involved in insulin secretion/function and glucose homeostasis.

### MTNR1B genetic variability is associated with gestational diabetes in Czech women

D. Vejrazkova<sup>1</sup>, P. Lukasova<sup>1</sup>, M. Vankova<sup>1</sup>, O. Bradnova<sup>1</sup>, J. Vcelak<sup>1</sup>, V. Cirmanova<sup>1</sup>, K. Andelova<sup>2</sup>, H. Krejci<sup>3</sup>, B. Bendlova<sup>1</sup>;

<sup>1</sup>Institute of Endocrinology, <sup>2</sup>Department of Mother and Child Care,

<sup>3</sup>Department of Obstetrics and Gynecology, 1st Faculty of Medicine, Charles University and General University Hospital in Prague, Prague, Czech Republic.

**Background and aims:** The gene *MTNR1B* encodes a receptor for melatonin, the main regulator of sleep cycle and circadian rhythm. Melatonin receptors are expressed in the brain and also in human pancreatic  $\beta$ -cells. This finding implies that genetic variants in the gene might affect glucose tolerance. Meta-analysis confirmed that rs10830963 shows the most robust association. The aim of our study was to assess and compare the SNP rs10830963 in the Czech GDM patients and in control normoglycemic women without history

of GDM. We also aimed to study relations between the risk conferring allele G of the SNP and biochemical as well as anthropometric characteristics in both groups.

**Materials and methods:** Our cohort of subjects consisted of 880 women, 458 of them were diagnosed with GDM (age 34,0±6,12 years; BMI 24,3±4,93 kg/m<sup>2</sup>) and they met the 0.5-1.5 year interval after the childbirth. 422 were normoglycemic control women without history of GDM (age 34,8±15,09 years; BMI 23,7±4,18 kg/m<sup>2</sup>). We evaluated broad biochemical (3-hour oGTT, lipid profile, thyroid and steroid hormones, liver enzymes) and anthropometric (BMI, WHR, waist circumference, fat distribution, total body fat content) parameters in all participants. We used the ABI TaqMan SNP Genotyping Assays to genotype for rs10830963. Statistical analysis was conducted using the NCSS 2004 software.

**Results:** In accordance with available literature data, the risk allele G was in our study significantly more frequent in the GDM group (38.3 % vs 29.4 % in controls, test power 0.96; OR 1.49 CI 95% [1.22; 1.82]  $pOR=0.0001$ ). Despite of higher frequency, the G allele in the GDM group was not associated with any markers of glucose metabolism nor with anthropometric data. In contrast, controls showed significant association of the allele G with fasting plasma glucose (median 4.95 mmol/l in GG genotype vs. 4.60 mmol/l in CG as well as in CC genotypes;  $p=0.002$  and  $p<0.001$ , resp.) and also with postchallenge levels of glycemia during the 30., 60., and 90. min. of the oGTT. Fasting insulinemia was in controls similar across the genotypes, nevertheless, postchallenge insulin levels were higher in GG homozygotes compared with CC genotype in 90. and 180. min. of oGTT, the same results were observed in C-peptide concentrations. Consequently, Cederholm index of insulin sensitivity and HOMA-F index were higher in CC homozygotes in comparison with risk GG genotype ( $p=0.02$  and  $p=0.05$ , resp.).

**Conclusion:** Significantly higher frequency of the risk conferring allele G in GDM group indicates that *MTNR1B* SNP rs10830963 is involved in gestational diabetes mellitus in Czech women. However, the association of the SNP with glucose metabolism, which is obvious in healthy control group of women, disappears completely in women of similar age and BMI who have experienced GDM.

## PS 093 Gestational diabetes mellitus management

### 1092

#### Gestational diabetes mellitus and health care cost: short- and long-term association

A. Danyliv<sup>1,2</sup>, P. Gillespie<sup>1</sup>, C. O'Neill<sup>1</sup>, F. Dunne<sup>2,3</sup>,

ATLANTIC DIP (Diabetes in Pregnancy) Research Team;

<sup>1</sup>School of Business and Economics, <sup>2</sup>School of Medicine, Clinical Sciences Institute, <sup>3</sup>Galway Diabetes Research Centre, National University of Ireland Galway, Ireland.

**Background and aims:** There is an extensive body of literature showing that gestational diabetes mellitus (GDM) diagnosed on WHO criteria is associated with maternal, ante- and neonatal complications. Yet, little is known about the health care cost associated with GDM beyond the period immediately after the delivery and maternity care cost associated with GDM on the International Association of Diabetes and Pregnancy Study Group (IADPSG) criteria. In this paper, we assess the association of the GDM diagnosis on the IADPSG criteria with the health resource utilization during maternity care and in longer term, two to five years after the index pregnancy.

**Materials and methods:** Maternity care utilization was measured for a sample of 658 women drawn from the Atlantic Diabetes in Pregnancy (ATLANTIC DIP) collaborative network who have had pregnancy two to five years previously. Annual health care utilization two to five years after the index pregnancy was assessed for a sub-sample of 348 women who returned a follow-up questionnaire. Irish cost weights were applied to the health care resource utilization to assess the cost of care. The difference in resource utilization and cost between women with GDM and normal glucose tolerance in the index pregnancy was assessed in a series of uni-variate and multivariate analyses.

**Results:** The independent effect of GDM is approximately additional € 817.6 to the maternity cost and additional € 680.5 to the annual health care cost two to five years after the delivery. However, at the group/population level the effect might be higher due to inherent background differences of the women with GDM and NGT, especially worse body mass indicators. The excess in the maternity care cost is caused by higher likelihood of caesarean section and neonatal unit admissions in women with GDM. For the follow-up health care cost, most of the excess is related to higher chances of hospitalizations and outpatient unit visits not related directly to diabetes care. Diabetes care (diabetes nurse, dietitian, diabetes day centre, insulin and oral glucose agents, and blood sugar tests) constitutes smaller but still substantial part of the cost increase.

**Conclusion:** Thus, our results suggest that GDM on IADPSG criteria is associated with increased cost of maternity care and health care two to five years after the index pregnancy. This excess is not so much caused by the glucose tolerance treatment and monitoring routines as by more intensive use of hospital services, indicating worse health status of GDM women. Hence, this diagnosis objectively represents a serious condition altering health care cost around and beyond pregnancy. These findings provide information for further cost-effectiveness studies of the programs of GDM screening, treatment and monitoring in Irish setting.

### 1093

#### The effect of professional continuous glucose monitoring on glycaemic control and hypoglycaemia in insulin-requiring gestational diabetes mellitus

S.S. Paramasivam<sup>1</sup>, A.T.B. Tan<sup>1</sup>, S.P. Chan<sup>1</sup>, P.C. Tan<sup>2</sup>, S.Z. Omar<sup>2</sup>, J. Ratnasingam<sup>1</sup>, L. Ibrahim<sup>1</sup>, L.L. Lim<sup>1</sup>, R.A. Razak<sup>1</sup>, F.Z.M. Shah<sup>1</sup>, S.R. Vethakkan<sup>1</sup>;

<sup>1</sup>Endocrinology, <sup>2</sup>Obstetrics and Gynaecology, University of Malaya, Kuala Lumpur, Malaysia.

**Background and aims:** Reducing hyperglycemia in gestational diabetes mellitus (GDM) improves pregnancy outcomes and reduces perinatal morbidity. Continuous Glucose Monitoring (CGM) is ideal for monitoring glucose levels where tight glycaemic control without hypoglycaemia is required for a short period of time. While CGM is known to improve glycaemic control/pregnancy outcomes in women with pre-gestational diabetes the same has

not been established in GDM. **Aims:** To determine if professional CGM improves glycaemic control with less hypoglycaemia in insulin-requiring GDM. **Materials and methods:** In this prospective, open-label trial 24 women with insulin requiring GDM, gestation < 28 weeks, were randomized to 2 groups. Group 1 (CGM) (n=11) underwent CGM using the iPro2 Enlite 6-day sensor at 28, 32 and 36 weeks gestation while Group 2 (control) did not. All patients performed 7 point fingerstick glucose profiles 3x/week, recorded hypoglycemic events (symptoms without glucose readings or fingerstick fasting glucose < 3.5/nonfasting glucose < 4.0 mmol/L) and were reviewed at 1-2 weeks intervals. In group 1, both CGM and fingerstick data were used to manage diabetes while women in group 2 were managed based on fingerstick data alone. HbA1c was measured at weeks 28, 33 and 37. Euglycemia on CGM was defined as 3.5-6.7 mmol/L.

**Results:** There were no significant differences in mean age, prepregnancy BMI, HbA1c and total insulin dose between groups at baseline. In the control group, mean HbA1c rose significantly from week 28 (5.31±0.52%) to 33 (5.42±0.56%) to 37 (5.6±0.63%), while HbA1c in the CGM group did not change significantly from week 28 (5.06±0.3%) to 33 (4.95±0.34%) and 37 (5.01±0.35%). HbA1c was significantly higher in controls compared with CGM at 33 and 37 weeks gestation. In the CGM group, 100% of patients at 37 weeks had HbA1c < 5.6% compared to only 46.2% in controls (p=0.006). There was also a significant difference in mean change in HbA1c from 28 weeks to 37 weeks between the 2 groups (CGM -0.05%, control +0.29%, p=0.017). Mean time spent in euglycemia in the CGM group increased from the 1<sup>st</sup> to the 3<sup>rd</sup> CGMS at week 28 and 36 respectively (79.18±10.01% to 85.00±7.69%, p=NS) and mean time spent in hyperglycemia decreased (18.82±10.73% to 11.55±7.07%, p=NS). There was however an increase in mean time spent in hypoglycemia (2.00±2.83% to 3.45±3.78%, p=NS). 63.6% of patients in the CGM group (7/11) showed increased frequency of hypoglycemia from 28 weeks to 37 weeks compared to 30.8% (4/13) in the control group. The CGM group showed a significant increase in mean total insulin dose at 37 weeks compared to controls (52.91±27.92 vs 33.92±14.98 units, p<0.05). Mean birth weight in the CGM group was lower compared to controls (2851.8±323.3 vs 3065.8±464.0 g, p=NS).

**Conclusion:** Glycaemic control in the women who underwent CGM was significantly better compared to women who received usual antenatal care based on fingerstick glucose alone. Use of CGM however, was associated with an increase in hypoglycemic events explained perhaps by the concomitant increase in total insulin received as a result of greater awareness of hyperglycemia by the managing team.

### 1094

#### Gestational diabetes mellitus: the first prospective randomised study of metformin-glyburide vs insulin

J.-L. Ardilouze<sup>1,2</sup>, J. Ménard<sup>2</sup>, P. Perron<sup>1,2</sup>, G. Houde<sup>1,2</sup>, J.-M. Moutquin<sup>3,2</sup>, M.-F. Hivert<sup>1,4</sup>, J.-P. Baillargeon<sup>1,2</sup>;

<sup>1</sup>Department of Medicine, <sup>2</sup>Centre de Recherche du Centre Hospitalier Universitaire de Sherbrooke, <sup>3</sup>Department of Obstetrics and Gynecology, University of Sherbrooke, Canada, <sup>4</sup>Harvard Pilgrim Health Care Institute, Department of Population Medicine, Boston, USA.

**Background and aims:** Oral hypoglycemic agents (metformin - Met - and glyburide - Gly) have been used separately to treat gestational diabetes mellitus (GDM), with various failure rates imposing insulin therapy. Because GDM is mostly the consequence of insulin resistance and beta-cell deficiency, we reasoned that a combination of both drugs (Met-Gly) might efficiently treat women with GDM and may decrease the failure rate. For ethical and safety considerations, only half-maximal dosages were prescribed as per Health Canada suggestions. Here, we assessed maternal glycaemic control (GC) and neonatal issues.

**Materials and methods:** We performed a randomized controlled study comparing a Met-Gly combination of half-maximal doses (Met 1250 mg/day, Gly 10 mg/day, with an incremental increase in dosages) to intensive insulin therapy (aspart/lispro and N/NPH) in women with GDM who did not achieve Canadian Diabetes Association treatment goals under diet (±exercise as indicated) therapy (capillary fasting glucose value < 5.3 mmol/L and 2-hr postprandial glucose value < 6.7 mmol/L). GC was defined as the 2-week mean of capillary glucose values (fasting and 2 hours after each 3 meals) measured daily (mean of 14 values for each recording time point).

**Results:** Treatments started at 29.3±3.8/30.1±3.1 weeks of gestation, respectively, in the Met-Gly (n=35) and the insulin (n=33) groups, while there was no difference between groups in age (31.1±4.7/30.7±4.4 yrs), weight

(85.3±17.5/85.3±22.9 kg), BMI (32.0±5.4/32.2±7.2 kg/m<sup>2</sup>) and GC recorded during the previous 2 weeks: fasting glucose value was 5.3±0.7/5.3±0.6; postprandial glucose values were: 6.3±0.8/6.3±0.7, 6.6±0.8/6.4±0.6 and 6.8±0.8/6.8±0.9 mmol/L, respectively post breakfast, lunch and supper. At delivery, in the Met-Gly group, 8 women were taking Met only (844±265 mg daily), 14 were taking Met (1179±153 mg) and Gly (3.9±1.9 mg), 10 were on Met-Gly+insulin (1333±250 mg, 8.6±2.2 mg and 12.7±9.9 units) and 3 were on insulin alone. In the 13 women taking insulin (37%), injections were started 4.2±2.1 weeks after initiation of Met-Gly treatment. There was no difference in insulin doses between women taking insulin alone in the Met-Gly group and women in the insulin group: breakfast: 7.0±4.2/11.3±9.0, lunch: 8.5±4.9/9.6±8.1, supper: 11.0±4.2/10.3±6.8, bedtime: 11.0±7.1/18.7±15.1 units. During the 2 weeks prior to delivery, no difference was observed in GC between groups (fasting: 4.7±0.3/4.8±0.3; postprandial 5.8±0.4/5.9±0.5; 5.8±0.5/5.9±0.5; 6.0±0.5/6.1±0.5 mmol/L). At delivery, we found no difference in the number of caesarean sections (9/8), neonatal birth weight (3360±389/3227±570 g), gestational age (38.7±1.1/38.4±1.5 weeks) or neonatal hypoglycemia (21/15).

**Conclusion:** Our data suggest that a majority of women with GDM could benefit from hypoglycemic agents: a combination of mild doses of Met-Gly successfully controlled GC in >60% women with GDM, with neonatal outcomes that are comparable to those of neonates born to women with GDM on insulin therapy.

### Metformin in gestational diabetes and fasting glucose as a predictor of treatment failure

M.O. Khin<sup>1</sup>, S. Gates<sup>2</sup>, P. Saravanan<sup>1,3</sup>,

<sup>1</sup>Division of Metabolic and Vascular Health, <sup>2</sup>Clinical Trial Unit, Warwick Medical School, University of Warwick, Coventry, <sup>3</sup>Department of Diabetes & Endocrinology, George Eliot Hospital, Nuneaton, UK.

**Background and aims:** Gestational Diabetes (GDM) is common and affects up to 18% of pregnancy. Proper glycaemic control is the key to the reduction of GDM-related maternal and neonatal morbidity and mortality. The current guidelines suggest insulin or metformin only after dietary failure. Almost half of metformin-treated GDM need supplementary insulin. Identifying the characteristics of women who fail metformin may help to define optimal therapeutic strategy in GDM.

**Materials and methods:** This was a historical cohort of GDM in a District General Hospital, UK between 2009 and 2012. GDM was diagnosed by 75 g OGTT test between 24–28 weeks of gestation with fasting level ≥6.1 mmol/l and/or 2-hour post-prandial (PP) level ≥ 7.8 mmol/l. Treatment targets were: pre-meals 4–5.5 and 1-hour post meals < 7.8 mmol/l. The treatment was escalated if 2–3 readings per week were above target. Daily metformin dose was 500–2000 mg. Non-parametric tests were applied appropriately to compare the treatment groups. Logistic regression and receiver operator curve (ROC) were performed to identify the predictors of metformin failure.

**Results:** Of the 299 being diagnosed and treated, complete treatment data were available in 228. Out of 228, 31(14%) were diet(D) alone, 141(62%) were on metformin(M) and 46(15%) on insulin(I) until delivery. 10 stopped metformin for gastrointestinal intolerance and were excluded from analysis. Compared to D group, despite older age(29 vs 32 years, p<0.05), greater BMI(27.45 vs 31.5, p<0.01), higher fasting(4.5 vs 4.9 mmol/l, p<0.01) & PP(8.1 vs 8.5 mmol/l, p<0.05) and earlier gestational age(GA) at OGTT (30<sup>+3</sup> vs 26<sup>+4</sup> weeks, p<0.001) in M group, the outcomes(birth weight, Apgar scores at 1 and 5 minutes, caesarean section, shoulder dystocia and NICU admission rates) were similar, but borderline higher average HbA<sub>1c</sub> (5.35 vs 5.5 %, p=0.05) and earlier GA at delivery (39 vs 38<sup>+2</sup> weeks, p<0.01) in M group. The maternal characters between M and I groups had no significant difference, and M group had lower average HbA<sub>1c</sub> (5.7 vs 5.5%, p<0.05) and all other outcomes were similar. 57% (80/141) of the metformin-treated GDM needed insulin. Both metformin success(M alone) and failure(M+I) groups had similar post-treatment HbA<sub>1c</sub> (5.45 vs 5.5%, p=0.38). The failure group had higher maternal age (30 vs 32 years, p<0.05) and fasting level at OGTT (4.6 vs 5.2 mmol/l, p<0.001) and lower GA at dietary failure (29<sup>+2</sup> vs 27<sup>+6</sup> weeks, p<0.01). Metformin failure was predicted if fasting OGTT level > 4.8 mmol/l (69% sensitivity, 63% specificity). If the fasting level of IADPSG (International Association of Diabetes and Pregnancy Study Groups) criteria (≥5.1 mmol/l) was used, the positive predictive value was 79%. Premature delivery (<37 weeks) were higher in the failure group (OR 12.6; 95% CI 1.6, 99.8).

**Conclusion:** Metformin can be a better alternative than insulin for optimal glycaemic control in GDM. As metformin can benefit greater than diet alone, metformin should be initiated early at the diagnosis of GDM, based on fasting glucose at diagnosis. It is also important to consider adding basal insulin at initiation of metformin or alternative treatment option for the GDM identified by IADPSG fasting criteria for optimal treatment strategy.

## 1096

### Type 2 diabetes mellitus genetic risk variant T in TCF7L2 rs7903146 in women is associated with an increased probability of insulin therapy in gestational diabetes mellitus

L. Potasso<sup>1</sup>, N. Perakakis<sup>1</sup>, A. Lamprinou<sup>2</sup>, E. Polyzou<sup>3</sup>, D. Kassanos<sup>3</sup>, A. Peter<sup>2</sup>, R. Rasenack<sup>4</sup>, G. Páth<sup>1</sup>, J. Seufert<sup>1</sup>, K. Laubner<sup>1</sup>;

<sup>1</sup>Internal medicine II, Uniklinik Freiburg, ,

<sup>2</sup>Clin. medicine IV, Uniklinik Tübingen, Germany, <sup>3</sup>Obstetrics and Gynaecology, University Hospital of Attikon, Athens, Greece,

<sup>4</sup>Gynaecology and Obstetrics, Uniklinik Freiburg, Germany.

**Background and aims:** Single nucleotide polymorphisms (SNPs) within the transcription factor 7-like 2 (TCF7L2) gene are well known risk variants for type 2 diabetes mellitus (T2DM). The rs7903146 SNP is involved in glucose- and incretin-induced insulin secretion and in proinsulin conversion. The aim of this international multicentric analysis was to assess and compare the effect of the TCF7L2 rs7903146 T risk variant on the development and clinical course of gestational diabetes mellitus (GDM).

**Materials and methods:** We genotyped the C/T polymorphism of the TCF7L2 gene variant rs7903146 in 150 unrelated Caucasian women with a history of GDM and in 160 non-diabetic pregnant women as control. The enrolment took place in Germany and in Greece. The prevalence of non-risk CC and risk TT alleles in the two groups was compared. Moreover, in the GDM group we evaluated the impact of the T risk allele on clinical sequelae and outcomes, defined as need for therapy with insulin and macrosomy of the offspring.

**Results:** The TT variant was associated with increased risk of GDM (p=0.021). Women carrying the T risk allele mutation had a lower BMI (mean 24.86 kg/m<sup>2</sup> for TT vs 26.06 kg/m<sup>2</sup> for CC), and a higher probability of initiation of insulin therapy, both in homozygotes (p = 0.02) and heterozygotes (p=0.001) for the mutation. No statistically significant effect of the T allele on the development of macrosomy was detected (p > 0.05).

**Conclusion:** The TT genotype of TCF7L2 rs7903146 is associated with an increased risk of GDM in Caucasian women. This confirms the hypothesis of a common genetic background between GDM and T2DM. Moreover, the T allele is associated with the necessity of therapy with insulin in GDM, both in homozygotes as well as in heterozygotes, independently from BMI. These results suggest an independent effect of the T risk allele on the severity of GDM.

## 1097

### Blood pressure, microalbuminuria and weight gain in women with gestational diabetes

A. Galdon, O. Gonzalez Albarrán, A. Matei, M. Cano, S. Calvo; Endocrinology, Hospital Ramón y Cajal, Madrid, Spain.

**Background and aims:** Women with prior gestational diabetes mellitus (GDM) are at increased risk of developing type 2 diabetes and associated vasculopathy. Moreover, more than 30% of the women have overweight or obesity. The aim of the present work was to study the relationship between overweight/obesity and weight gain during the pregnancy and the development of hypertension in women with gestational Diabetes. Moreover, we studied the urinary albumin excretion and its possible relationship with blood pressure levels and the glucose abnormalities in women with GDM.

**Materials and methods:** We prospectively studied 422 women with GDM. We evaluated: glucose control (HbA<sub>1c</sub>/monthly, need of insulin therapy), BMI (before the pregnancy), Weight gain (according to IOM, 2009). Blood pressure was measured at each office visit. We defined hypertension when the confirmed blood pressure levels were SBP/DBP ≥140/90 mmHg or antihypertensive treatment. Microalbuminuria and glomerular filtration by MDRD were measured. We collected obstetric history, personal history of GDM and personal and family history of cardiovascular risk factors.

**Results:** The mean age was 33,45 ± 4,5 yrs.; 26,25% smoking, 15,6% history of dyslipemia, 30% had history of previous abortions, 62,34% of women had first-degree relatives with type 2 DM and 59,25% had family history of hy-

pertension. 43 of the women with GDM (10,2%) presented hypertension during the pregnancy. The time of diagnosed of hypertension was  $27 \pm 4,2$  weeks. The prevalence of overweight /Obesity (estimated by BMI before pregnancy) was significant higher in the group of GDM women with hypertension (mean BMI=28,86 $\pm$ 4,5 kg/m<sup>2</sup>) during the pregnancy as compared to the GDM women without hypertension(mean BMI= 28,86 $\pm$ 4,5 kg/m<sup>2</sup>), 72% in the group with hypertension vs. 23% in the GDM women without hypertension ( $p<0.005$ ). The weight gain during the pregnancy was higher in the group of GDM women with hypertension (28% of them had an increase in their weight higher that the IOM recommendations, 2009), by contrast, only 13% of GDM women without hypertension We found a significant relationship between the levels of SBP/DBP and the levels of urinary albumin excretion ( $r=0.42$ ,  $p<0.05$ ). Greater percentage of GDM women with hypertension needed insulin therapy for the glucose control as compared with GDM without hypertension ( $p<0.05$ ).

**Conclusion:** Women with GDM, the overweight/obesity before pregnancy and the increase in the weight during the pregnancy are related with the development of hypertension.

## 1098

### Hypertension in type 2 diabetic pregnancy: 24hr ambulatory blood pressure monitoring vs conventional office cuff measurement

G. Roma<sup>1</sup>, E.R.M. Belinfante<sup>2</sup>, O. Bitterman<sup>1</sup>, P. Chianello<sup>1</sup>, M. Framarino<sup>3</sup>, C. Giuliani<sup>1</sup>, V. Toscano<sup>1</sup>, H.L. Lutgers<sup>4</sup>, A. Napoli<sup>1</sup>;

<sup>1</sup>Department of Clinical and Molecular Medicine, S. Andrea Hospital, Sapienza University, Rome, Italy, <sup>2</sup>Rijksuniversiteit Groningen, UMCG, Netherlands, <sup>3</sup>Department of Obstetrics and Gynecology, Sapienza University, Rome, Italy, <sup>4</sup>Department of Endocrinology and Metabolism, University Medical Center Groningen, Netherlands.

**Background and aims:** There are only few data on hypertension in type 2 diabetic pregnancy. Hypertension diagnosis is conventionally based on office conventional measurements. However, nowadays new technologies exist that give relevant additional information on blood pressure. Our primary aims were: 1) To determine the additional value of 24h-blood pressure monitoring (ABPM) in terms of hypertension prevalence and prediction of pregnancy outcome in comparison to conventional approach. 2) To characterize and model the blood pressure profiles of the type 2 diabetic women that developed hypertension during pregnancy.

**Materials and methods:** Retrospective study of 52 type 2 diabetic pregnant women, age 24-39yrs, diabetes duration of at least 1 year (on average 9.5yrs), and average pregestational BMI of 26.99kg/m<sup>2</sup> were followed throughout entire pregnancy. Blood pressure (BP) was measured with both the conventional method and 24h-ABPM. According to the guidelines, hypertension (conventional BP levels $\geq$ 140/90mmHg) was classified as chronic, gestational, or preeclampsia. The 24h-ABPM (cut-offs 24hr $\geq$ 130/80, daytime 135/85, night-time $\geq$ 120/70mmHg) defined white-coat, sustained and masked hypertension. Data were processed using the IBM program 'SPSS 20'. X2, Fisher's and Kruskal-Wallis test were performed when appropriate. P-values  $<0,05$  were considered significant.

**Results:** The two methods classified different patients as hypertensive. Conventional method identified 13 (25%) women with hypertensive disorders (6 sustained + 7 white-coat hypertension). 24h-ABPM identified 17 women with hypertensive disorders (32.7%) (6 sustained + 11 masked hypertension). Six women were classified as hypertensive with both methods (sustained hypertension). Thus 24h-ABPM hypothetically spared 7 subjects (white-coat) from unnecessarily intensive therapy. In the third trimester, short-term variability of both daytime ( $p<0.034$ ) and 24h-measurements ( $p<0.001$ ) of hypertensive women were significantly higher than in normotensive women. First trimester 24h-ABPM curves of women who developed hypertension later in pregnancy were consistently higher compared to those who didn't develop hypertension. Hypertensive disorders did not alter maternal and fetal outcome(just one case with preeclampsia).

**Conclusion:** 24h-ABPM showed significantly more accuracy in diagnosing and predicting the onset of hypertension already since the first trimester in type 2 diabetic pregnancies. Moreover, it succeeded in identifying masked, sustained and white-coat hypertension over the conventional method, fundamentally improving the opportunity for appropriate treatment We would strongly suggest to use 24h-ABPM in the screening for hypertension in high risk groups such as type 2 diabetic pregnancies.

## 1099

### Gestational diabetes and obstetric cholestasis: a 10 year retrospective cohort review of outcomes and predictors

J. Marathe<sup>1</sup>, W. Lim<sup>2</sup>, G.A. Dekker<sup>2,3</sup>, W.M. Hague<sup>3,4</sup>;

<sup>1</sup>Division of Medicine, Queen Elizabeth Hospital, Woodville South,

<sup>2</sup>Women's and Children's Division, Lyell McEwin Hospital, Elizabeth Vale,

<sup>3</sup>Robinson Institute, University of Adelaide,

<sup>4</sup>Women's and Children's Hospital, Adelaide, Australia.

**Background and aims:** Obstetric cholestasis (OC) is a gestational liver disorder of unclear aetiology, associated with increased perinatal morbidity and mortality. Recent reports have suggested a link between OC and gestational diabetes (GDM), which also carries increased perinatal risks. Only two series of patients have been published to date with little information on what may predict the development of GDM in OC patients, and no Australian data currently published. Our aims were to look at the diagnosis of GDM associated with OC, review the outcomes of cases associated with both, and to screen for predictors that may indicate patients to be at increased risk of developing GDM.

**Materials and methods:** A retrospective case review was conducted of all pregnancies associated with antenatally-diagnosed OC (diagnosed by serum bile acids (SBA)  $\geq 10$   $\mu\text{mol/L}$  with associated pruritus) at two major hospitals providing 80% of public antenatal care in South Australia, Australia between 2001 and 2010. All files were reviewed for severity of OC (severe = SBA  $\geq 40$   $\mu\text{mol/L}$ ), fetal and maternal complications, presence of GDM (defined by Australian guidelines current at the time of pregnancy), and additional, including demographic, information deemed relevant. As an initial analysis binary predictors were analysed against the presence of GDM using the chi-squared test, and then by multivariate analysis using logistic regression.  $P < 0.05$  was considered significant.

**Results:** 346 women were identified as being diagnosed with OC during 390 individual pregnancies over the 10 year period; 47 pregnancies were also affected by GDM (14% of total pregnancies affected by OC + GDM); 6 women had diabetes prior to pregnancy, and were excluded from subsequent analysis. There were no fetal deaths in OC + GDM pregnancies, and 85% of deliveries occurred at or after 36 weeks in this group (vs. 86% in OC only pregnancies;  $P=0.8$ ). Univariate analysis for predictors of GDM was conducted using the variables listed in the table; the only variables that remained significant in the multivariate analysis were [normal] Body Mass Index (BMI) ( $P=0.002$ ) and not being on ursodeoxycholic acid ( $P=0.001$ ).

**Conclusion:** The data supports the finding of an increased rate of GDM in pregnancies complicated by OC, at almost double the local rate when compared with the general pregnant population. This is the largest identified cohort to date with both conditions, and is the first series to suggest that normal BMI and not being on ursodeoxycholic acid may decrease the risk of developing OC-associated GDM. Although it is reassuring that there were no deaths, there is still the potential for a complicated course, and further investigation with larger cohorts, and more variables as potential predictors should be investigated.

| Binary Variable<br><i>*Italicised outcomes indicate the modelled outcome</i> | Univariate analysis (P) | Multivariate analysis (odds ratio, 95% confidence interval, P) |

## PS 094 Pregnancy outcomes in gestational diabetes mellitus

### 1100

#### Improved outcome of women with gestational diabetes mellitus

C. Nilsson<sup>1</sup>, D. Ursing<sup>2</sup>, H. Strevens<sup>3</sup>, M. Landin-Olsson<sup>2</sup>;

<sup>1</sup>Department of Paediatrics, Institution of Clinical Science, Helsingborg,

<sup>2</sup>Department of Endocrinology, <sup>3</sup>Department of Obstetrics and

Gynaecology, Institution of Clinical Science, Lund, Sweden.

**Background and aims:** The number of women with gestational diabetes mellitus (GDM) during pregnancy is increasing around the world, with a 10–100% increase in some race/ethnicity groups. GDM affects 1–14% of all pregnant women and is more common in populations with high frequency of type 2 diabetes. Among known risk factors for GDM is higher age, overweight, prior GDM and/or family history of diabetes. There are complications for the mother and child associated with GDM, both during and after pregnancy. With better maternity care and glucose control during pregnancy we expect improvement in outcome. The aim of this study was to compare pregnancy outcome of women with GDM 2013 against women with GDM 1995–1998.

**Materials and methods:** Since 1995 in our region in Sweden, all pregnant women are tested with a 2-hour oral glucose tolerance test (OGTT) consisting of 75 g glucose in solution as a general screening for GDM in the 28th gestational week. The cut off value for GDM in Sweden is  $\geq 10.0$  mmol/l in capillary plasma glucose and is based on the European Association for the Study of Diabetes (EASD) recommendations. Women who receive a GDM diagnosis are transferred to our specialised maternity unit with a team of obstetrician, diabetologist, midwife and dietician. In 2013, 115 women received GDM diagnosis and as comparisons we choose all women who had GDM during 1995–1998 (n=115) in our region. The women's medical journals from their GDM pregnancy were studied retrospectively. Duplex pregnancies (n=2 2013, n=3 1995–1998) as well as infants born before 37 weeks of gestation (n=10 2013, n=11 1995–1998) and after 41 weeks of gestation (n=0 2013, n=3 1995–1998) were excluded from the analysis regarding the newborn.

**Results:** When comparing women who had GDM 2013 against women with GDM 1995–1998, there was no significant difference between the groups regarding age of the mother, ethnicity, family history of diabetes, gestational length, HbA1c, insulin treatment during pregnancy, height of the mother, length of the newborn and apgar score at 5 and 10 minutes of the newborn. However, first weight of the women during GDM pregnancy 2013 was significantly higher than the weight of women with GDM 1995–1998, 71 kg (43–119) (n=114) and 64 kg (43–133) (n=111; p=0.007) respectively. However, there was no significant difference in weight of the mother at delivery. For women with GDM 2013 weight at delivery was 80 kg (54–130) (n=49) and for women with GDM 1995–1998 weight at delivery was 78 kg (55–138) (n=77; p=NS). Birth weight of the child in GDM pregnancies 2013 was 3508 g  $\pm$  487 (n=81) and in GDM pregnancies 1995–1998 3741 g  $\pm$  589 (n=94; p=0.005). The percent of caesarean delivery was 24% in the GDM pregnancies 2013 and 17% in the GDM pregnancies 1995–1998 (p=0.04).

**Conclusion:** Even though women with GDM 2013 weigh more when they start the pregnancy there is no difference in weight at delivery compared to women with GDM 1995–1998. This is also reflected on the newborn, that 2013 had significantly lower birth weight but with the same gestational length as 1995–1998. We believe that this is due to a more active and intense treatment of women with GDM during pregnancy together with higher frequency of caesarean delivery. Prevention of large infants is crucial to avoid complications during delivery.

### 1101

#### Gestational diabetes: perinatal outcomes compared to background population and pregestational diabetes

J.C. Wiebe<sup>1,2</sup>, B. Vega Guedes<sup>3,2</sup>, A. López Alonso<sup>3</sup>, O. Ramírez García<sup>3</sup>, F. Cabrera Morales<sup>3</sup>, L. Valle Morales<sup>3</sup>, J.A. García Hernández<sup>3,2</sup>, A.M. Wäger<sup>1,2</sup>;

<sup>1</sup>Endocrinology Dept, Complejo Hospitalario Universitario Insular-Materno Infantil de Gran Canaria, <sup>2</sup>Instituto Universitario de Investigaciones Biomédicas y Sanitarias, Universidad de Las Palmas de Gran Canaria, <sup>3</sup>Gynaecology and Obstetrics Dept., Complejo Hospitalario Universitario Insular-Materno Infantil de Gran Canaria, Las Palmas de Gran Canaria, Spain.

**Background and aims:** Prevalence of gestational diabetes (GD) ranges between 5–14% and is associated with an increased risk of maternal and fetal complications. The aim of this study was to assess the prevalence of GD and its outcomes in our population and to compare perinatal results with those of the general population (GP) and pregestational diabetes (PD).

**Materials and methods:** All patients with GD (NDDG criteria) who delivered at our centre (reference for our region) between January 2011 and December 2012 were identified, and their records were reviewed and compared to those with pregestational diabetes and the background population. Statistical analysis was performed using Microsoft Excel and SPSS for Windows. For frequency comparisons between groups, chi-squared was used. A bilateral p<0.05 was considered significant.

**Results:** A total of 11480 deliveries were registered, 874 of whom (7.6%) had GD and 123 (1%) PD (44.6% type 1). Women with GD were more frequently above 35 than the GP (43.7% vs 28.9% p=0.004), similar to those with PD (41%), more frequently overweight/obese (BMI > 25 kg/m<sup>2</sup>) than the GP (62.6% vs 42.9% p<0.05), but similar to the PD (75% p=0.15) and more often multiparous than the GP (68.4% vs 40.2% p<0.05) and PD (54.6% p=0.04). There was a trend towards more induction of labour (42.3% vs 31.7% p=0.06) and cesarean sections (21.2% vs 14.8% p=0.07) in GD than in the GP, but less cesarean sections than in the PD (43.9% p<0.05) and no differences in gestational age at delivery. No significant differences were found in perinatal mortality when compared to the GP (5.7% vs 3.8% p=0.32) or the PD (8% vs 7.7% p=0.7). Macrosomy (>4Kg) was more frequently seen in the GD than in the GP (10% vs 9.9% p<0.05), but less than in the PD (26.7% p<0.05). Shoulder dystocia occurred as often as in the GP (1% vs 0.73% p=0.75), but less than in the PD (6.5% p<0.05). No differences were found in Apgar scores or pH at birth. Admission to the Neonatal Unit was more frequent in the GD than the GP (19.4% vs 10.2% p=0.004) and tended to be less than the PD (28.5% p=0.08).

**Conclusion:** The prevalence of GD in our population is in the lower range of what has been described in other populations. Women with GD are at higher risk (age, obesity) and have worse perinatal results than the general population, although better than women with PD.

Supported by: ISCIII PI11/02441

### 1102

#### Maternal and infant outcomes of women with milder degrees of GDM treated with diet only compared to women with normal glucose tolerance

O. Kgosidialwa, F. Dunne, A. Egan, L. Carmody, B. Kirwan; Galway University Hospital, Ireland.

**Background and aims:** The prevalence of GDM has increased worldwide in part as a result of increasing obesity rates but also as a result of the implementation of the new evidence based IADPSG criteria. GDM results in increased health care costs and efforts to reduce these costs without increasing adverse effects to mother and child need to be considered. Thus the aim of this study was to ascertain if any subset of milder degrees of GDM treated with diet only have comparable outcomes to those with NGT and thus may be suitable for ongoing management in a less intensive setting in primary or community care.

**Materials and methods:** This observational retrospective cohort study carried out a secondary analysis of the ATLANTIC DIP dataset. Two groups of women one with diet treated GDM and one with NGT were extracted from an anonymised dataset and compared. The impact of BMI in addition to a diagnosis of GDM was also analysed. The following maternal (caesarean section, polyhydramnios, pre-eclampsia) and infant outcomes (LGA, admission to neonatal unit, hypoglycemia and congenital malformations) were examined. Pearson's Chi squared test was used to ascertain statistical differences.

between GDM and NGT. Logistic regression was used to model relationships between maternal and infant outcomes and BMI as a categorical variable (<25, 25–30, >30) in the two groups.

**Results:** 5806 women were identified, 887 with GDM and 4919 with NGT. Baseline characteristics were similar between the groups. Women with GDM had a higher risk of polyhydramnios (OR= 3.06; 95% CI 1.72–5.44) and C-section (OR=1.32; 95% CI 1.06–1.66) compared to women with NGT. A BMI >30 further increased the risk of C-section (OR =2.76 95% CI 2.20–3.46). C-section rate in women with BMI >30 was twice as common in GDM compared to NGT women (60.3% vs 31.6%,  $P<0.05$ ). Rates of PET were not influenced by GDM status but were increased with BMI >30 (OR=2.21 95% CI 1.55–3.16). Infants of mothers with GDM had a higher risk of hypoglycemia (OR 6.39 95%CI 3.34–12.3) and congenital malformations (OR= 1.77 95%CI= 1.37–2.29) compared to infants of NGT mothers. BMI did not impact on this any further. Rates of LGA were greatest with BMI >30 (OR 1.76 95% CI 1.44–2.16). Neonates of GDM mothers were twice likely to be admitted to the neonatal unit compared to neonates of NGT mothers (18.5% vs 9.1%,  $P<0.05$ ).

**Conclusion:** Milder forms of GDM requiring dietary intervention only are associated with a higher risk of adverse maternal and infant morbidities when compared to women with NGT. These adverse events increase further in those with a BMI >30. Thus these women need to be monitored and treated in the high intensity multi disciplinary hospital environment and are not suitable for ongoing less intensive care in the primary care or community setting. *Supported by: HRB*

## 1103

### Analysis of pregnancy outcomes in gestational diabetes mellitus based on the new IADPSG criteria compared to the former criteria

M. Egloff<sup>1</sup>, K. Gariani<sup>1</sup>, S. Prati<sup>1</sup>, J. Philippe<sup>1</sup>, M. Boulvain<sup>2</sup>, F.R. Jornayvaz<sup>1</sup>,  
<sup>1</sup>Division of Endocrinology, Diabetology, Hypertension and Nutrition,  
<sup>2</sup>Division of Obstetrics, Geneva University Hospitals, Switzerland.

**Background and aims:** Results from the Hyperglycemia and Adverse Pregnancy Outcomes (HAPO) study led the International Association of Diabetes and Pregnancy Study Groups (IADPSG) to propose new diagnostic criteria for Gestational Diabetes Mellitus (GDM). The new IADPSG criteria have lower glucose concentration thresholds, with an increase in GDM prevalence as a consequence. In our institution, these criteria were implemented in September 2011. The aim of this study was to determine if the use of the new diagnostic criteria led to changes in the management and in the occurrence of pregnancy complications among women diagnosed with GDM compared to the old diagnostic criteria.

**Materials and methods:** We conducted a retrospective study of women with GDM followed at a single multidisciplinary university center. We included all consecutive women between July 2009 and December 2010 (group 1) diagnosed using the old criteria (O'Sullivan followed by a 100 g oral glucose tolerance test) and between January 2012 and April 2013 (group 2) using the revised criteria (IADPSG consensus, 75 g oral glucose tolerance test in the fasting state). All women were instructed to adapt their diet and record self-monitoring of blood glucose according to international guidelines. No oral antidiabetic drugs were used. Parameters assessed were: percentage of women requiring insulin therapy; and pregnancy complications: caesarean section, macrosomia (birth weight >90<sup>th</sup> percentile) and preeclampsia. Management guidelines have not been modified between the two periods.

**Results:** We included 286 women with GDM, 129 in group 1 and 157 in group 2. Mean age was similar between groups (34.0±5.4 (group 1) versus 33.0±5.2 (group 2) [years],  $P=0.12$ ), as were BMI (25.2±5.3 versus 26.1±5.1 [kg/m<sup>2</sup>],  $P=0.17$ ) and weight gain during pregnancy (13.3±5.7 versus 13.2±6.9 [kg],  $P=0.94$ ). There was a trend - although not significant - towards a lower percentage of women requiring insulin therapy in group 2 (55.0% (group 1) versus 43.3% (group 2),  $P=0.06$ ) However, we did not find a significant difference in the number of caesarean section (38.9% versus 43.1%,  $P=0.55$ ), the number of babies born with macrosomia (37.6% versus 33.0%,  $P=0.74$ ) and the occurrence of preeclampsia (1.6% versus 1.3%,  $P=1.0$ ).

**Conclusion:** Our study indicates that, when using the new IADPSG criteria, we include women with a less severe GDM, as less women required insulin in addition to dietary advice. There was no significant difference in caesarean section, macrosomia and preeclampsia.

## 1104

### Excessive weight gain and pregnancy outcomes in pregestational and gestational diabetes

J. Sastre<sup>1</sup>, F. Del Val<sup>1</sup>, C.M. Cortes<sup>1</sup>, A.M. Luque<sup>1</sup>, M. Olivar<sup>1</sup>, A. Marco<sup>1</sup>, V. Peña<sup>1</sup>, A. Pantoja<sup>2</sup>, M. Veganzones<sup>3</sup>, J. López<sup>2</sup>;  
<sup>1</sup>Endocrinology, <sup>2</sup>Pediatrics,  
<sup>3</sup>Obstetrics, Complejo Hospitalario de Toledo, Spain.

**Background and aims:** Women with diabetes mellitus (DM) during pregnancy are at higher risk of adverse maternal and neonatal outcomes. Excessive gestational weight gain (GWG) is a potential risk factor for these adverse results. In 2009 the Institute of Medicine (IOM) established recommendations for appropriate GWG in non-diabetic women. We try to examine if excessive GWG, using IOM recommendations, in pregnancies with pregestational diabetes mellitus (PGDM) or gestational diabetes (GDM) is associated with higher adverse pregnancy outcomes.

**Materials and methods:** We performed a retrospective study of 2773 singleton pregnancies in women with DM [(259 PGDM (176 type 1 DM, 83 type 2 DM), 2514 GDM)]. Maternal weight and body mass index (BMI) had been recorded pre-pregnancy and at the time of delivery. GWG was calculated and compared with IOM guidelines to assess if the upper limit per BMI category was breached. Examined maternal outcomes included pre-eclampsia, gestational hypertension and cesarean delivery. Fetal outcomes included large for gestational age (LGA), macrosomia and neonatal morbidity. Multivariate analyses were performed and odds ratio calculated using a logistic regression analysis adjusted with age, parity, ethnicity, pre-pregnancy BMI, and neonatal sex.

**Results:** 1. Women with PGDM: 46,2% demonstrated excessive GWG. In the excessive GWG group a higher percentage were overweight (60,2%) or obese (56,2%,  $p<0,01$ ). There were no significant differences in GWG between type 1 and type 2 DM. Excessive GWG was associated with higher odds for LGA (OR 2,5 , CI 1,4-4,7  $p<0,01$ ), macrosomia (OR 6,4 , CI 2,2-20  $p<0,01$ ) and cesarean delivery (OR 2,1, CI 1,1-3,9  $p<0,05$ ). 2. Women with GDM: 18,3% demonstrated excessive GWG. A higher percentage in the group with excessive GWG were overweight (40,2%) or obese (35,2%,  $p<0,01$ ). Insulinization was more frequent in the excessive GWG group (43,0% vs 52,6%,  $p<0,01$ ). Excessive GWG was associated with higher odds for LGA (OR 2,3, CI 1,7-3,1  $p<0,01$ ), macrosomia (OR 2,2 , CI 1,5-3,3  $p<0,01$ ) and cesarean delivery (OR 1,6, CI 1,3-2,0  $p<0,05$ ).

**Conclusion:** Excessive GWG confers an additional risk for LGA, macrosomia and cesarean delivery of both GDM and PGDM. Multidisciplinary lifestyle intervention programs must be implemented to achieve weight control in all women with diabetes during pregnancy.

## 1105

### Mental health in early pregnancy is associated with pregnancy outcome in women with pregestational diabetes

N.F. Callesen<sup>1,2</sup>, A.L. Secher<sup>1,2</sup>, P. Cramon<sup>3</sup>, L. Ringholm<sup>1,2</sup>, T. Watt<sup>2</sup>, P. Damm<sup>1,3</sup>, E.R. Mathiesen<sup>1,2</sup>;  
<sup>1</sup>Center for Pregnant Women with Diabetes, <sup>2</sup>Department of Endocrinology,  
<sup>3</sup>Department of Obstetrics, Rigshospitalet, Copenhagen, Denmark.

**Background and aims:** This study aims to explore the role of early pregnancy locus of control, presence of anxiety and depression, and health-related quality of life for pregnancy outcomes in women with pregestational diabetes.

**Materials and methods:** A cohort of 148 pregnant women with diabetes (118 type 1 diabetes and 30 type 2 diabetes), originating from a clinical trial cohort from 2009 to 2011, completed three internationally validated questionnaires; Multidimensional Health Locus of Control, Hospital Anxiety and Depression Scale and 36-Item Short-Form Health Survey - SF 36 at 8 weeks of gestation. Selected pregnancy outcomes were preterm delivery (<37 weeks) and neonatal overweight (large for gestational age, birth weight >90<sup>th</sup> percentile). Differences between groups were analysed by unpaired t-test. Three women giving birth to a small for gestational age infant were excluded from the analyses of the large for gestational age group vs. appropriate for gestational age group.

**Results:** Women with preterm delivery (n=28) had worse quality of life scores for the SF-36 Mental Component Summary (mean 42.8 (SD 13.1) vs. 48.8 (9.7),  $p=0.03$ ), SF-36 Emotional Role Limitations (58.3 (38.1) vs. 82.9 (31.3),  $p=0.0005$ ) and SF-36 Mental Health (67.7 (20.4) vs. 75.2 (15.8),  $p=0.04$ ) at 8 weeks of gestation, compared to women delivering at term. Both women delivering preterm and women delivering at term had high levels of internal locus of control (30.4 (5.5) vs. 29.8 (4.9), maximum score 36,  $p=0.57$ ), and

comparable lower levels of locus of control attributed to chance, doctors and other people. The level of anxiety and depression was generally low without any differences between the groups. As compared to women with appropriate for gestational age infants (n=86), women with large for gestational age infants (n=59) had similar scores for locus of control, anxiety and depression, and health-related quality of life. High levels of internal locus of control were seen both in women with large for gestational age and appropriate for gestational age infants (30.0 (4.5) vs. 29.8 (5.3), p=0.85).

**Conclusion:** Women with pregestational diabetes who delivered preterm were characterised by worse mental quality of life in early pregnancy.

### 1106

#### Pregnancy outcome in depressive and GDM subjects in Bangladesh: a hospital based comparative study

K. Natasha;

Community Medicine, Institute of Health and Society, Faculty of Medicine, Oslo, Norway.

**Background and aims:** In Bangladesh the prevalence rate of depression in adult population is only 4.6%. Gestational Diabetes Mellitus (GDM) is also alarming here but the actual prevalence rate of both diseases in pregnancy is still lacking, though they are common and result in serious consequences for mother and foetus. To our knowledge there has been little research addressing the association between them in pregnancy and the outcome. These data are deficient even in South Asia let alone Bangladesh. This study was the corollary part of one study (which tried to find out prevalence of depression and associated factors, among GDM subjects and to compare with Non GDM) to reveal the outcome of pregnancy with depression and GDM and compared.

**Materials and methods:** A total of 748 pregnant women participated in the study. They were followed up from their 1st visit (not included after 13th week) to 1st week after delivery for at least 3 checkups. Depressive symptoms was scored following MADRS scale (0-12=not, 13-19=mildly, 20-34 moderately, 35-60=severely - depressed). Blood glucose was measured on every visit following WHO criteria; GDM was diagnosed within 24th to 28th weeks. Delivery procedure, Birth weight and APGAR score at 1st and 5th minute were assessed for the neonate.

**Results:** Prevalence of depression among pregnant women was 12.69%. The rate was higher in GDM (n 366) subjects (21.73%) with mean age 28.34 years than NGDM (n 382) subjects (7.73%) with mean age 27.17 years. Over all mean depressive score was higher at 3 stages in GDM group. Rate of caesarean section, number of live birth, and birth weight was higher but APGAR score at 2 stages were lower in GDM group. Mean age, Parity and birth weight of baby was higher but mean education years, mean APGAR scores of babies at both time period was lower in depressed groups (all 3 stages). Pregnant who were depressed specially in last trimester seem to have more rate of CS. Though gestational age at delivery did not vary much among the depressed and non depressed group. Chi square test and 't tests' proved there was significant association with depressive scores with gestational age and birth weight. Physical Exercise and Weight gain rate is under analysis

**Conclusion:** The important finding of this study was the elevated prevalence rate of depression in pregnancy which was greater than assumed. And pregnancy outcomes are strongly associated with GDM and Depression. Developing countries do not focus much on mental health but it is becoming ultimate necessity for future.

### 1107

#### Atlantic DIP: diabetes in pregnancy is the most significant risk factor for caesarean delivery

L. Carmody, A.M. Egan, O. Kgosidialwa, B. Kirwan, F. Dunne; Galway Diabetes Research Centre, National University of Ireland Galway, Ireland.

**Background and aims:** Diabetes mellitus (DM) is a common medical disorder of pregnancy. Caesarean delivery (CD) is associated with increased cost and maternal morbidity. Our aim was to determine the influence of DM on risk of CD in our cohort of patients enrolled in the Atlantic Diabetes in Pregnancy (DIP) study.

**Materials and methods:** Women with singleton pregnancies of 23 weeks or more estimated gestational age were identified and 6526 unique deliveries included. This included 4688 (71.8%) pregnancies with normal maternal glucose tolerance (NGT), 282 (4.3%) with pregestational diabetes mellitus type 1 and type 2 (PGDM) and 1556 (23.9%) with gestational diabetes mellitus (GDM). GDM was defined according to IADPSG criteria. Backwards stepwise logistic regression was utilised to evaluate the independent influence of selected variables on CD risk including diabetes mellitus (DM), maternal smoking and obesity, nulliparity, hypertension, ethnicity and macrosomia.

**Results:** In total, 1968 (30.16%) pregnancies resulted in CD. In the setting of NGT pregnancies there were 1196 (25.51%) with CD, 181 (64.18%) with PGDM and 591 (37.98%) with GDM (p<0.001). Evaluating the group as a whole using regression models, the presence of DM (either pregestational or gestational) significantly increased the odds for CD (aOR 1.73, p<0.001, 95% CI 1.51-1.99). Maternal obesity was also noted to be a significant risk factor (aOR 1.72, p<0.001, CI 1.509-1.974). Other identified risks for CD in our cohort include foetal macrosomia (aOR 1.61, p=0.003, CI 1.18-2.2), hypertension (aOR 1.66, p<0.001, CI 1.38-2.01), nulliparity (aOR 1.45, p<0.001, CI 1.27-1.65) and increasing maternal age (aOR 1.05, p<0.001, CI 1.04-1.06). When GDM was evaluated as an independent risk factor, it was also found to increase the odds for CD (aOR 1.36, p<0.001, CI 1.18-1.58) and analysing this subgroup of women (n=1556), persistent risk factors for CD include obesity (aOR 1.99, p<0.001, CI 1.57-2.52) and maternal age (aOR 1.04, p=0.002, CI 1.01-1.07). In the setting of PGDM (n=181), this underlying diagnosis greatly increases the odds of CD (aOR 4.95, p<0.001, CI 3.75-6.52) and was the only independent risk identified within this group of women.

**Conclusion:** Despite significant advances in the management of patients with diabetes in pregnancy, DM remains the most significant, independent risk factor for the adverse outcome of CD. Future research should focus on methods of reducing this risk.

## PS 095 Postpartum outcomes

### 1108

#### Evaluating haemoglobin A<sub>1c</sub> and metabolic syndrome versus oral glucose tolerance test in postpartum diabetes screening

M. Tome, M.J. Picon, J. Alcaide, I. Cornejo, M. Molina, F. Tinahones; University Hospital Virgen de la Victoria, Malaga, Spain.

**Background and aims:** Gestational diabetes mellitus (GDM) increases the risk of type 2 diabetes (DM-2). Guidelines of clinical practice recommend postpartum screening with oral glucose tolerance test (TTOG). Compliance rates of women performing this test are low because this is an uncomfortable test. We investigated the reliability of other postpartum screening test in order to increase the compliance of women in postpartum.

**Materials and methods:** We evaluated 419 women with a history of GDM in postpartum screening using hemoglobin A<sub>1c</sub> (A1C), HDL cholesterol, triglycerides, blood pressure and waist circumference and compared them with TTOG one year after delivery. We classified these patients into normal or pathological carbohydrate metabolism according to TTOG, A1C (following ADA criteria) and diagnostic criteria for the metabolic syndrome (MS) attending to ATPIII Expert Panel.

**Results:** Based on the TTOG 257 women (61,3%) had normal carbohydrate metabolism and 162 women (38,7%) had a pathological status: 69 (16,5%) impaired fasting glucose (IFG), 43 (10,3%) impaired glucose tolerance (IGT), 30 (7,2%) IFG+IGT and 14 (4,7%) had diabetes. According to the A1C criteria, 331 (77,9%) had normal carbohydrate metabolism and 84 (19,8%) had a pathological status: 82 (19,3%) prediabetes and 2 (0,5%) had diabetes. Attending to MS, 341 (80,2%) were normal and 64 (15,1%) had at least 3 diagnostic criteria for MS.

**Conclusion:** A1c and MS diagnostic criteria underestimate carbohydrate metabolism reassessment in women with a history of GDM compared to the gold standard TTOG.

### 1109

#### The role of HbA<sub>1c</sub> for detection of diabetes and abnormal glucose tolerance after pregnancy with gestational diabetes mellitus

R. Claesson, M. Ekelund, C. Ignell, K. Berntorp; Department of Clinical Sciences, Malmö, Lund University, Malmö, Sweden.

**Background and aims:** Recently, HbA<sub>1c</sub> has been proposed as a diagnostic tool to identify individuals with undiagnosed diabetes, or who are at risk of diabetes. Women with gestational diabetes mellitus (GDM) represent a high risk group for type 2 diabetes development. According to Swedish national guidelines life style intervention and follow-up of these women after pregnancy have high priority, but it is not made clear by which measures these women should be followed. The aim of the present study was to compare the performance of HbA<sub>1c</sub> with established glucose criteria during an oral glucose tolerance test (OGTT) and to assess HbA<sub>1c</sub> as a screening test for undiagnosed diabetes and pre-diabetes after pregnancy with GDM.

**Materials and methods:** Glucose homeostasis was reevaluated 1-5 years after delivery in 140 women with prior GDM by means of OGTTs and simultaneous HbA<sub>1c</sub> measurements. Glucose tolerance was defined according to World Health Organization criteria. HbA<sub>1c</sub>  $\geq$ 48 mmol/mol was used for diabetes diagnosis and HbA<sub>1c</sub> 39-47 mmol/mol to define high risk women (pre-diabetes).

**Results:** Mean  $\pm$  SD for age and body mass index of included women were 35.4  $\pm$  5.6 years and 26.6  $\pm$  2.3 kg/m<sup>2</sup>, respectively. A median (interquartile range) of 26 (21-60) months had elapsed since their GDM pregnancy. Based on the OGTT 62 women (44%) had normal glucose tolerance, 50 (36%) pre-diabetes, and 28 (20%) diabetes, as compared to 114 (81%), 21 (15%) and 5 (4%), respectively, using HbA<sub>1c</sub> criteria. The agreement between diagnoses resulting from HbA<sub>1c</sub> and OGTT criteria was estimated by constructing cross tables and calculation of the  $\kappa$  coefficient ( $\kappa$ ). The consistency in classifying diabetes versus non-diabetes was 82% (115/140) and  $\kappa$  0.194, indicating poor agreement. The corresponding figures for the classification of any degree of abnormal glucose tolerance were 59% (82/140),  $\kappa$  0.227. Combining HbA<sub>1c</sub> with fasting glucose criteria improved the agreement to fair ( $\kappa$  0.596), but was no better than using the fasting glucose test alone ( $\kappa$  0.599). The area under the receiver operating characteristic curve for HbA<sub>1c</sub> and fasting glucose to detect any degree of abnormal glucose tolerance was 0.708 and 0.834, respec-

tively. Diagnostic accuracy was assessed using sensitivity, specificity, positive predicted value (PPV) and negative predictive value (NPV). Proposed cut points of HbA<sub>1c</sub> had low sensitivity (30%) and modest NPV (52%) to detect any degree of abnormal glucose tolerance, whereas specificity and PPV were high. The combined use of HbA<sub>1c</sub> and fasting glucose criteria improved the performance (sensitivity 67%, specificity 95%, PPV 95%, NPV 69%), but was similar to the use of the fasting glucose test alone. The latter identified 63% (49/78) of the women with pre-diabetes or diabetes in the study cohort. However, combined with a lower cut point of HbA<sub>1c</sub> ( $\geq$ 31 mmol/mol), an additional 59 women were identified, among whom 36% had pre-diabetes or diabetes based on post glucose load hyperglycemia.

**Conclusion:** Proposed thresholds of HbA<sub>1c</sub> had low diagnostic sensitivity. Combined with a fasting glucose test the performance was no better than using a fasting glucose test alone. Considering that early detection of pre-diabetes is of utmost importance in these women to prevent the development of diabetes, combining a fasting glucose test with a lower cut point of HbA<sub>1c</sub> may be an alternate approach to select women for an OGTT to identify those with isolated post glucose load hyperglycemia.

### 1110

#### Glucose intolerance after a recent history of gestational diabetes

K. Benhalima<sup>1</sup>, L. Leuridan<sup>1</sup>, P. Calewaert<sup>1</sup>, R. Devlieger<sup>2</sup>, J. Verhaeghe<sup>2</sup>, C. Mathieu<sup>1</sup>;

<sup>1</sup>Endocrinology, <sup>2</sup>Obstetrics & Gynecology, University Hospital of Gasthuisberg, Leuven, Belgium.

**Background and aims:** The prevalence and the risk factors for glucose intolerance in early postpartum remain unclear in different populations. Our aim was to evaluate the uptake of our current screening strategy postpartum, the prevalence and the risk factors for glucose intolerance in women with a recent history of gestational diabetes (GDM).

**Materials and methods:** Retrospective analysis of the medical files of our university hospital from 01-01-2010 till 31-12-2013 of women with a recent history of GDM diagnosed with the Carpenter & Coustan criteria. Since 2010 all women with a history of GDM are advised to undergo a 75g oral glucose tolerance test (OGTT) between 6-24 weeks postpartum. Indices of insulin sensitivity (the Matsuda index and the reciprocal of the homeostasis model assessment of insulin resistance, 1/HOMA-IR) and an index of beta-cell function, the Insulin Secretion-Sensitivity Index-2 (ISSI-2) were calculated based on the OGTT during pregnancy and postpartum. Multivariable logistic regression was used to adjust for confounders.

**Results:** Over a 4 year period, 231 women were identified with a recent history of GDM. Of all women, 21.4% (46) did not attend the scheduled postpartum OGTT. Compared to women who received an OGTT postpartum, women who did not attend the postpartum OGTT smoked more often before pregnancy (10.9% vs 2.4%,  $p=0.021$ ), had more often a previous history of GDM (21.7% vs 10.7%,  $p=0.042$ ), less often breastfed (56.5% vs 75.7%,  $p=0.011$ ) and had a lower insulin sensitivity based on the OGTT during pregnancy [the Matsuda index 2.2 (1.5-3.1) vs 2.8 (1.9-3.8),  $p=0.033$  and 1/HOMA-IR 0.015 (0.010-0.023) vs 0.020 (0.012-0.032),  $p=0.030$ ]. Of all women (169) who received an OGTT postpartum, 40.8% (69) had pre-diabetes (14.9% impaired fasting glucose, 32.5% impaired glucose tolerance and 7.1% both impaired fasting and impaired glucose tolerance) and 5.3% (9) had overt diabetes. Compared to women with a normal OGTT postpartum, women with pre-diabetes or diabetes were more often overweight (39.7% vs 25.3%,  $p=0.009$ ) or obese at first prenatal visit (27.4% vs 19.5%,  $p=0.037$ ), were more often multiparous (44.0% vs 26.6%,  $p=0.028$ ), had a higher glucose challenge test [168.0mg/dl (153.0-190.0) vs 159.0mg/dl (149.5-175.5),  $p=0.007$ ], had an earlier diagnosis of GDM [gestational weeks 26.0 (25.0-28.0) vs 27.0 (25.0-29.0),  $p=0.030$ ], had a higher median fasting [94.5mg/dl (84.2-101.7) vs 88.0mg/dl (81.0-99.0),  $p=0.006$ ] and 2 hour glucose value during pregnancy [175.0mg/dl (162.0-198.0) vs 168.0mg/dl (158.0-181.0),  $p=0.003$ ] and were more often treated with basal-bolus insulin injections (52.0% vs 17.4%,  $p=0.032$ ). Women with glucose intolerance postpartum also had a lower beta-cell function and lower insulin sensitivity, remaining significant after adjustment for age, BMI, ethnicity, breastfeeding, contraception, multiparity and corticoid treatment [ISSI-2 in pregnancy 1.5 $\pm$ 0.5 vs 1.7 $\pm$ 0.4,  $p=0.029$ ; ISSI-2 postpartum 1.5 (1.2-1.9) vs 2.2 (1.8-2.6),  $p=0.020$ ; Matsuda index postpartum 3.8 (2.6-6.2) vs 6.0 (4.3-8.8),  $p=0.021$ ].

**Conclusion:** Glucose intolerance is frequent in early postpartum and these women have a lower beta-cell function and lower insulin sensitivity. One fifth

of women did not attend the scheduled OGTT postpartum and these women have an adverse risk profile compared to women who received the OGTT postpartum.

### The risk of future glucose intolerance in women with history of gestational diabetes

O. Yilmaz<sup>1</sup>, N. Dincçag<sup>2</sup>, S. Celik<sup>3</sup>, S. Ozel<sup>3</sup>, C. Idiz<sup>3</sup>, F. Turker<sup>2</sup>, A.K. Uzum<sup>2</sup>, N. Gul<sup>2</sup>, G. Yenidunya<sup>2</sup>, I. Satman<sup>2</sup>;

<sup>1</sup>Internal Medicine Department, <sup>2</sup>Endocrinology and Metabolism Division, <sup>3</sup>Bioinformatics and Medical Informatics Department, Istanbul University, Turkey.

**Background and aims:** In women with gestational diabetes mellitus (GDM) abnormal glucose metabolism normalizes soon after delivery. However, the history of GDM predisposes to carbohydrate intolerance in the future. The aim of this study was to evaluate risk factors predicting to future development of diabetes mellitus (DM) in women with a history of GDM.

**Materials and methods:** 221 women with history of GDM were enrolled into the study. A 75 g OGTT was performed within 3 months following delivery (n=181) or 11±2 years after delivery(n=40). Based on ADA criteria participants were classified into 3 groups as normal glucose tolerance; NGT (group 1), IGT and/ or IFG (group 2) and DM (group 3) We evaluated the relationship between status of carbohydrate metabolism after delivery and possible risk factors such as: age-at- gestation; BMI; family history of DM; poor obstetric history; gestational week, A1C and OGTT glucose levels at diagnosis of GDM; weight gain and insulin requirement during index pregnancy.

**Results:** As shown in the table below, 16.2 % of participants had any degree of glucose intolerance after delivery. Gestational age of women who progressed to prediabetes or diabetes was lower than the others. At diagnosis OGTT glucose levels were higher and family history and poor obstetric history was much more higher in group 2 and 3. Women who developed later carbohydrate intolerance had insulin requirement during pregnancy.

**Conclusion:** Age-at-gestation, having poor obstetric history, higher glucose levels (fasting, 1st, 2nd hr) at diagnosis of GDM and insulin requirement during pregnancy are crucial predictors of development of glucose intolerance in the future. Those women required careful and more frequent follow-up after delivery.

### Biomarkers of endothelial dysfunction in relation to impaired carbohydrate metabolism early after pregnancy with gestational diabetes mellitus

C.S. Göbl<sup>1,2</sup>, L. Bozkurt<sup>3</sup>, T. Prikoszovich<sup>3</sup>, A. Tura<sup>4</sup>, G. Pacini<sup>4</sup>, A. Kautzky-Willer<sup>3</sup>;

<sup>1</sup>Department of Obstetrics and Gynecology, Division of Obstetrics and Feto-Maternal Medicine, Medical University of Vienna, <sup>2</sup>Department of Internal Medicine III, Division of Endocrinology and Metabolism, Gender Medicine Unit, Medical University of Vienna, <sup>3</sup>Department of Internal Medicine III, Division of Endocrinology and Metabolism, Gender Medicine Unit, Medical University of Vienna, Austria, <sup>4</sup>Institute of Biomedical Engineering, Metabolic Unit, National Research Council, Padova, Italy.

**Background and aims:** The diagnosis of gestational diabetes mellitus (GDM) implicates an increased risk for the later development of type 2 diabetes. It was previously shown that metabolic reassessment early after delivery identifies females with particularly high risk. However, the relation to endothelial dysfunction, which might represent an early precursor of atherosclerosis and cardiovascular disease in females after pregnancy with GDM, is less well understood.

**Materials and methods:** 108 women with previous gestational diabetes (pGDM) and 40 controls were included 3-6 months after delivery and underwent specific metabolic assessments including a frequently sampled intravenous glucose tolerance test (FSIGT) and an oral glucose tolerance test (OGTT) to derive parameters of insulin sensitivity and  $\beta$ -cell dysfunction in addition to dynamics of glucose, insulin, C-peptide, proinsulin and amylin. The area under the curve was calculated by the trapezoidal rule including measurements of fasting, as well as 30', 60', 90' and 120' post load concentrations. OGTTs were repeated in females with pGDM over 10 years of follow-up to identify subjects with diabetes manifestation. Circulating ICAM-1 (intracellular-adhesion-molecule-1), VCAM-1 (vascular-cell-adhesion-molecule-1) and E-selectin, representing biomarkers of endothelial dysfunction were assessed at baseline and annually over five years after index pregnancy.

**Results:** Adhesion molecules and E-selectin were significantly related to insulin sensitivity estimated from the FSIGT (SI-FSIGT): ICAM-1:  $r=-0.23$ ,  $p=0.009$ ; VCAM-1:  $r=-0.22$ ,  $p=0.011$ ; E-selectin:  $r=-0.21$ ,  $p=0.018$ . Fractional polynomial regression models revealed further associations between ICAM-1 and AUC-glucose ( $p=0.003$ ), AUC-proinsulin ( $p=0.005$ ) and AUC-amylin ( $p=0.017$ ) as well as between E-selectin and AUC-glucose ( $p=0.013$ ) and BMI ( $p=0.004$ ) after adjustment for the degree of insulin resistance. Moreover, adhesion molecules remained significantly elevated in pGDM subjects as compared to the control group in a multivariable model including SI-FSIGT, age and BMI. 21% of females after pregnancy with GDM developed diabetes during the follow-up period. Longitudinal analysis revealed significantly higher ICAM-1 and E-selectin levels in subjects with progression to overt diabetes.

**Conclusion:** Biomarkers of endothelial dysfunction are related to impaired carbohydrate metabolism in subjects with recent history of GDM. This observation might indicate the later development of overt cardiovascular disorders in this specific risk collective. Follow-up examinations with clearly defined cardiovascular endpoints are recommended to perform an accurate risk stratification.

### Non-alcoholic fatty liver disease is prevalent in non-diabetic women with previous gestational diabetes mellitus regardless of their glucose tolerance

S. Foghsgaard<sup>1,2</sup>, L. Vedtofte<sup>1</sup>, C. Andersen<sup>1</sup>, E.S. Andersen<sup>1</sup>, L.L. Gluud<sup>1</sup>, C. Strandberg<sup>3</sup>, T. Buhl<sup>4</sup>, E.R. Mathiesen<sup>5</sup>, P. Damm<sup>6</sup>, J.A. Svare<sup>7</sup>, F.K. Knop<sup>1</sup>, T. Vilsbøll<sup>1</sup>;

<sup>1</sup>Diabetes Research Center, <sup>2</sup>Department of Biomedical Sciences, Panum Institute, <sup>3</sup>Department of Radiology, <sup>4</sup>Department of Nuclear Medicine, Gentofte Hospital, University of Copenhagen, <sup>5</sup>Center for Pregnant Women with Diabetes, Department of Endocrinology, <sup>6</sup>Center for Pregnant Women with Diabetes, Department of Obstetrics, Rigshospitalet, University of Copenhagen, <sup>7</sup>Department of Obstetrics and Gynaecology, Herlev Hospital; University of Copenhagen, Denmark.

**Background and aims:** Gestational diabetes mellitus (GDM) increases the risk of developing type 2 diabetes later in life. Furthermore, type 2 diabetes and obesity are associated with non-alcoholic fatty liver disease (NAFLD).

NAFLD is defined as a condition with excessive fat accumulation in the liver and absence of significant alcohol consumption. We examined glucose tolerance and fat distribution in obese, non-diabetic women with prior GDM.

**Materials and methods:** Based on a 75g-OGTT, non-diabetic women with previous GDM were classified as having normal glucose tolerance (NGT) or prediabetes (impaired fasting glucose and/or impaired glucose tolerance). Insulin resistance (IR) was assessed by HOMA-IR. All women underwent an ultrasound scan of the liver to detect fat accumulation, blood sampling, and a dual energy X-ray absorptiometry (DXA) scan. The android-to-gynoid fat-ratio and total visceral fat mass were calculated based on the DXA scan. A questionnaire was used to evaluate alcohol consumption habits.

**Results:** Women with previous GDM were included (n=70; age: 38±5 years (mean±SD); BMI: 31±5 kg/m<sup>2</sup>; HbA<sub>1c</sub>: 34±4 mmol/mol (5.4±0.4%); HOMA-IR: 1.2±0.6; duration since GDM: 5±2 years). Twenty four women had NGT (fasting plasma glucose (FPG) 5.4±0.3 mM; 2h-OGTT plasma glucose (PG): 6.7±1.4 mM) and 46 women had prediabetes (FPG 5.5±0.5 mM; 2h-OGTT PG: 9.2±1.1 mM). NAFLD was diagnosed in 5 (21%) women with NGT and 15 (33%) with prediabetes). Glucose tolerance status (NGT or prediabetes) did not coincide with NAFLD (p=0.39). Multivariable logistic regression analyses showed that NAFLD was positively associated with HOMA-IR (p=0.035), BMI (p=0.004), C-peptide (p=0.038), mass of visceral fat (p=0.004), the android-to-gynoid fat-ratio (p=0.027), and plasma levels of alanine aminotransferase (p=0.018) and aspartate aminotransferase (p=0.028).

**Conclusion:** NAFLD is prevalent in non-diabetic women with previous GDM regardless of their glucose tolerance status, but is associated with HOMA-IR, high BMI, high C-peptide levels, android fat distribution, and elevated plasma liver enzymes.

**Incretin function in adult offspring of women with diabetes in pregnancy**  
L. Kelstrup<sup>1</sup>, T.D. Clausen<sup>2</sup>, E.R. Mathiesen<sup>3,4</sup>, T. Hansen<sup>5,6</sup>, J.J. Holst<sup>7</sup>, P. Damm<sup>1,4</sup>,

<sup>1</sup>Department of Obstetrics, Center for Pregnant Women with Diabetes, Copenhagen, Denmark, <sup>2</sup>Department of Gynecology and Obstetrics, Hilleroed, <sup>3</sup>Department of Endocrinology, Center for Pregnant Women with Diabetes, Copenhagen, <sup>4</sup>Faculty of Health Sciences, University of Copenhagen, <sup>5</sup>Marie Krogh Center for Metabolic Research, Copenhagen, <sup>6</sup>Faculty of Health Sciences, University of Southern Denmark, Odense, <sup>7</sup>University of Copenhagen, The Novo Nordisk Foundation Center for Basic Metabolic Research, Copenhagen, Denmark.

**Background and aims:** Fetal exposure to maternal diabetes is associated with increased risk of pre-diabetes and type 2 diabetes (T2DM) in the offspring. The pathogenesis of T2DM seems to involve dysfunction of the incretin hormones glucose-dependent insulinotropic polypeptide (GIP) and glucagon-like peptide-1 (GLP-1), as well as hyperglucagonemia. Our aim was to investigate the levels of the incretin hormones GIP, GLP-1 and glucagon in adult offspring exposed to intrauterine hyperglycemia.

**Materials and methods:** A cohort of 587 Caucasian offspring, without known diabetes was followed up at the age of 18-27 years. We included two groups exposed to maternal diabetes in *utero*: offspring of women with gestational diabetes mellitus (O-GDM) or type 1 diabetes (O-T1DM). Two reference groups were included: offspring of women with risk factors for GDM, but normo-glycemia during pregnancy (O-NoGDM) and offspring from the background population (O-BP). The subjects underwent a 75-g oral glucose tolerance test (OGTT) with venous blood samples at 0, 30, 120 min.

**Results:** Significantly lower levels of GLP-1 in the fasting state was found in the 2 diabetes-exposed groups (O-GDM and O-T1DM) compared to O-BP (p=0.032 and 0.004 respectively). The levels of glucagon during OGTT (time=30 min.) showed a tendency towards higher level in O-GDM compared to the unexposed groups (O-NoGDM and O-BP). No association between levels of GIP and exposure status was found.

**Conclusion:** Reduced levels of GLP-1 in the fasting state and increased levels of glucagon during OGTT may contribute to the increased risk of glucose intolerance among adult offspring born to women with diabetes during pregnancy.

## PS 096 Pregnancy in type 1 diabetes

### 1115

**Hyperglycaemia remains the major risk factor of major foetal complications in pregnant women with type 1 diabetes and good glycaemic control**

J. Skupien, K. Cyganek, B. Katra, I. Janas, P. Witek, M.T. Malecki; Department of Metabolic Diseases, Jagiellonian University Medical College, Krakow, Poland.

**Background and aims:** In women with type 1 diabetes pregnancy is associated with increased risk of adverse outcomes. The aim of this study was to ascertain the association of glycemic control, estimated with HbA<sub>1c</sub>, with selected serious adverse pregnancy outcomes, such as preterm labor, congenital malformations low birth weight and stillbirths in a group of pregnant women with very good metabolic control.

**Materials and methods:** The study cohort comprised 510 women with type 1 diabetes. They received intensive diabetes management during the period of pregnancy in an academic outpatient reference center between 1998 and 2012. We excluded multiple pregnancies (n=9), miscarriages (before 20<sup>th</sup> week of gestation, n=40), cases with missing outcomes and lost to follow-up (n=6). Of the remaining 455, 183 women (40.2%) entered the intensive management program before conception (pregnancy planning). HbA<sub>1c</sub> was measured in 3 pregnancy trimesters, in a laboratory implementing internal and external quality assurance protocols, with an assay (high performance liquid chromatography) that was adjusted to DCCT standard.

**Results:** The median HbA<sub>1c</sub> in the 1<sup>st</sup>, 2<sup>nd</sup> and 3<sup>rd</sup> trimester was 6.5%, 5.7% and 5.6%, respectively. Only 155 (34.1%) women in the 1<sup>st</sup> trimester, 44 (9.7%) in 2<sup>nd</sup> and 39 (8.6%) in 3<sup>rd</sup> had HbA<sub>1c</sub> 7.0% or higher. In spite of that, we observed 70 (15.4%) preterm labors (two between 20<sup>th</sup> and 26<sup>th</sup> week of gestation). There were 34 (7.5%) cases of low birth weight (below 2500 g), 10 of them occurred in term newborns. There were also 10 (2.2%) stillbirths and 28 (6.1%) congenital malformations in live births. Additional 4 cases of congenital malformations occurred in stillborn fetuses. The strongest predictor of preterm delivery was the 3<sup>rd</sup> trimester HbA<sub>1c</sub>: relative odds of preterm delivery per 1% increase in HbA<sub>1c</sub> was 1.46, p=0.004. First and 2<sup>nd</sup> trimester HbA<sub>1c</sub> had weaker impact: odds ratios were 1.20 (p=0.06) and 1.35 (p=0.01), respectively (both per 1% increase in HbA<sub>1c</sub>). Of note, 97% preterm labors took place after 26<sup>th</sup> week of gestation. Interestingly we did not observe significant relationship between low birth weight and HbA<sub>1c</sub>, while the odds of this complication increased by 1.48 (p=0.02) per each additional 5 years of maternal age. The 1<sup>st</sup> trimester HbA<sub>1c</sub> (but not 2<sup>nd</sup> or 3<sup>rd</sup>) was associated with the risk of stillbirths: relative odds per 1% increase of HbA<sub>1c</sub> was 1.70, p=0.005. Similarly, 1<sup>st</sup> trimester HbA<sub>1c</sub>, but not 2<sup>nd</sup> or 3<sup>rd</sup>, was associated with the risk of congenital malformations (relative odds per 1% increase of HbA<sub>1c</sub> was 1.41, p=0.005). Although pregnancy planning resulted in 0.8% (6.8 vs. 6.0%) reduction of median HbA<sub>1c</sub> in the 1<sup>st</sup> trimester and 0.3% (5.8 vs. 5.5%) in the 3<sup>rd</sup>, it was not sufficient to significantly lower the risk of adverse outcomes (odds ratio 0.80, p=0.35 for the composite outcome of preterm deliveries, stillbirths and malformations).

**Conclusion:** Despite very good glycemic control the risk of the examined adverse outcomes of pregnancy in women with type 1 diabetes remains high. In this study preterm labors were associated predominantly with the 3<sup>rd</sup> trimester HbA<sub>1c</sub> but less with earlier glycemic exposure. Hyperglycemia during the first trimester of pregnancy, the period of embryonic organogenesis, was associated with increased risk of congenital malformations and stillbirths. These results emphasize the need for maintaining normoglycemia throughout the whole course of pregnancy.

### 1116

**Fixed rate intravenous insulin infusion for euglycaemic diabetic ketoacidosis to a pregnant type 1 diabetic with good foetal outcome**

K. Tofeek, L. Pichai Pillai, C. Bond, S. Ramtoola, M. Littley; Diabetes and Endocrinology, Royal Blackburn Hospital, Lancashire, UK.

**Background and aims:** Diabetic Ketoacidosis (DKA) is a life threatening condition during pregnancy. It carries high mortality (up to 30%) for both infant and mother. Ketosis has been implicated in foetal distress and causes adverse neurological outcome. During pregnancy, euglycemic diabetic ketoacidosis requires prompt recognition and treatment. The current national guideline in UK recommends using a fixed dose of insulin infusion (0.1units/kg/hr),

titration of fluids to keep this infusion continuously running and continuation of long acting insulin during management of DKA. We report a case of euglycemic DKA in a pregnant Type 1 diabetic who received fixed rate insulin infusion with complete recovery.

**Materials and methods:** A 24 year old type 1 diabetic for 10 years attended the antenatal clinic in a District General Hospital for antenatal management of her 2<sup>nd</sup> pregnancy. Her antenatal period had been uneventful till 24 weeks, with a satisfactory diabetes control (HbA1c of 50 mmol/mol) on a basal bolus regimen. She presented to the antenatal clinic with history of nausea, recurrent vomiting, abdominal pain and headache for preceding 6 days. She had stopped taking her short acting insulin but continued with her basal insulin. Clinically she was dehydrated. Investigations showed plasma glucose 6.5 mmol/l and blood ketones 3.9. Venous blood gas showed acidity (PH) 7.21, bicarbonate 9 and lactate 0.9. Rest of the biochemical investigations were unremarkable. Cardiotocography for fetal monitoring was normal

**Results:** A diagnosis of euglycemic diabetic ketoacidosis was confirmed, fixed dose of intravenous insulin with dextrose infusion was initiated as per Joint British Diabetes Societies (JBDS) guidelines. She was transferred to HDU for close monitoring. No precipitating factors for DKA was found. She made an excellent recovery and discharged home in 2 days. She delivered by caesarean section at term with good foetal outcome.

**Conclusion:** Euglycemic DKA is poorly understood in non-specialist practice, but it is important to recognize the condition early. Poor oral intake due to vomiting and nausea as well as pregnancy were the only contributing factors in our case. Fixed rate intravenous insulin has been part of the DKA pathway (JBDS Guidelines) only recently along with bedside measurement of metabolic changes. The rationales for this recommendation are: faster resolution of ketosis with higher insulin and glucose concentrations thereby rapid recovery with reduction in the length of stay, and significant delay in the normalisation of pH with a sliding scale protocol. Euglycemic DKA, although uncommon, still continues to be perceived in clinical practice. Type 1 diabetic patient presenting with nausea and vomiting and found to have a normal glucose may still have life-threatening ketoacidosis, and an evaluation of their acid/base status is still revealed. Identification of such presentation timely is crucial and also the need for early fixed rate intravenous insulin infusion along with dextrose which will prevent significant morbidity for both the mother and the foetus like in our case.

## 1117

### Higher gestational weight gain is associated with increasing offspring birth weight independent of maternal glycaemic control in women with type 1 diabetes

E.R. Mathiesen<sup>1,2</sup>, A.L. Secher<sup>1,2</sup>, C.B. Parellada<sup>1,2</sup>, L. Ringholm<sup>1,2</sup>, B. Ásbjörnsdóttir<sup>1,2</sup>, P. Damm<sup>1,3</sup>,

<sup>1</sup>Center for Pregnant Women with Diabetes, <sup>2</sup>Department of Endocrinology, <sup>3</sup>Department of Obstetrics, Rigshospitalet, Copenhagen, Denmark.

**Background and aims:** To evaluate the association between gestational weight gain and offspring birth weight in singleton term pregnancies of women with type 1 diabetes.

**Materials and methods:** One-hundred-and-fifteen consecutive women referred <14 weeks were retrospectively classified as underweight (pre-pregnancy BMI <18.5 kg/m<sup>2</sup>, n=1), normal weight (18.5-25.0, n=65), overweight (25.0-29.9, n=39) or obese (≥30.0, n=10). Gestational weight gain was categorized as excessive, appropriate or insufficient according to the Institute of Medicine recommendations for each BMI class.

**Results:** HbA1c at 8 and 36 weeks was comparable between women with excessive (n=62), appropriate (n=37) and insufficient (n=16) gestational weight gain (median 6.7 (range 5.6-8.4) vs. 6.5 (5.4-8.3) vs. 6.6 (5.6-8.3) % (50 (38-68) vs. 48 (36-67) vs. 49 (38-67) mmol/mol), p=0.78, and 6.0 (5.1-6.9) vs. 6.0 (4.7-7.1) vs. 6.3 (5.1-7.0) % (42 (32-52) vs. 42 (28-54) vs. 45 (32-53) mmol/mol), p=0.40, respectively) and pre-pregnancy BMI was 25 (18-41) vs. 24 (18-31) vs. 23 (20-30) kg/m<sup>2</sup> (p=0.05). Offspring birth weight and birth weight z-score decreased across the groups (3,681 (2,374-4,500) vs. 3,395 (2,910-4,322) vs. 3,295 (2,766-4,340) g, p=0.02, and 1.08 (-1.90-3.25) vs. 0.45 (-0.83-3.18) vs. -0.02 (-1.51-2.96), p=0.009). In a multiple linear regression analysis, gestational weight gain (kg) was positively associated with offspring birth weight (g) (β=19, p=0.02) and birth weight z-score (β=0.06, p=0.008), when adjusted for pre-pregnancy BMI, HbA1c at 36 weeks, smoking, parity and ethnicity.

**Conclusion:** Higher gestational weight gain in women with type 1 diabetes was associated with increasing offspring birth weight independent of glycaemic control and pre-pregnancy BMI.

**Background and aims:** The renin-angiotensin system plays an important role in regulation of blood pressure, and abnormalities predispose to cardiovascular disease. Preeclampsia (PE), a hypertensive disorder of pregnancy, is ~4 fold more prevalent in women with diabetes, but underlying mechanism is not fully understood. In this prospective study of type 1 diabetic (T1DM) women, we aimed to determine whether plasma levels of angiotensin-converting enzyme (ACE), angiotensinogen, and prorenin were altered early in pregnancy in women with subsequent PE, and whether they could serve as early markers for PE.

**Materials and methods:** Maternal plasma ACE, angiotensinogen and prorenin were measured longitudinally by ELISA at approximately 12, 22, and 32 weeks of pregnancy in 23 women with T1DM who subsequently developed PE (DMPE+), 24 diabetic women who did not have PE (DMPE-), and 20 non-diabetic normotensive women (DM-PE-). The three subject groups were matched for age, diabetes duration, HbA1C, and parity, as appropriate. Diabetic women were entirely complication-free before pregnancy. All study visits took place before the clinical onset of PE.

**Results:** Plasma concentrations of both ACE and prorenin were similar in the DMPE+ vs. DMPE- women at all three trimesters, but angiotensinogen was significantly lower in DMPE+ than DMPE- subjects at the 3rd trimester (P<0.01). Interestingly, all diabetic women, whether they subsequently developed PE or not, showed significantly higher levels of ACE and lower levels of angiotensinogen at the 1st trimester compared with non-diabetic controls (P<0.01), suggesting increased activity of the renin-angiotensin pathway.

**Conclusion:** Plasma levels of ACE, angiotensinogen, and prorenin cannot be used for early prediction of PE in women with T1DM. However, the renin-angiotensin system appears to be abnormally active early in pregnancy in women with T1DM, creating 'fertile soil' for the subsequent development of PE.

**Impact of parity on glycaemic control, cardiovascular risk factors and diabetes-related chronic complications: a multicentre study in Brazil**C.A. Negrato<sup>1</sup>, M.B. Gomes<sup>2</sup><sup>1</sup>Internal Medicine, Bauru's Diabetics Association, Bauru,<sup>2</sup>Diabetes Unit, State University of Rio de Janeiro, Brazil.

**Background and aims:** Pregnancy in women with preexisting diabetes can predispose these women to some diabetes-related chronic complications or accelerate the course of these complications if they are already present. The aim of this study was to determine the impact of parity on glycemic control, cardiovascular risk factors and diabetes-related chronic complications in women with type 1 diabetes in Brazil.

**Materials and methods:** This was a multicenter cross-sectional study conducted between December 2008 and December 2010 in 28 public clinics in 20 cities from the four Brazilian geographic regions. Data were obtained from 1,532 female patients, 59.2% Caucasian, aged  $25.2 \pm 10.6$  years. The diabetes mean duration was  $11.5 \pm 8.2$  years. Patient information (clinical factors and number of pregnancies) were obtained through a questionnaire and a chart review. Number of pregnancies were stratified in five groups: group 0 (no pregnancy), group 1 (one pregnancy), group 2 (two pregnancies), group 3 (three pregnancies) and group 4 ( $\geq$ four pregnancies).

**Results:** The comparison between the patients stratified according to parity showed that patients from groups 0, 1 and 2 were younger than patients from group 4 ( $p < 0.001$ ). Patients from groups 0 and group 1, had been diagnosed with diabetes with lower age and had less mean diabetes duration than patients from the other groups ( $p < 0.001$ ). The age at menarche was not different between the four groups ( $p = 0.3$ ). Overweight or obesity was present in 538 patients (35.1%). Patients from group 0 had lower BMI than patients from the other groups. A linear association was found between the frequency of overweight or obesity and parity ( $p = 0.004$ ). A difference between the five groups was observed for the mean of HbA1c without difference between-groups. A higher frequency of hypertension and higher levels of systolic and diastolic blood pressure were observed in group 4 in comparison to the other groups ( $p < 0.01$  for all comparisons). Metformin was used by 162 patients (10.6%) and its use was related to parity ( $p = 0.02$ ). The number of pregnancies was related to the presence of diabetes-related chronic complications (micro and macrovascular). A lower frequency of non-proliferative and proliferative retinopathy and macrovascular complications was noted in patients from group 0 in comparison to the other groups ( $p < 0.01$ ). A tendency for an association between parity and nephropathy was also observed ( $p = 0.056$ ).

**Conclusion:** Parity in women with type 1 diabetes is strongly associated with the presence of cardiovascular risk factors and diabetes-related chronic complications. Further prospective studies must be addressed to establish the relationship between the impact of pregnancy upon starting and/or deteriorating cardiovascular risk factors and diabetes-related chronic complications.

## 1120

**Association between breast-feeding duration with post-pregnancy glycaemic control and body weight in women with type 1 diabetes**M.T. Małecki<sup>1</sup>, B. Katra<sup>1</sup>, K. Cyganek<sup>1</sup>, P. Blizanowska<sup>2</sup>, B. Matejko<sup>1</sup>;<sup>1</sup>Department of Metabolic Diseases,<sup>2</sup>Department of Pharmacy, Jagiellonian University, Kraków, Poland.

**Background and aims:** In accordance with the new WHO guidelines, breast-feeding (BF) is recommended until the sixth month of the baby's life. Such model of feeding reduces the risk of digestive tract infections with infants and their susceptibility to illnesses. Apart from obvious benefits for the infant's health, it has also beneficial effect on the mother's health. BF may be more challenging in women with type 1 diabetes (T1DM) because of difficulties in maintaining their glycaemic control. The frequency of long-term BF in T1DM women and its relationships with clinical course of T1DM is unknown.

**Materials and methods:** The aim of the study was assessment of frequency of long BF (defined as 6 months or longer) in T1DM women and its impact on post-pregnancy glycaemic control as well as body weight. We collected data on BF from singleton pregnancies in 176 consecutive women with T1DM (mean age 27.8 yrs, mean BMI 23.3, mean T1DM duration 11.9) who were under our medical care between 1999–2012. They were contacted to complete a standard questionnaire on BF. Their medical records were available for the analysis. We divided all post-pregnancy follow-up data into three groups:

within 6 months after delivery (period I), 6–12 months after delivery (period II), and more than 12 months (period III).

**Results:** The majority of T1DM women ( $n = 110$ , 62.5%) breastfed for at least 6 months. The clinical characteristics of long-term BF T1DM women vs. short-term BF T1DM women was as follow: mean age - 28.4 yrs. vs. 26.7 ( $p = 0.01$ ), mean T1DM duration - 11.9 yrs. vs.  $\pm 11.4$  ( $p = 0.64$ ), mean BMI before pregnancy - 23.5 kg/m<sup>2</sup> vs. 23.6 ( $p = 0.64$ ), proportion of pregnancy planning - 68% vs. 56 ( $p = 0.10$ ). The HbA1c level in the long-term BF was lower at period II and III of the post-pregnancy follow-up (6.0% vs. 7.7%  $p = 0.05$ ; 6.9% vs. 7.9%;  $p = 0.02$ , respectively). BMI did not differ between long-term BF and short-term BF group at any follow-up period.

**Conclusion:** Long-term BF seems to be associated with lower HbA1c, but not BMI, after the pregnancy. Type 1 diabetes and breast-feeding require a change in the habits and routines of everyday life. This results could be a better treatment motivation in this group of patients.

## 1121

**Presence of components of the metabolic syndrome in offspring of mothers with type 1 diabetes**Z. Vlachová<sup>1</sup>, B. Bytøft<sup>2</sup>, S. Knorr<sup>3</sup>, T.D. Clausen<sup>4</sup>, R. Beck-Jensen<sup>5</sup>, K. Højlund<sup>1</sup>, E.R. Mathiesen<sup>6</sup>, P. Ovesen<sup>7</sup>, H. Beck-Nielsen<sup>1</sup>, C.H. Gravholt<sup>3</sup>, P. Damm<sup>2</sup>, D.M. Jensen<sup>1</sup>;

<sup>1</sup>Department of Endocrinology, Diabetes Research Center, Odense University Hospital, <sup>2</sup>Department of Obstetrics, Center for Pregnant Women with Diabetes, Rigshospitalet, Copenhagen, <sup>3</sup>Department of Endocrinology and Internal Medicine, Aarhus University Hospital, <sup>4</sup>Department of Gynecology and Obstetrics, Hillerød Hospital, <sup>5</sup>University Department of Growth and Reproduction, Rigshospitalet, <sup>6</sup>Department of Endocrinology, Rigshospitalet, Copenhagen, <sup>7</sup>Department of Gynecology and Obstetrics, Aarhus University Hospital, Denmark.

**Background and aims:** Some studies have shown that intrauterine exposure to maternal type 1 diabetes (T1DM) may have long-term effects on the offspring including increased risk of obesity and type 2 diabetes. However, the knowledge of the long-term impact of various maternal glycaemic levels during pregnancy is scarce. We aimed to study body composition and other metabolic risk factors in offspring of T1DM mothers compared to offspring of non-diabetic mothers with specific focus on associations between maternal glycaemic control during pregnancy and long-term outcomes of the offspring.

**Materials and methods:** During 1993 to 1999 pregnancies of women with T1DM in Denmark were prospectively reported to a central registry in the Danish Diabetes Association ( $n = 1215$ ). Maternal glycaemic status along with pregnancy outcome and complications were recorded. We invited 746 children from these pregnancies to a follow-up examination. A group of control children matched with respect to date of birth, sex and postal code was identified from the National Central Person Registry. Anthropometric measurements and blood sampling for metabolic characterization inclusive an oral glucose tolerance test were performed.

**Results:** We examined 277 children of women with T1DM (mean age 16.7 (13.0 - 19.8 years)) and 304 control children (mean age 16.8 (13.5 - 20.4 years)). Offspring of women with T1DM had significantly higher body mass index standard deviation score (BMI-sds) based on Danish reference curves for BMI adjusted for age and sex ( $\Delta$ BMI-sds: 0.46 (95% CI; 0.27 - 0.65)), waist circumference ( $\Delta$ : 3.6; 2.4 - 4.9 cm), waist-to-hip ratio ( $\Delta$ : 0.009; 0.002 - 0.016), fasting serum insulin ( $\Delta$ : 6.9; 2.0 - 11.6 pmol/l) and 2 h serum insulin ( $\Delta$ : 43.5; 14.4 - 72.7 pmol/l) compared to control offspring. Furthermore we observed that offspring of T1DM mothers with peri-conceptual HbA1c levels above 8% (63 mmol/mol) had higher BMI, waist circumference and 2 h serum insulin than offspring of mothers whose peri-conceptual HbA1c was below 7% (53 mmol/mol).

**Conclusion:** Offspring of mothers with T1DM have a more unfavourable metabolic profile than children of non-diabetic mothers. Our data indicate that maternal intrauterine hyperglycemia plays a significant role in this.

## PS 097 Neuropathy: biomarkers and mechanisms

### 1122

**Cardiovascular autonomic tone relation to obesity stage, metabolic syndrome, advanced glycation end products and other metabolic parameters in prediabetes**

R. Dimova, T. Tankova, N. Chakarova, G. Grozeva, L. Dakovska; Medical University Sofia, Clinical Center of Endocrinology, Bulgaria.

**Background and aims:** The aim of the study was to assess cardiovascular autonomic function (CAF) at different stage of obesity and in the presence of metabolic syndrome (MetS), and its relation to metabolic parameters and advanced glycation end products (AGEs) in subjects with prediabetes - impaired fasting glucose (IFG) and impaired glucose tolerance (IGT).

**Materials and methods:** A total of 148 subjects - 91 females and 57 males (mean age 50.4±13.6years, mean BMI 32.4±8.8kg/m<sup>2</sup>) with prediabetes - 83 with IFG, 29 with IGT and 36 with IFG+IGT, divided into 5 groups according to BMI: 15 normal weight, 43 overweight, 48 obesity class I, 25 class II, and 17 class III, and into 2 groups according to the presence of MetS - 118 with MetS and 30 controls were enrolled. Glucose tolerance was studied during OGTT. Anthropometric indices, blood pressure and serum lipids were measured. AGEs were evaluated by skin autofluorescence (AGE-Reader). Body composition was estimated by impedance analysis (InBody 720). CAF was assessed by ANX-3.0 using frequency-domain analysis during standard clinical tests - deep breathing, Valsalva and standing from a seated position.

**Results:** No statistically significant difference in CAF was established between the groups according to BMI and the presence of MetS, as well as between subgroups according to glucose intolerance. In subjects with prediabetes sympathetic and parasympathetic tone at rest and during applied clinical tests showed negative correlation with visceral fat area, AGEs, and HbA1c and did not demonstrate significant correlation with BMI, waist circumference, lipid profile and blood pressure.

**Conclusion:** Obesity stage and MetS are not associated with CAF deterioration in prediabetes on their own. Central obesity, HbA1c, and AGEs accumulation appear to be the main determinants of autonomic imbalance and increase cardiovascular risk at the early stages of glucose intolerance.

**Decreased beta cell function is associated with cardiovascular autonomic neuropathy in newly diagnosed type 2 diabetic patients**

X.b. Yang<sup>1</sup>, H.r. DENG<sup>1</sup>, W. Xu<sup>1</sup>, Y.h. Zhu<sup>1</sup>, S.d. Lin<sup>2</sup>, H.z. Yang<sup>3</sup>, D.h. Cai<sup>4</sup>, J.p. Weng<sup>5</sup>;

<sup>1</sup>Third Affiliated Hospital of Sun Yat-sen University, Guangzhou,

<sup>2</sup>First Affiliated Hospital of Shantou University Medical College,

<sup>3</sup>Guangdong Provincial People's Hospital, <sup>4</sup>Zhujiang Hospital, Southern Medical University, Guangzhou, China.

**Background and aims:** Cardiovascular autonomic neuropathy (CAN) is closely associated with increased mortality in diabetic patients. Several risk factors of CAN have been clearly clarified. However, the impact of beta-cell function on CAN, especially in newly diagnosed type 2 diabetic patients, is still controversial. Therefore, this study aimed to investigate the association between beta-cell function and CAN in newly diagnosed type 2 diabetic patients.

**Materials and methods:** 90 newly diagnosed type 2 diabetic patients (68.9% male, mean age: 45 years old) were enrolled. Standard battery of Ewing tests, including Valsalva manoeuvre (Valsalva ratio), the deep breathing test of expiration-to-inspiration ratio and the lying to standing test among the heart rate tests, and the orthostatic hypotension test, were used to identify CAN. Based on the results from Ewing tests, subjects were then further divided into two groups: diabetic patients with CAN (CAN+ group) or without CAN (CAN- group). Fasting glucose, insulin and c-peptide were measured. HOMA-B and HOMA-IR were calculated.

**Results:** The positive rate of CAN in newly diagnosed type 2 diabetic patients was 22.2%. Compared with CAN- group (n=70), CAN+ group (n=20) had significantly lower fasting insulin, c-peptide and HOMA-B [median (interquartile range): 5.34(3.50~8.57)mu/L VS 8.75(4.92~13.87) mu/L, P=0.045; 0.51(0.39~0.65)nmol/L VS 0.75(0.51~0.98)nmol/L, P=0.14;

15.75(9.52~36.36) VS 32.28(18.67~61.04), P=0.012, respectively]. No significant difference was observed in HOMA-IR between groups. Fasting c-peptide was correlated with Valsalva ratio (r=0.24, P= 0.043) and the lying to standing test (r=0.26, P=0.023). Logistic regression analysis revealed that HOMA-B was an independent protective factor of CAN in this population (OR: 0.97, 95%CI: 0.94~0.99, P=0.027).

**Conclusion:** Prevalence of cardiovascular autonomic nerve is high in newly diagnosed type 2 diabetic patients. Decreased beta-cell function is associated with CAN in this population.

### 1124

**Autonomic dysfunction is associated with loss of postprandial glycaemic control in newly diagnosed type 2 diabetes patients**

T.F. Dejgaard<sup>1</sup>, J. Fleischer<sup>2</sup>, S.L. Cichosz<sup>2</sup>, P. Hoeyem<sup>2</sup>, E. Laugesen<sup>2</sup>, P.L. Poulsen<sup>2</sup>, J.S. Christiansen<sup>2</sup>, L. Tarnow<sup>2,3</sup>, T.K. Hansen<sup>2</sup>;

<sup>1</sup>Steno Diabetes Center, Gentofte, <sup>2</sup>Institute of Clin. Medicine, Aarhus University and Dept. of Endocrinology and Internal Medicine, Aarhus University Hospital, <sup>3</sup>Nordsjaellands Hospital, Hilleroed, Denmark.

**Background and aims:** Maintaining tight blood glucose control by minimizing the magnitude and frequency of glucose excursions and especially postprandial glucose control is essential in achieving an ideal glycaemic control. Glycaemic variability may play a significant role in the development of diabetic neuropathy e.g. through activated oxidative stress. The aim of the present study was to investigate the association between autonomic dysfunction and postprandial glucose control in newly diagnosed type 2 diabetes patients.

**Materials and methods:** A total of 81 patients diagnosed within the last 5 years with type 2 diabetes according to WHO-criteria were consecutively recruited for this observational cohort study. All patients were equipped with a continuous glucose monitor (CGM) for three days and performed self-monitored blood glucose measurements (SMBG) at least four times per day during this period. Afterwards they were all tested for cardiac autonomic neuropathy (CAN) using conventional cardiovascular reflex tests (response to standing, deep breathing and Valsalva manoeuvre) and divided according to the presence of CAN. Postprandial glucose measures were calculated using CGM for each group based on the time of SMBG before main meals.

**Results:** The cohort consisted of 38 women and 43 men with non-insulin-treated type 2 diabetes, a mean age of 58 (±11) years, a BMI of 30 (±4), and an HbA1c of 6.6 (± 0.7) %. CAN was present in 22 subjects (9 women and 13 men). The groups with and without CAN were similar with respect to blood pressure, HbA1c, cholesterol levels and had comparable smoking habits. The nocturnal glucose drop and dawn glucose levels were significantly higher in the group with CAN as compared with patients without CAN (7.4 versus 6.5 mmol/L, P=0.017) and (7.9 versus 7.2 mmol/L, P=0.045). The breakfast premeal glucose was not different between patients with or without CAN, but peak glucose after breakfast was significantly higher in patients with CAN (11.4 versus 9.7 mmol/L, P=0.009), and the autonomic dysfunction group had significantly larger excursions 0.5-1.5 hour post meal (P<0.04, Figure 1). No difference in glucose was seen between groups at lunch or dinner. After adjusting for gender, age, systolic blood pressure, resting heart rate and BMI, the presence of CAN still had a significant influence on breakfast peak glucose (P=0.005) and the postprandial breakfast glucose increase.

**Conclusion:** CAN is associated with loss of postprandial control in newly diagnosed type 2 diabetes patients. These findings emphasise the importance of screening for autonomic changes early in diabetes and the need for under-

standing the complex interaction between postprandial glucose excursions and the development of autonomic neuropathy.

**Figure 1** - Postprandial excursions 0-4 hours post breakfast in subjects with and without CAN. Star (\*) indicates significant differences between groups

Clinical Trial Registration Number: NCT00674271

## 1125

### Artery stiffness parameters in patients with cardiovascular autonomic neuropathy and type 2 diabetes mellitus

V.A. Serhiyenko, V.B. Segin, S. Ajmi, A.A. Serhiyenko; Endocrinology, National, Lviv, Ukraine.

**Background and aims:** Artery stiffness parameters are known as a potentially applicable atherosclerotic risk marker and strongest predictors of cardiovascular morbidity and mortality. This study was aimed to investigate the parameters of arterial stiffness in patients with type 2 diabetes mellitus (DM) and cardiovascular autonomic neuropathy (CAN).

**Materials and methods:** The study involved 65 patients with type 2 DM of age  $54.7 \pm 3.8$  years, median BMI  $28.5 \pm 0.9$  kg/m<sup>2</sup> and HbA1c level  $7.4 \pm 0.6\%$ , among them 12 patients without cardiovascular diseases (CVD) and CAN, 14 patients with mild, 18 - moderate and 21 severe CAN. Control - 12 healthy volunteers. The diagnosis of CAN was based on the results of 5 standard cardiovascular tests, 24-hour HRV. The 24-hour blood pressure profiles, aorta (AIxao) and brachial augmentation index (AIxbr), pulse wave velocity (PWV) and ambulatory arterial stiffness index (AASI) were assessed by TensioMedTM Arteriograph 24 (Hungary). Statistics: ANOVA.

**Results:** We found that development of mild CAN in patients with type 2 DM is associated with statistically significant increase of artery stiffness indices (AIxao +22.1%, AIxbr +41.9%, AASI +16.7%,  $p < 0.05$ ; PWV +13.5%,  $p < 0.01$ ) compared to patients without verified CVD and CAN. The average value of PWV was considered as high (10.1 m/sec). Among the patients of this group in 7.1% we observed the optimal value of AIxbr, in 50.0% - normal, 42.9% - elevated; in 42.9% - normal value of PWV and in 57.1% - elevated. The arterial stiffness parameters in patients with moderate CAN exceed the physiological values, in particular AIxao +26.2%,  $p < 0.01$ ; AIxbr +66.2%,  $p < 0.001$ ; PWV +24.7%,  $p < 0.001$ ; AASI +30.6%,  $p < 0.01$  compared to group without CVD and CAN. PWV was statistically significant higher compared to patients with mild CAN (+9.9%,  $p < 0.05$ ). The value of AIxbr was normal in 55.5%, elevated in 38.9%, pathological in 5.6%; PWV in 16.7% - normal, 50.0% - elevated and in 33.3% of cases pathological. The development of severe CAN was characterized by elevated and pathological values of arterial stiffness parameters, in particular AIxao +37.8%, AIxbr +81.2%, PWV +37.1% and AASI +55.6%,  $p < 0.001$  compared to patients without CVD and CAN. The values of PWV and AASI were statistically significant higher compared to patients with mild (+20.8% and +33.3%,  $p < 0.001$ ) and moderate CAN (+9.9% and +19.2%,  $p < 0.05$ ). Among the patients of this group mostly elevated and pathological parameters were observed: in 42.9% - elevated parameters of AIxbr; in 23.8% - PWV; in 38.1% - pathological levels of AIxbr; 61.9% - PWV; normal value of PWV was observed in 14.3% of patients, AIxbr in 19.0% (table).

**Conclusion:** The development and progression of CAN is associated by increasing of artery stiffness parameters, in particular mild CAN by elevated PWV, moderate - by elevated and severe by elevated and pathological values of all investigated parameters. Non-invasive arteriography may be included in complex algorithm for CAN diagnosis and reduction of artery stiffness parameters should be one of the treatment goals.

### Low serum ficolin-3 levels indicate peripheral neuropathy in diabetic patients

X. Zhang, Y. Hu, J. Shen, F. Liu, W. Jia;

Endocrinology & Metabolism, Shanghai Jiaotong University Affiliated Sixth People's Hos, China.

**Background and aims:** Diabetic peripheral neuropathy (DPN) is one of the most common chronic complications of diabetes. The inflammatory mechanisms involving complement activation has been shown to take part in the pathophysiology of DPN. Ficolin-3, a soluble molecule of the innate system, has a primary role in the activation of the lectin pathway in the complement system. In the present study we aimed to elucidate the possible connection between serum ficolin-3 levels and DPN in diabetes mellitus.

**Materials and methods:** Consecutive diabetic inpatients at the Shanghai Clinical Medical Center of Diabetes from January 2012 to December 2013 were randomly recruited in this cross-sectional study. The demographic and clinical variables were obtained through a questionnaire. Serum ficolin-3 concentration was measured with ELISA. DPN was diagnosed by abnormalities in two or more of three major categories (positive symptoms, increased vibration perception threshold (VPT) values, and slowed nerve conducting velocities (NCVs)). Patients were divided into two groups including DPN and non-DPN group.

**Results:** A total of 466 patients (mean age,  $57.98 \pm 11.09$  years; male/female, 256/210; mean diabetes duration, 9(4-15) years) were finally enrolled in this study. There was no difference in serum ficolin-3 levels in male and female patients ( $25.00 \pm 11.52$ ) vs ( $23.74 \pm 12.27$ ) ng/mL,  $P = 0.257$ ], also no difference was found in the prevalence of DPN in male and female patients. There were significantly difference in ficolin-3 levels among patients without diabetic complications ( $n = 156$ ,  $27.15 \pm 10.23$  ng/ml), complicated with only DPN ( $n = 40$ ,  $18.30 \pm 8.99$  ng/ml), only diabetic nephropathy ( $n = 25$ ,  $24.78 \pm 9.63$  ng/ml), as well as only diabetic retinopathy group ( $n = 58$ ,  $25.27 \pm 10.26$  ng/ml) ( $P < 0.001$ ). Serum ficolin-3 levels were lower in DPN patients compared with non-DPN patients ( $18.73 \pm 10.75$  vs  $26.69 \pm 10.68$  ng/mL,  $P < 0.001$ ). Ficolin-3 levels were negatively correlated to VPT ( $r = -0.158$ ,  $P = 0.025$ ). Partial spearman correlation analysis further indicated that ficolin-3 was still associated with VPT ( $r = -0.283$ ,  $p = 0.001$ ) even after adjusted for age, diabetes duration, smoking, hypertension, alanine aminotransferase and Glomerular filtration rate. Logistic regression analysis of DPN showed that age (OR, 1.047; 95%CI (1.005-1.092);  $p = 0.029$ ), diabetes duration (OR, 1.10; 95%CI 1.040-1.166;  $p = 0.001$ ), ficolin-3 (OR, 0.939; 95%CI 0.910-0.970;  $p < 0.001$ ) were independent associated factors for DPN. The prevalence of DPN among ficolin-3 quartiles was compared too, and the results revealed that it's elevated with the descending serum ficolin-3 concentrations. Par-

Participants in the lowest quartile of serum ficolin-3 had a significantly increased risk of DPN compared with those belongs to the highest quartiles. Compared with Quartile1 (referent), patients in Quartile2 (OR, 2.76; 95%CI, 1.56-4.88;  $P < 0.001$ ), Quartile 3 (OR, 3.02; 95%CI, 1.69-5.40;  $P < 0.001$ ) and Quartile4 (OR, 6.84; 95%CI, 3.39-13.80;  $P < 0.001$ ) had higher risk of DPN.

**Conclusion:** Ficolin-3 levels decrease in diabetic patients with DPN, strongly inversely correlated with VPT. The risk of DPN increased with the decrease of serum ficolin-3 levels. Therefore, decreased ficolin-3 level may be a biomarker of DPN in diabetic population.

### High serum cystatin C indicates diabetic peripheral neuropathy in type 2 diabetes

Y. Hu<sup>1</sup>, F. Liu<sup>1</sup>, J. Shen<sup>1</sup>, H. Zeng<sup>1</sup>, L. Li<sup>1</sup>, J. Zhao<sup>2</sup>, J. Zhao<sup>3</sup>, F. Lu<sup>1</sup>, W. Jia<sup>1</sup>;

<sup>1</sup>Endocrinology & Metabolism, <sup>2</sup>Vascular Surgery,

<sup>3</sup>Interventional Radiology, Shanghai Jiaotong University Affiliated Sixth People's Hospital, China.

**Background and aims:** Recent studies have shown that cystatin C is a predictor of mortality and cardiovascular diseases. We carried out this study to explore the relationship between serum cystatin C and diabetic peripheral neuropathy (DPN)

**Materials and methods:** Totally 937 diabetic patients were randomly enrolled in this cross-sectional study. The demographic and clinical variables were obtained through a questionnaire. Serum cystatin C concentration was measured with immunoturbidimetry. DPN was evaluated by neurological symptoms, neuro-thesiometer and electromyography.

**Results:** Serum cystatin C levels were higher in confirmed DPN patients [1.3(1.1-1.5)mg/L] compared with unconfirmed DPN [1.1(0.9-1.3)mg/L,  $p < 0.001$ ] and non-DPN patients (1.0(0.9-1.3)mg/L,  $p < 0.001$ ). Spearman correlation analysis showed that confirmed DPN was positively related to age ( $r = 0.196$ ,  $p < 0.001$ ), diabetes duration ( $r = 0.141$ ,  $p < 0.001$ ), hypertension ( $r = 0.128$ ,  $p < 0.001$ ), CysC ( $r = 0.154$ ,  $p < 0.001$ ), Cr ( $r = 0.066$ ,  $p < 0.05$ ) and urinary albumin ( $r = 0.144$ ,  $p < 0.001$ ), and negatively related to GFR ( $r = -0.164$ ,  $p < 0.001$ ). Patients were then divided into quartiles according to the serum CysC levels. Compared with cystatin C Quartile1 (referent), the risk of confirmed DPN was significantly higher in Quartile2 (OR, 1.753; 95%CI 1.055-2.912;  $p < 0.05$ ), Quartile3 (OR, 2.463; 95%CI 1.445-4.917;  $p < 0.001$ ) and Quartile4 (OR, 5.867; 95%CI 2.075-16.589;  $p < 0.001$ ). Finally, receiver operating characteristic (ROC) analysis revealed that the optimal cutoff point of cystatin C to predict DPN (OR, 2.380; 95%CI 1.577-3.592;  $p < 0.0001$ ) in diabetic patients without diabetic nephropathy was 1.25mg/L (AUC = 0.704, 95% CI 0.645-0.763, Youden index = 0.305, sensitivity: 61.8%, specificity: 68.6%).

**Conclusion:** Cystatin C levels are higher in diabetic patients with DPN, and high serum cystatin C may be a risk factor and potential biomarker for diabetic peripheral neuropathy.

Figure 1 DPN risk in different CysC quartiles.

## 1128

### GABA-dependent pain facilitation of spinal 5-HT3 receptor in diabetic neuropathic pain

C.S.C. Morgado<sup>1</sup>, M.A. Silva<sup>1</sup>, D.A. Martins<sup>2</sup>, I.F. Tavares<sup>1</sup>;

<sup>1</sup>Department of Experimental Biology, <sup>2</sup>Department of Experimental Biology, Faculty of Medicine of Porto, University of Porto, Portugal.

**Background and aims:** Diabetic neuropathic pain (DNP) is a frequent complication of diabetes, associated with increased morbidity and reduced quality of life. Impaired spinal pain inhibition is likely to contribute to DNP, namely the increased GABA content and the shift in its role from inhibitory to excitatory through its action on GABA A receptors (GABAAR). The activation of spinal 5-HT3 receptor (5-HT3R) is known to induce GABA release and its inhibition was shown to be anti-hyperalgesic in streptozotocin (STZ)-diabetic rats. We hypothesised that the anti-hyperalgesic effect of 5-HT3R inhibition is mediated by counteracting the excitatory role of GABA through GABAAR at the spinal cord of STZ-diabetic rats. In this study we evaluated the effect of intrathecal administration of muscimol (GABAAR agonist) on the mechanical hyperalgesia reversal induced by 5-HT3R inhibition.

**Materials and methods:** Diabetes was induced in male Wistar rats by intraperitoneal injection of STZ solution (60 mg/Kg). Control animals received only the vehicle. Blood glucose concentration was quantified in blood samples taken from the tail vein and only STZ-injected rats with glycaemia higher than 270 mg/dl were considered diabetic and included in the study. At 4 weeks post-injection, a catheter was implanted in the lumbar spinal cord subarachnoid space for drug administration. Mechanical nociception was evaluated by paw-pressure test in control and STZ-diabetic rats after intrathecal delivery of saline (STZ+saline; ctr+saline) or Y-25130 hydrochloride (Y-25130, 5-HT3R antagonist, 30 fmol, STZ+Y-25130; ctr+Y-25130). An additional group of STZ+saline and STZ+Y-25130 diabetic rats received intrathecal administrations of muscimol (0.3 ug) at 3,5h after saline or Y-25130 infusions (STZ+saline+musc; STZ+Y-25130+musc) and the PPT were evaluated 30 min after. Means were compared by ANOVA repeated measures or one-way ANOVA followed by Tukey post-hoc test and are presented as mean ± SEM.

**Results:** The STZ-diabetic rats presented significantly increased blood glucose levels and decreased body weights at 4 weeks after diabetes induction when compared with control rats. The STZ-diabetic rats developed mechanical hyperalgesia as demonstrated by the significantly lower paw pressure threshold (PPT) when compared with control animals (STZ:  $5.74 \pm 0.71$ ; control:  $10.42 \pm 0.20$ ,  $p < 0.001$ ). Intrathecal delivery of Y-25130 in STZ-diabetic rats significantly increased the PPT, with a maximum peak effect at 4h post-administration (STZ+saline:  $6.10 \pm 0.32$ ; STZ+Y-25130:  $10.98 \pm 0.74$ ,  $p < 0.01$ ). The administration of muscimol 30 min before the peak maximum effect of Y-25130 abolished its anti-hyperalgesic effect in STZ-diabetic rats (PPT in STZ+Y-25130:  $10.98 \pm 0.74$ ; STZ+Y-25130+Musc:  $5.70 \pm 0.64$ ,  $p < 0.01$ ).

**Conclusion:** These findings suggest that the activation of 5-HT3R at the spinal cord of STZ-diabetic rats is likely to increase GABAergic neurotransmission. Considering the previously reported shift in the role of GABA, through the activation of GABAAR, in STZ-diabetic rats, this is likely to be facilitating pain spinal transmission. The use of 5-HT3R antagonists may then be considered as a promising pharmacological treatment in alleviating mechanical hyperalgesia induced by diabetes.

## 1129

### Glucosamine induced Schwann cell death and nerve conduction delay associated with activation of hexokinase

H. Mizukami<sup>1</sup>, S. Ogasawara<sup>1</sup>, K. Sango<sup>2</sup>, K. Tsuboi<sup>1</sup>, C.K. Sookja<sup>3</sup>, S. Yagihashi<sup>1</sup>;

<sup>1</sup>Pathology and Molecular Medicine, Hirosaki University, Hirosaki,

<sup>2</sup>Peripheral Nerve Research Laboratory, Tokyo Metropolitan Medical

Research Institute, Setagaya, Japan, <sup>3</sup>Department of Anatomy, University of Hong-Kong, China.

**Background and aims:** Glucosamine is one of the amino-sugars, widely sold on the market for relief of symptoms in patients with arthritis. In our previous studies, comprehensive metabolomics analysis enabled us to find accumulation of glucosamine (GlcN) in the sciatic nerve of STZ-diabetic mice. GlcN is known to metabolize to GlcN-6-phosphate via hexokinase (Hex), but its metabolic sequelae is not well understood. In this study, we therefore ex-

amined whether excessive GlcN-Hex flux influences on Schwann cell survival in vitro and peripheral nerve function in vivo.

**Materials and methods:** Schwann cell line (IMS32) maintained in DMEM supplemented with 10% FBS in 5% CO<sub>2</sub> was stimulated with 10 mM GlcN. Western blot was conducted for the evaluation of apoptosis to identify cleaved caspase3 (CC3) and for the expression of modified glycosylation (O-GlcNAc). Hex activation was separately examined in the fractionated mitochondria and cytosole of IMS32 exposed to GlcN. Specific siRNA for Hex I was applied to see the effects of the Hex I on GlcN-Hex pathway on Schwann cell survival. To see the effects of GlcN on Hex expression in the peripheral nerve in vivo, male C57Bl/6J mice, 12 weeks of age were administered (i.p.) with 2 g/kg GlcN and nerve conduction velocity was measured. A half of the animals were pretreated with inosine (100 mg/kg, i.p.), as an ATP donor, one hour prior to GlcN administration. Normal control mice were given saline alone to serve for comparison.

**Results:** In vitro experiment revealed that GlcN exposure elicited increased CC3 expression in Schwann cells. Concurrently, O-GlcNAc expression was increased with GlcN exposure, but it was not proportional to the extent of apoptosis. Hex I expression in mitochondria fraction was markedly increased after GlcN exposure irrespective of glucose concentration. Knock down of Hex I by siRNA suppressed the expression of GlcN-induced CC3 activation and caused prolonged cell survival. Mice injected with GlcN exhibited enhanced Hex expression of mitochondrial fraction and delayed nerve conduction, which was prevented by pretreatment with inosine.

**Conclusion:** GlcN exposure induced Schwann cell death with Hex activation in vitro and nerve conduction delay in vivo. Inhibition of Hex activation by siRNA in vitro and inosine pretreatment significantly inhibited GlcN-induced Schwann cell death or neuropathic changes. These findings suggest that GlcN-Hex activation may have a pathogenetic role in diabetic neuropathy.

## PS 098 Mechanisms and outcomes of neuropathy

### 1130

#### Glycaemic variability as measured by continuous glucose monitoring and diabetic cardiovascular autonomic neuropathy in patients with type 2 diabetes

J. Ji-Eun, O. Sewon, J. Sang-Man, K. Jae Hyeon;  
Endocrinology and Metabolism, Samsung Medical Center, Seoul, Republic of Korea.

**Background and aims:** It is still not clear whether glycemic variability contributes to the development of diabetic autonomic neuropathy. We investigated the association between glycemic variability determined by continuous glucose monitoring (CGM) and diabetic cardiovascular autonomic neuropathy in the patients with type 2 diabetes.

**Materials and methods:** A total of 184 patients with type 2 diabetes with estimated glomerular filtration rate of >30ml/min/1.73m<sup>2</sup> who wore a CGM device for 72 hours were enrolled. As parameters of glycemic variability, the standard deviation (SD) around the mean and the coefficient of variation (CV, SD/mean) were obtained from the CGM data. All subjects were investigated for five standard cardiovascular reflex tests according to the Ewing's protocol. Diabetic cardiovascular autonomic neuropathy was defined as the presence of at least two abnormal tests or autonomic neuropathy points  $\geq 2$ .

**Results:** Among the enrolled patients, 97 had diabetic cardiovascular autonomic neuropathy (52.7%, neuropathy group). SD (49.76 $\pm$ 19.28 vs 46.05 $\pm$ 21.24, P=0.22) and CV (28.63 $\pm$ 8.24 vs 28.33 $\pm$ 9.88, P=0.81) did not differ between neuropathy and control group. The hemoglobin A1c (HbA1c, %) was higher in neuropathy group (8.43 $\pm$ 1.48 vs 7.95 $\pm$ 1.32, P=0.02) than in the control group. The duration of diabetes was longer in neuropathy group than in control group (12.49 $\pm$ 7.52 vs 6.72 $\pm$ 6.72 year, P=0.048). In binary logistic regression analysis, CV and SD failed to contribute to the final model.

**Conclusion:** We failed to show an independent association between glycemic variability as measured by CGM and diabetic cardiovascular autonomic neuropathy in the patients with type 2 diabetes.

### 1131

#### Effects of diabetic peripheral neuropathy on the use of vision during walking

J.C. Handsaker<sup>1</sup>, S.J. Brown<sup>1</sup>, C.N. Maganaris<sup>2,1</sup>, F. Bowling<sup>3</sup>,  
D.E. Marple-Horvat<sup>1</sup>, A.J.M. Boulton<sup>3</sup>, N.D. Reeves<sup>1</sup>;

<sup>1</sup>Manchester Metropolitan University,

<sup>2</sup>Liverpool John Moores University, <sup>3</sup>University of Manchester, UK.

**Background and aims:** Due to a decrease in sensory feedback, patients with diabetic peripheral neuropathy (DPN) are expected to use vision as a way of detecting foot position during walking, restricting their ability to visually identify upcoming obstacles. By examining how people visually acquire (first look at) targets during walking, we can elucidate to what extent diabetes patients use their eyes to identify foot position, and plan subsequent stepping during walking.

**Materials and methods:** Twelve participants (4 with diabetic peripheral neuropathy [DPN], 4 with non-neuropathic diabetes [D], and 4 healthy controls [C]) negotiated a stepping walkway, stepping on irregularly placed targets as accurately as possible whilst walking at a natural gait velocity. The timing of horizontal eye movements during stepping were measured using an eye-tracking device, with respect to foot-target contact. Mean group differences were analysed using a one-way ANOVA (p<0.05).

**Results:** Patients with DPN visually acquired the targets significantly later (C: -0.63  $\pm$  0.20; D: -0.41  $\pm$  0.12; and PN: -0.41  $\pm$  0.14s [p<0.05]) (Fig 1.), and remained looking at them for significantly longer after the foot had contacted the ground (C: 0.00  $\pm$  0.08; D: 0.01  $\pm$  0.08; and PN: 0.06  $\pm$  0.14s [p<0.05]). Patients with DPN also spent significantly less time in total looking at targets than the control group (C: 0.62  $\pm$  0.16; D: 0.42  $\pm$  0.15; and DPN: 0.5  $\pm$  0.21s [p<0.05]), but took significantly longer to look between targets (C: 0.1  $\pm$  0.04; D: 0.11  $\pm$  0.06; and DPN: 0.14  $\pm$  0.11s [p<0.05]).

**Conclusion:** Patients with neuropathy appear to use vision as a method of detecting when foot placement occurs during stepping. Unlike healthy controls, who look to the next target prior to foot-ground contact, patients with neuropathy remain looking at the target until after foot-ground contact, in

an attempt to increase stepping accuracy. Patients with neuropathy also take longer to look from one target to another, which may indicate the presence of motor neuropathy in the extra-ocular muscles. The increased time to look between targets may therefore be an explanation for the later acquisition of the subsequent target. This visual gaze strategy may restrict the ability of patients with neuropathy to identify upcoming obstacles, increasing the chances of tripping and falling.

Figure 1. Mean group differences in timing, of when the target was visually acquired (blue bar), and when the eyes were looking from one target to another (green bar), with reference to foot-target contact occurring at 0s.

### 1132

#### Influence of cardiovascular autonomic neuropathy on the next fate of type 1 diabetic patients; 10 years follow up

S. Lacigova, J. Brozova, D. Cechurova, J. Tomesova, Z. Rusavy; Medical Dept.I., University Hospital, Pilsen, Czech Republic.

**Background and aims:** Cardiovascular autonomic neuropathy (CAN) is considered to impair morbidity and mortality of diabetic patients (DM). We did not believe in pessimistic results of some studies. Aim of our observational retrospective study was to answer to these questions: 1. In what parameters differed DM with CAN (CAN+) and without CAN (CAN-) at baseline of observation? 2. Did the presence of CAN impair morbidity in next 10 years? 3. Was there the higher mortality among CAN+? What were the reasons of mortality?

**Materials and methods:** During the years 2002-2004 we evaluated CAN in 278 type 1DM (Ewing battery). CAN+ involved 111, CAN- involved 167 patients. In spite of positive test, majority of patients were asymptomatic. We have compared the control of DM, weight, presence of microangiopathic complications (retinopathy, nephropathy, peripheral neuropathy, diabetic foot) and cardiovascular disease and other risk factors (hypertension, hyperlipoproteinemia and smoking) between groups (CAN+ vs CAN-) at baseline and 10 years after. Median (interquartile range), Wilcoxon non paired test, contingency table, mono- and multifactorial regression and multivariate Regression step-wise were used for statistical evaluation.

**Results:** 1. Group CAN+ was older (47 vs 33 years;  $p < 0.001$ ), with longer duration of DM (20 vs 12 years;  $p < 0.01$ ), with worse metabolic control (HbA1c) (73 vs 68 mmol/mol;  $p < 0.05$ ), higher systolic (130 vs 120 mmHg;  $p < 0.001$ ) and diastolic (80 vs 70 mmHg;  $p < 0.01$ ) blood pressure and lower glomerular filtration rate (eGF) (1.16 vs 1.35 ml/s;  $p < 0.001$ ). Retinopathy (67.6 vs 21.6 %;  $p < 0.001$ ), neuropathy (59.5 vs 18.6%;  $p < 0.001$ ), diabetic foot (6.3 vs 0%;  $p < 0.01$ ) and albuminuria (41.4 vs 11.4 %;  $p < 0.001$ ) were more frequent in CAN+ at baseline. Same trend was observed in cardiovascular disease (6.3 vs 0.6%;  $p < 0.01$ ), hypertension (32.4 vs 6.6%;  $p < 0.001$ ) and hyperlipoproteinemia (29.7 vs 16.8 %;  $p < 0.05$ ). The ratio of smokers (19 vs 21.6 %) was similar in both groups. 2. During the follow up period there were more new cases of diabetic foot (8.2 vs 0.6%;  $p < 0.01$ ) and cardiovascular disease (24.7 vs 3.7%;  $p < 0.001$ ) in CAN+. The incidence of other complications and risk factors were similar in both groups: retinopathy: 34 vs 35.9%; albuminuria 17.5 vs 9.2%; neuropathy 29.9 vs 21.5%; hypertension 35.1 vs 30.7%; hyperlipoproteinemia 38.1 vs 29.5%; smoking 1.03 vs 0%. Group CAN+ gained less weight (3 vs 5 kg;  $p < 0.001$ ) and the differences in systolic (0 vs 5 mmHg;  $p < 0.05$ ) and diastolic (0 vs 0 mmHg;  $p < 0.05$ ) blood pressure were smaller, therefore blood pressure in both group were same by the end of the study. The differences in HbA1c did not differ in both groups. 3. In follow up period deceased 18 patients in both groups (18/278; 6.5%), 14 of them from CAN+ (14/111; 12.6%) and 4 from CAN- (4/167; 2.4%) ( $p < 0.001$ ). The strongest parameter for mortality was the presence of CAN ( $p < 0.01$ ) and systolic blood pressure at baseline ( $p < 0.05$ ). Influence of age and duration of DM were insignificant (multivariate

regression step-wise model). The complications of DM (8x), cardiovascular disease (3x) and the other reasons (7x) were the causes of death.

**Conclusion:** In 1DM patients with CAN the incidence of cardiovascular disease was 7 times, of diabetic foot was 14 times and mortality rate was 5 times higher compared to 1DM without CAN. The incidence of the other complications was similar in both groups.

#### Heart rate response to the exercise is impaired even in a mild degree of dysglycaemia

J. Tomono, H. Adachi;

Gunma Prefectural Cardiovascular Center, Maebashi, Japan.

**Background and aims:** Impaired heart rate (HR) response to the exercise, chronotropic incompetence, is known to be one of the predictors of prognosis, and it is induced by myocardial ischemia and/or autonomic nervous dysfunction. Although diabetes mellitus is well known to induce the autonomic nervous dysfunction, relationship between chronotropic incompetence and the degree of dysglycaemia is not fully studied yet. We planned to investigate the relationship between them.

**Materials and methods:** Consecutive 68 angina pectoris patients with complete revascularisation were enrolled. They performed cardiopulmonary exercise test (CPX) and 75g oral glucose tolerance test (OGTT) at the almost the same date. They were divided into two groups according to the result of OGTT (normal glucose tolerance (NGT) group (n=30) and impaired glucose tolerance (IGT) group (n=38)). Chronotropic incompetence was assessed as follows: HR difference between peak and rest ( $\delta$ HR), HR increase divided by work rate increase ( $\delta$ HR/ $\delta$ WR) and HR recovery 1 minute after exertion (HRR).

**Results:** All three parameters were smaller in IGT group than NGT group,  $\delta$ HR: 46.2 $\pm$ 3.2 vs. 57.0 $\pm$ 3.6 ( $p = 0.029$ ),  $\delta$ HR/ $\delta$ WR: 0.53 $\pm$ 0.032 vs. 0.66 $\pm$ 0.037 ( $p = 0.011$ ), and HRR: 16.5 $\pm$ 1.5 vs. 21.7 $\pm$ 1.6 ( $p = 0.023$ ), respectively.

**Conclusion:** This study clarified that chronotropic incompetence occurs even in the patients with mild dysglycaemia.

### 1134

#### Brain perfusion in painful diabetic neuropathy

M. Greig<sup>1</sup>, I.D. Wilkinson<sup>1</sup>, P. Shillo<sup>2</sup>, D. Selvarajah<sup>2</sup>, R. Gandhi<sup>3</sup>, S. Tesfaye<sup>3</sup>;

<sup>1</sup>Academic Radiology, <sup>2</sup>Diabetes, University of Sheffield,

<sup>3</sup>Diabetes, Sheffield Teaching Hospitals, UK.

**Background and aims:** Diabetic neuropathy (DN) has been linked to abnormalities in structure and function of the brain on Magnetic Resonance (MR). This study sought to explore intracranial vascular perfusion in patients with type-1 diabetes, with and without painful DN (PDN) and those without diabetes (HV).

**Materials and methods:** Groups: PDN=7; T1DM without neuropathy (D-NN)=8 & HV=7. MR images were obtained at 3T (Ingenia, Philips Healthcare) using a Dynamic Susceptibility Contrast, T2\*-weighted technique (TR/TE=1250/35; 72 dynamics) to assess the passage of a bolus of intravenous gadolinium-chelate passing through the cerebral vascular bed. Contrast perfusion was determined (Nordic NeuroLab ICE, Bergen, Norway) to yield the rBF (cerebral blood flow), rBV (volume) and mTT (mean transit time) in the SC (sensory cortex), Thalami (Thal) and parieto-occipital white matter (POWM). **Results:** Statistically significant differences were observed (ANOVA) between PDN and D-NN group mean mTT as well as PDN and HV group mean mTT [ eg. SC-mTT: PDN mean=2.87,SD=0.35; D-NN mean=3.46,SD=0.51; HV mean=3.72,SD 0.73, $p = 0.004$ ; Thal-mTT:PDN mean=2.89, SD=0.48; D-NN mean=3.41,SD=0.55; HV mean=3.82, SD=0.63,  $p = 0.004$ ]. BV and BF did not show significant mean differences between the 3 groups.

**Conclusion:** These early results (from a large on-going study) suggest cerebrovascular perfusion is altered within the brain parenchyma of subjects with PDN when compared to both diabetic and non-diabetic control groups. Microvascular dysfunction may have important implications in our understanding of the brain's involvement in DN, the search for functional neuropathic markers and indicators of future therapeutic intervention. Further work is warranted to further characterise this cerebrovascular involvement.

**Insulin resistance associated interhemispheric coordination deficits in type 2 diabetes mellitus patients: a resting-state study**

W. Xia, S. Wang, P. Wang, Y. Yang, R. Huang, R. Cai, H. Sun;  
Affiliated Zhongda Hospital of Southeast University, Nanjing, China.

**Background and aims:** Type 2 diabetes mellitus (T2DM) has an inextricable link with mild cognitive impairment (MCI) and Alzheimer's disease (AD). T2DM shares several same pathogenesis with AD as well as MCI, which might be mediated by insulin resistance. This study aims to investigate whether decreased interhemispheric coordination exists in T2DM patients using resting-state functional magnetic resonance imaging (rs-fMRI). If so, we further examine whether interhemispheric coordination deficits are associated with the insulin resistance among these patients.

**Materials and methods:** We compared the interhemispheric resting state functional connectivity of 32 T2DM patients and 30 age-, sex-, and education-matched healthy controls using rs-fMRI, computed using a recently proposed measurement named "voxel-mirrored homotopic connectivity (VMHC)". Pearson's correlation coefficients were measured to detect the relationship between rs-fMRI information and clinical data.

**Results:** Compared with the healthy controls, the patients showed significant decreases in VMHC in several brain regions within default mode network (DMN). Additionally, the VMHC values in the middle temporal gyrus (MTG) and superior frontal gyrus were found to be correlated inversely with the score of the Trail Making Test-B ( $r = -0.404$ ,  $p = 0.027$ ;  $r = -0.544$ ,  $p = 0.002$ , respectively) among the T2DM patients. Most importantly, log homeostasis model assessment-insulin resistance (HOMA-IR) had negative correlations with the VMHC values in the MTG among patients ( $r = -0.528$ ,  $p = 0.003$ ).

**Conclusion:** Patients with T2DM suffer disturbed interhemispheric correlation in several DMN regions, especially in the MTG, which is associated with insulin resistance. We suppose insulin resistance might play a not negligible role in the cognitive dysfunction in T2DM through damaging the MTG function.

Clinical Trial Registration Number: ChiCTR-ONRC-13003095

## 1136

**Increased grey matter volume loss in diabetic neuropathic subjects with depression**

S. Tesfaye<sup>1</sup>, R. Gandhi<sup>1</sup>, I.D. Wilkinson<sup>2</sup>, D. Selvarajah<sup>3</sup>;

<sup>1</sup>Academic Department of Diabetes and Endocrinology, Sheffield Teaching Hospitals NHS Foundation Trust, <sup>2</sup>Academic Department of Radiology, <sup>3</sup>Department of Human Metabolism, University of Sheffield, UK.

**Background and aims:** Using functional magnetic resonance imaging (fMRI), we have demonstrated increased neuronal activation within regions of the brain involved in emotional pain processing. We have also recently reported a significant volume loss in somatosensory cortex peripheral grey matter in patients with both painful and painless diabetic peripheral neuropathy (DPN). As several studies have strongly linked chronic mood disorders (depression and/or anxiety) that are very common in patients with DPN, with brain atrophy, we investigated the relationship between brain volumes and mood disorders in subjects with DPN.

**Materials and methods:** 24 subjects with type 1 diabetes [No-DPN (n=8), Painful DPN (8) and Painless DPN (8)] underwent detailed neurophysiological assessments to quantify severity of DPN [NIS(LL)+7tests]. All subjects underwent volumetric (0.8x0.8x0.8mm<sup>3</sup> resolution) brain MRI at 3T. Images were analysed using FSL (fMRIB, Oxford). Symptoms of depression were assessed using the Hospital Anxiety and Depression Scale (HADS-D).

**Results:** There were no significant differences in age ( $p=0.69$ ) and duration of diabetes ( $p=0.57$ ) between groups. As expected subjects with painful [9.6(6.6)] and painless [10.2(7.3)] DPN had significantly greater Neuropathy Composite Scores compared the No-DPN group [1.85(1.3);  $p=0.02$ ]. Moreover, subjects with painful DPN had significantly greater depression (HADS-D;  $p<0.001$ ) scores compared to the other study groups. Adjusted peripheral gray matter volume was statistically significantly lower in subjects with painless and painful DPN (mean 599.6 mL [SEM 9.8 mL] and 585.4 mL [10.0 mL], respectively) compared with those with No DPN (626.5 mL [5.7 mL]) and HVs (639.9 mL [7.2 mL]; ANCOVA,  $P = 0.001$ ). We also found a significant negative correlation between both, peripheral grey matter ( $\rho = -0.43$ ;  $p=0.04$ ) and deep grey matter ( $\rho = -0.51$ ;  $p=0.02$ ) volumes with HADS-D scores after adjusting for known variables (age, microvascular disease status). There was no significant correlation between HADS-D score and other brain volumes (white matter and CSF).

**Conclusion:** We have for the first time demonstrated increased grey matter atrophy in DPN subjects with depressive symptoms. Although, previous studies have reported increased brain atrophy in subjects with depression in non diabetic people, this is the first study to demonstrate this association in DPN. Further studies are now required to examine if the brain atrophy related to depression is localised to regions involved in emotional pain processing and the temporal relationship of mood disorders to the neuropathic process.

**Gender differences in impact of self-reported diabetes and neuropathy on quality of life in a large study on Romanian patients**

C.I. Bondor<sup>1</sup>, E.J. Vinik<sup>2</sup>, A.I. Vinik<sup>2</sup>, B. Florea<sup>1</sup>, N.A. Găvan<sup>3</sup>, I.A. Vereșiu<sup>4</sup>;

<sup>1</sup>Medical Informatics and Biostatistics, Iuliu Hatieganu University of Medicine and Pharmacy, Cluj-Napoca, Romania, <sup>2</sup>Eastern Virginia Medical School, Norfolk, USA, <sup>3</sup>Society for Diabetic Neuropathy, <sup>4</sup>Diabetes, Nutrition and Metabolic Diseases, County Clinical Emergency Hospital, Cluj-Napoca, Romania.

**Background and aims:** Objective was to evaluate the gender differences between total and 5 subdomains of Norfolk Quality Of Life Diabetic Neuropathy (QOL-DN) scores in self-reported diabetes with and without neuropathy (DN).

**Materials and methods:** In this cross-sectional survey, conducted between June and December 2012, 181 healthcare providers from 51 Romanian cities distributed the linguistically translated Romanian Norfolk QOL-DN questionnaire to their patients. Patients completed 35 questions related to their own health perception over the previous 4 weeks, resulting in 21,861 validated forms of 23,543 completed. Total QOL and each domain arithmetic means and standard errors (SEM) were computed.

**Results:** This is the largest study on gender differences in perception of QOL in patients with self-reported diabetes with and without neuropathy. Female patients reported higher scores than males on Total QOL ( $p<0.001$ ) with greatest impact on AN, symptoms and ADLs in both patients with and with-

out neuropathy. Most important, significantly more male patients (25.1%) than female (20.8%) reported DN complications - foot ulcers, gangrene and amputations ( $p < 0.001$ ), although all scores except SFN were significantly higher in women than in men. Both male and females had Total QOL and all 5 subdomains scores significant greater with DN and even greater with ulcers, gangrene or amputations ( $p < 0.001$ ).

**Conclusion:** Diabetes has a greater impact on QOL and all its domains in women than in men based on scores obtained with Norfolk QOL-DN questionnaire. Neuropathy and its complications of foot ulcers, gangrene and amputations greatly worsened QOL in both sexes and reduced but retained differences between the sexes.

Gender differences between Norfolk QOL-DN (Total and Subscale Scores (Mean  $\pm$  SEM)) in 21,756 Romanian Patients with Self-Reported Diabetes Mellitus with and without DN Complications

## PS 099 Diabetic foot: prevention and treatment

### 1138

**A comparative study of E-Med scan and foot mate print technologies in diabetic neuropathy ascertainment, Dar es Salaam, Tanzania**

Z.G. Abbas<sup>1,2</sup>, J.K. Lutale<sup>1</sup>, L.K. Archibald<sup>3</sup>;

<sup>1</sup>Internal Medicine, Muhimbili University College Of Health Science,

<sup>2</sup>Internal Medicine, Abbas Medical Centre, Dar es Salaam, United Republic of Tanzania, <sup>3</sup>Internal Medicine, College of Medicine, University of Florida, Gainesville, USA.

**Background and aims:** In Africa, diabetic foot ulceration is often associated with peripheral neuropathy (PN) and substantial morbidity and mortality. Thus, new affordable technologies for PN screening have the potential to improve patient outcomes across the African continent and other economically less-developed countries. We carried out this study to (i) evaluate two technologies\_the foot E-med scan system (EMS) and the simple Foot Mate print (FMP)\_in plantar pressure measurement; and (ii) correlate these measurements with PN ascertained clinically.

**Materials and methods:** During Jan 2011 - Nov 2013 (study period), all patients attending a diabetes centre in Dar es Salaam, Tanzania, were evaluated clinically following informed consent. Pressure at various sites on each foot was measured with EMS technology and FMP with an ink pad (dark areas reflected high pressures.) PN was ascertained at standard anatomic sites with a thermal sensation machine for pain (warm, heat, cold), monofilament for protective sensation, and biothesiometer for vibration.

**Results:** Of 1407 patients enrolled during the study period, 801 (60%) were male and 747 (53%) had PN by clinical assessment. Median age =52 (range: 11-90) years; median body mass index=29 (range: 14-59) kg/sq m. Patients with PN were significantly more likely than those without PN to be older (54 vs. 50 years,  $p < 0.01$ ) or to have a longer diabetes duration (6 vs. 4 years,  $p < 0.001$ ). In addition, per EMS technology, patients with PN were more likely to have significantly higher plantar pressures at the big toe ( $p < 0.0001$ ), 3rd, 4th, and 5th toes ( $p < 0.0001$ ), central hind foot ( $p < 0.05$ ), and mid hind foot ( $p = 0.005$ ) versus patients without PN. In contrast, FMP recorded high plantar pressures for PN patients only at the 2nd ( $p < 0.05$ ) and 3rd ( $p = 0.008$ ) toes. **Conclusion:** Pressure measurements were largely predictive of PN. While EMS was more sensitive than FMP in detecting high plantar pressures in patients with underlying PN confirmed by thermal sensation, biothesiometry, and monofilament testing across various anatomic areas of the foot, FMP was sensitive in predicting problems mainly in the toes rather than the hind foot. Despite these differences, both technologies have key major roles to play in the management of diabetic foot complications in Africa and other countries with limited resources.

### 1139

**The Diabetes Modernisation Initiative (DMI) for Foot Health:**

**“What does good look like?” Challenges in integrating foot care services across Southwark and Lambeth in London, UK**

P.R.J. Vas<sup>1</sup>, M. Simmgem<sup>1</sup>, M. Ferdinand<sup>2</sup>, T. Patel<sup>2</sup>, M. Fisk<sup>3</sup>, L. Price<sup>3</sup>, J. Collins<sup>2</sup>, M.E. Edmonds<sup>1</sup>, C. Gayle<sup>1</sup>;

<sup>1</sup>King's College Hospital, <sup>2</sup>Guy's and St Thomas' NHS Foundation Trust,

<sup>3</sup>GSTT Community Podiatry Service Lambeth and Southwark, London, UK.

**Background and aims:** The Diabetes Modernisation Initiative (DMI) in Southwark and Lambeth, two Boroughs in London, set out to bring together a working group of providers and commissioners to explore and develop further foot health improvements across care boundaries. The main areas of focus were to improve the number, quality and accuracy of foot assessments being completed in Primary Care practices. There also was a lack of information as to whether patients were being seen in the most appropriate care setting according to their risk classification.

**Materials and methods:** The working group in partnership with the Southwark Clinical Commissioning Group (CCG) investigated the risk stratification in primary care against actual patient activity in hospital and community settings in order to understand the scale of the discrepancies seen in reporting.

**Results:** From 2011/12 to 2012/13 the number of patients receiving a foot-risk assessment in Primary Care in the Borough of Southwark increased by

13% (to 84.4% of patients on the Diabetes register). In 2012/13, 17% of patients were classified as moderate or high risk, which requires regular community podiatry input. However, the actual patient activity indicated that only 8% of such patients with diabetes were seen - a gap of over half. Based on population studies of prevalence of foot risk, it would have been expected that as much as 20-30% diabetes individuals would have a moderate or high classification score. A greater disparity between hospital activity and Primary Care was seen in active diabetes foot disease. Only 0.6% of patients were coded as active, while 4% of patients were actually being seen in the two local acute Trusts' hospital foot clinics - a 6-fold difference.

**Conclusion:** The DMI found that only one in four patients identified to have moderate and high foot risk currently receives the desired foot follow-up. Furthermore, there was a substantial difference in active diabetes foot burden as perceived by Primary Care to that in fact seen at hospital clinics. Incorrect coding and risk stratification may have considerable impact on future commissioning of diabetes foot services as well as personnel. Improvements in coding can potentially lead to more efficient and responsive foot health services. The challenge of non-integrated care for diabetes foot patients has been met by DMI by bringing together all healthcare providers and commissioners to devise a joint strategy across sectors. This includes a locally adapted traffic light risk screening tool, structured referral forms and standardised clinical letters, now in ubiquitous use across the host CCGs. Criteria for bi-directional patient referral and discharge across community and hospital settings have now been implemented.

Supported by: DMI

## 1140

### Barriers to inpatient diabetic foot examination

A.J. Welch, A.I. Eyre-Brook, E.J. Rogers, P. Verlekar, R.J.C. Guy; Diabetes, Hampshire Hospitals NHS Trust, Basingstoke, UK.

**Background and aims:** Despite NICE guidelines and Putting Feet First, only 38% of patients with diabetes receive a foot assessment in England and Wales within 24 hours of admission (National Diabetes Inpatient Audit 2013). A local audit has demonstrated an increase in foot examinations from 13 to 53% following education and introduction of a diabetic foot sticker in the acute medical admissions proforma. Our aim was to identify the major barriers to diabetic foot examination and to explain why compliance was so low.

**Materials and methods:** A self-administered questionnaire was designed to reflect knowledge, training, practice, confidence and barriers to diabetic foot examination. The survey was given to 110 doctors, 4 diabetic specialist nurses and 3 medical students involved in acute medical admissions.

**Results:** The response rate was 71%: 51% were doctors in training, 30% consultants and 9% medical students/diabetic nurses. Although 96% thought foot examination important, only 56% would do this routinely. The other 44% required a further clinical indication before they would perform an examination, such as a diabetic foot ulcer or sepsis. The greatest barriers to examination were: time constraints (86%), occlusive dressings (78%), forgetting (69%), lack of equipment (64%), lack of training (56%) and patients being too ill (41%). Foot odour was a problem for 16% and foot phobia in 11%. 69% admitted to examining less than half of their admissions and 94% examined less than half of patients' footwear. This was despite 60% highlighting poor footwear as one of the greatest risk factors for ulceration. 31% of

respondents have had no formal foot examination training, including 44% of all consultants. The preponderance (45%) of training was undertaken at medical school, the quality of which was only rated as good or excellent by 39%. Little teaching was organised on the wards (18%), in hospital (14%) or online (6%). Confidence was expressed in diagnosing vascular disease (86%) and neuropathy (84%), but staff lacked confidence with acute Charcot joints (73%), neuro-ischaemic ulcers (52%), acute osteomyelitis (49%) and neuropathic ulcers (47%). Staff thought the greatest risks for foot ulceration were: poor blood sugar control (80%), ill-fitting footwear (60%), peripheral neuropathy (54%) and peripheral vascular disease (49%). Respondents grossly overestimated the number of patients presenting with a foot ulcer leading to a new diagnosis of type 2 diabetes (median 15%). However, the prediction of amputation rates in diabetic patients with an ulcer over a 20 year period was more accurate: median 20%.

**Conclusion:** Despite awareness that diabetic foot examination is important, there continues to be unwillingness to perform this crucial examination unless clinical indications are present. Lack of time, barrier dressings, forgetting, equipment shortages and poor training account for most incomplete examinations. Staff lack confidence in their ability to diagnose acute Charcot joints and osteomyelitis and a significant number, especially consultants have had no formal training. Simple local interventions have the potential to significantly increase compliance with foot examinations. Regular hospital-based teaching should be made more widely available with refresher courses for consultants. Increasing resources, improving access to equipment, encouragement to remove occlusive dressings and reminders in admission booklets are all fundamental to improving the foot care of diabetic patients admitted to hospital.

## 1141

### Nonvisual foot examination for people with visual impairment

A.S. Williams<sup>1</sup>, B.D. Caldwell<sup>2</sup>, J.S. Kawalec<sup>2</sup>;

<sup>1</sup>Nursing, Case Western Reserve University, Cleveland,

<sup>2</sup>Kent State University College of Podiatric Medicine, Independence, USA.

**Background and aims:** Because people with both diabetes and visual impairment have high risk for ulcers and amputation, prevention is a top priority. Usual care in diabetes self-management education is to teach visually impaired people to seek sighted assistance for regular foot examination, yet clinical experience suggests that this advice is seldom heeded. One possible solution is to teach use of the nonvisual senses for foot self-examination. The purpose of this pilot study was to compare the efficacy, acceptability, and feasibility of nonvisual foot examination, using the senses of touch and smell, with usual care (examination of feet by a sighted person).

**Materials and methods:** Fifty-two visually impaired adults with type 2 diabetes received comprehensive diabetes self-management education, with the experimental and comparison groups receiving different foot examination instructions. The experimental group was taught nonvisual foot examination, i.e., use of their own hands for a systematic tactile inspection of feet for cuts, swelling, irregularities, or warmth, and use of the nose to detect unusual odors. The comparison group received usual care instructions for visually impaired persons, i.e., to have someone with good eyesight to check their feet. All kept large print or tactile diaries of how frequently foot examination was done at home and by whom; this was reported monthly to the research team in a phone call. All had baseline podiatric evaluations and follow-up evaluations at 3 and 6 months, with extra visits if medically necessary. Participant-reported foot symptoms and podiatrist-confirmed new foot problems were recorded at each visit following the baseline evaluation. Focus groups were held after the 6 month visit.

**Results:** Both the experimental and comparison Groups had their feet checked a mean of about 22 times per month, with no significant difference between groups ( $p = .69$ ). However, people in the experimental group followed the instructions they were given (i.e., checked their own feet) much more frequently ( $M = 1.03$ ) than people in the comparison group did so (i.e., had someone else check their feet) ( $M = .56$ ),  $F(1, 45) = 41.42$ ,  $p < .001$ . This result is consistent with qualitative information gathered through the focus groups. Many in the experimental group reported checking their own feet frequently, as they were taught, with occasional backup from sighted people. In contrast, many in the comparison group reported being reluctant to follow the instructions they had been given and ask for help checking their feet. They said they checked their own feet „as best they could“, using whatever vision they had or using self-invented tactile methods, and got help when it was not too embarrassing or difficult. At podiatrist visits, people in the experimental group reported a greater number of symptoms per visit ( $M =$

1.61) than people in the comparison group ( $M = 1.13$ ),  $F(2, 50) = 64.07$ ,  $p < .001$ , indicating a greater effectiveness of their home foot check methods.

**Conclusion:** Visually impaired people in this study who were advised to ask someone with good eyesight to check their feet did not do so regularly. Many invented their own method of self-checking in whatever way they are able. These invented methods were not as effective for detecting symptoms of foot problems at home as systematic nonvisual foot examination. Systematic methods of nonvisual foot examination should be routinely taught to visually impaired people with diabetes.

### Relationship between gait alterations and microvascular chronic complications in type 2 diabetic patients

E. Iacopi<sup>1</sup>, R. Giannarelli<sup>1</sup>, A. Coppelli<sup>1</sup>, D. Martelli<sup>2</sup>, G. Lamola<sup>2</sup>, M. Venturi<sup>2</sup>, C. Chisari<sup>2</sup>, S. Del Prato<sup>1</sup>, A. Piaggese<sup>3</sup>;

<sup>1</sup>Department of Endocrinology and Metabolism,

<sup>2</sup>Department of Neuro-Rehabilitation, <sup>3</sup>Diabetic Foot Section -

Department of Endocrinology and Metabolism, University of Pisa, Italy.

**Background and aims:** We evaluated gait alterations and their correlations with microvascular chronic complications in type 2 diabetic patients (T2DM).

**Materials and methods:** Thirty-six T2DM (M/F: 27/9; age: 63±10 yrs; diabetes duration: 12±11 yrs; BMI: 29.2±5.6 Kg/m<sup>2</sup>; HbA1c 8.1±0.9%) attending our outpatient clinic, were divided into 3 Groups: Group 1 (n=12) with no diabetic neuropathy (DN) and foot ulcerations (FU); Group 2 (n=10) with DN and no FU; Group 3 (n=15) with DN and non-infected, non-ischemic FU. We analyzed biomechanical alterations of lower limbs by motion analysis system (BTS Elite Clinic, BTS Bioengineering, Milan, Italy). Spatial-temporal and kinematics data were collected through photogrammetric infrared cameras while kinetics data with two forces plates. Data were correlated with patients' microvascular chronic complications; in particular, all patients were examined with indirect and direct retinoscopy and two non-stereoscopic 45° retinal photographs for each eye. The presence and severity of retinopathy (DR) was determined according to the Eurodiab Study classification.

**Results:** Step Width (SW) was greater in Group 2 (240.9±47.5 mm) and Group 3 (271.6±41.7 mm,  $p < 0.02$  vs group 1); ankle range of motion (ROM) was significantly lower in Group 3 (Group 1: 26.6±5.6°, Group 2: 26.0±4.9°, Group 3: 23.6±4.7° (Group 3  $p < 0.05$  vs Group 1 and 2)); foot ROM was significantly lower in Group 3 (Group 1: 37.2±6.6°, Group 2: 34.8±1.7°, Group 3: 30.2±1.5° (Group 3  $p < 0.02$  vs Group 1 and 2)). There was no difference in vertical ground-reaction forces. When the whole population was considered, a positive correlation was apparent between DR presence and severity and SW ( $r = 0.6$ ;  $p < 0.05$ ) and foot ROM ( $r = 0.65$ ;  $p < 0.05$ ).

**Conclusion:** Our study demonstrated a positive correlation between biomechanical alterations and presence and severity of DR in T2DM, suggesting a possible contribution of the involvement of the microvascular bed in the pathogenesis of FU.

## 1143

### Increased pulse pressure and reduced baroreflex gain precede diabetic foot complication by at least 10 years

M. Rorive, M. Tyberghein, M. Marchand, J.-C. Philips, A.J. Scheen; Division of Diabetes, Nutrition and Metabolic Disorders, University of Liège, Belgium.

**Background and aims:** This case-control retrospective study investigated whether abnormalities in arterial stiffness (estimated by increased pulse pressure: PP) and cardiovascular autonomic neuropathy (evaluated by decreased baroreflex gain: BRG) may be present far before the occurrence of diabetic foot complications and thus potentially used as predictive markers.

**Materials and methods:** PP and BRG were derived from a continuous (using a Finapres® device) blood pressure (BP) and heart rate (HR) during a standardised squatting test (1 min standing - 1 min squatting - 1 min standing). Measurements were collected in 20 diabetic patients with future diabetic foot complication (selected in our diabetes foot clinic, around 9±4 years after initial haemodynamic assessment), in 20 patients without diabetic foot - matched for type (10 T1D/10 T2D) and duration of diabetes (mean: 24 years), age (mean: 54 years), gender (15M/5F), BMI (mean: 28 kg/m<sup>2</sup>) and HbA1c (mean: 8,2%) - and in 20 nondiabetic well matched controls. PP

was calculated by the difference between systolic BP (SBP) and diastolic BP (mmHg) during the whole 3 min test and during squatting position while BRG (msec/mmHg) was calculated by the slope of the relationship between RR intervals and SBP during the transient phase from squatting to standing. **Results:** PP was higher in diabetic with (mean ± SD: 73±20,  $p < 0.0001$ ) and without future diabetic foot (68±17,  $p = 0.001$ ) than in controls (50±13 mmHg). During squatting, diabetic patients with later diabetic foot had much greater PP increases (+17±12 mmHg) than diabetic patients without diabetic foot (+8±9,  $p = 0.009$ ) or controls (+7±7,  $p = 0.003$ ). During squatting, increases of PP×HR products and SBP×HR products were more than doubled ( $p < 0.05$ ) in patients with versus without later diabetic foot (Table). Baroreflex gain was significantly decreased in patients with later diabetic foot than in patients than in controls (1.11±0.91 versus 2.46±2.32;  $p = 0.024$ ), but not significantly in patients free of diabetic foot (1.59±1.37;  $p = 0.163$ ).

**Conclusion:** Increased PP, mainly in squatting position, and decreased BRG were already present almost 10 years before the occurrence of a diabetic foot complication. These results are in favour of a contribution of arterial fitness and autonomic neuropathy in this complication. They also suggest that increased PP and decreased BRG may be considered as initial markers of future diabetic foot complications and thus may help selecting patients who should be more particularly supervised and advised to avoid diabetic foot complications.

### Microvascular dysfunction in diabetic Charcot neuroarthropathy

A. Araskiewicz, J. Soska, K. Borucka, M. Olszewska, P. Niedzwiecki, D. Zozulinska-Ziolkiewicz, B. Wierusz-Wysocka; Department of Internal Medicine and Diabetology, Poznan University of Medical Sciences, Poland.

**Background and aims:** Charcot neuroarthropathy is a form of diabetic foot syndrome characterized by bone and joints deformation. The pathogenesis of Charcot foot is uncertain. The aim of this study was to assess factors associated with the occurrence of Charcot neuroarthropathy in patients with diabetes.

**Materials and methods:** It is a case-control study. We evaluated 40 diabetic patients (31 men) with Charcot neuroarthropathy (CN-DM), median age 59 (IQR: 51-62), median disease duration 16 (9-24) years. The control group were 38 subjects with diabetes and without Charcot neuroarthropathy (DM), 29 men, median age 60 (55-62), median diabetes duration 15 (10-21) years. We assessed metabolic control of diabetes, serum C-reactive protein concentration (CRP) and cardiovascular autonomic neuropathy (ProsciCard III). We used AGE-Reader to measure skin autofluorescence (AF) associated with accumulation of advanced glycation end products that reflects long lasting metabolic control. Microvascular function was examined by laser Doppler flowmetry (PERIFLUX 5000) with thermal hyperemia and postocclusive reactive hyperemia.

**Results:** CN-DM patients as compared to DM subjects had better HbA1c level [7.5 (6.6-8.2) vs 8.2 (7.1-9.5)%,  $p = 0.01$ ] and higher CRP concentration [4.8 (2.3-11.0) vs 1.8 (0.6-4.1)mg/l,  $p < 0.001$ ]. The peak flow during thermal hyperemia (THmax) was lower in CN-DM subjects as compared to DM group

[163 (76-246) vs 254 (165-366)PU,  $p=0.001$ ]. Additionally, we found negative correlation between THmax and CRP concentration ( $R_s=-0.33$ ,  $p=0.03$ ), TG concentration ( $R_s=-0.46$ ,  $p=0.002$ ) and skin AF ( $R_s=-0.32$ ,  $p=0.04$ ) and positive correlation between THmax and HDL cholesterol level ( $R_s=0.58$ ,  $p<0.001$ ). The cardiovascular autonomic neuropathy (CAN) prevalence was higher in CN-DM subjects [62 vs 35%,  $p=0.01$ ].

**Conclusion:** Deterioration of microvascular function and autonomic system dysfunction might play a crucial role in the development of Charcot neuroarthropathy. Microvascular reactivity is related to long lasting metabolic control of diabetes and activation of inflammatory process.

### Endovascular revascularisation in type 2 diabetic patients with critical limb ischaemia: comparison of direct and indirect revascularisation according to angiosome model

A. Coppelli<sup>1</sup>, E. Iacopi<sup>1</sup>, I. Bargellini<sup>2</sup>, A. Cicorelli<sup>2</sup>, A. Lunardi<sup>2</sup>, C. Mattaliano<sup>3</sup>, C. Goretti<sup>3</sup>, R. Cioni<sup>2</sup>, S. Del Prato<sup>1</sup>, A. Piaggese<sup>3</sup>;

<sup>1</sup>Department of Endocrinology and Metabolism, <sup>2</sup>Department of Radiology,

<sup>3</sup>Diabetic Foot Section - Department of Endocrinology and Metabolism, University of Pisa, Italy.

**Background and aims:** The angiosome model (AM) is commonly used to guide bypass and endovascular procedures in the lower limb. We evaluated whether direct or indirect revascularization, according to AM, may affect clinical outcomes in diabetic patients with critical limb ischemia (CLI) undergoing percutaneous trans-luminal angioplasty (PTA).

**Materials and methods:** We retrospectively evaluated 137 type 2 diabetic patients (M/F: 93/44; age:  $72.9\pm 9.2$  yrs; BMI:  $27.7\pm 8.2$  kg/m<sup>2</sup>; diabetes duration:  $21.8\pm 13.4$  yrs; HbA1c  $8.4\pm 1.1\%$ ) consecutively admitted to our Department for CLI and foot lesions (FL) who underwent successful lower limb PTA. Patients were divided in 2 groups: direct (92 pts, 67%) or indirect (45 pts, 33%) depending on whether the flow to the artery directly feeding the site of ulceration, according to AM, was successfully acquired or not. Clinical outcomes (ulcer healing rate, major amputation or death) were compared in the two groups 3 months post PTA.

**Results:** Healing rate was higher in direct vs indirect group (58% vs 30%, respectively,  $p<0.02$ ). One major post-procedural amputation was necessary in the indirect group (2.2%) and none in the direct one. Mortality rate during the follow-up was 19% in direct vs 31% in indirect group ( $p=NS$ ).

**Conclusion:** Our data confirm that direct revascularization of arteries supplying the FL results in greater ulcer healing rate as compared to the indirect one. Thus, AM should be considered in diabetic patients with FL whenever possible.

### Perfusion scintigraphy as a method of stem cell therapy assessment in patients with critical limb ischaemia and diabetic foot

M. Dubský<sup>1</sup>, A. Jirkovská<sup>1</sup>, M. Bunčová<sup>2</sup>, R. Bem<sup>1</sup>, V. Fejfarová<sup>1</sup>, A. Nemcová<sup>1</sup>, V. Wosková<sup>1</sup>, J. Skibová<sup>1</sup>;

<sup>1</sup>Diabetes Centre, Institute for Clinical and Experimental Medicine,

<sup>2</sup>Department of Nuclear Medicine, Institute for Clinical and Experimental Medicine, Prague, Czech Republic.

**Background and aims:** There is a lack of imaging methods for microcirculation of the lower limbs in diabetic patients. Perfusion scintigraphy with Technetium-99-methoxy-isobutyl-isonitrile (MIBI) is often clinically used for the assessment of myocardial function because of its fast uptake in mitochondrial membrane. The aim of our study was to assess perfusion scintigraphy as eligible imaging method for perfusion of calf muscles after stem cell therapy and to compare it with changes of transcutaneous oxygen pressure (TcPO<sub>2</sub>).

**Materials and methods:** Perfusion scintigraphy with <sup>99m</sup>Tc-MIBI was performed before and 2 months after the autologous stem cell therapy in 19 patients with no-option critical limb ischemia (mean age  $63.3 \pm 9.1$  years, mean diabetes duration  $24.2 \pm 7.4$  years). TcPO<sub>2</sub> measurement was used as a standard method of non-invasive evaluation of limb ischemia. After application of 4 MBq/kg of <sup>99m</sup>Tc-MIBI a whole-body scan and SPECT/CT was performed; next bolus of 8 MBq/kg of <sup>99m</sup>Tc-MIBI was applied after a stress test (60times flexion and extension in ankle joint). Scintigraphic parameters such as rest count (RC) and exercising count (EC) after stress test were set up.

Ischemic ratio in rest (IRR) and after stress test (IRE) were defined as ratios of these parameters in treated to untreated (control) limb.

**Results:** We observed a significant improvement in IRR (from 0.44 to 0.49,  $p = 0.01$ ) as well as in IRE (from 0.47 to 0.51,  $p = 0.03$ ) after 2 months from cell treatment. The effect of stem cell therapy was confirmed by a significant increase of TcPO<sub>2</sub> values from baseline  $12.9 \pm 9$  to  $37.2 \pm 14.8$  mm Hg after 2 months ( $p = 0.0001$ ).

**Conclusion:** Our study showed a significant improvement in scintigraphic parameters after stem cell therapy in patients with ischemic diabetic foot which was in accordance with changes of TcPO<sub>2</sub>. Perfusion scintigraphy could be a promising technique to objectify the microcirculation of lower limbs.

## PS 100 Management of foot ulcers

### 1147

#### A longitudinal cohort of people presenting with diabetic foot ulcers in northern England

N. Holman<sup>1</sup>, P.J. Chadwick<sup>2</sup>, J. McAdam<sup>2</sup>, S. Haycocks<sup>2</sup>, B. Young<sup>3</sup>;

<sup>1</sup>Institute of Cardiovascular and Medical Sciences, University of Glasgow,

<sup>2</sup>Podiatry Department, Salford Royal Foundation NHS Trust, <sup>3</sup>Diabetes and Endocrinology, Salford Royal Foundation NHS Trust, UK.

**Background and aims:** It is known that people with diabetic foot ulcers have high morbidity and mortality but there is little contemporary data 'real world' data on this group of people outside specific research trials. This population based study examines the characteristics and outcomes of people with incident diabetic foot ulcers in a longitudinal cohort of people presenting with diabetic foot ulcers in Salford in the north of England.

**Materials and methods:** Since 2001 data on all people with an incident diabetic foot ulcer in Salford has been recorded in an electronic clinical system as part of routine clinical practice. This database has been linked with death registration records to identify all deaths up to June 2013. Regression models were created to examine factors associated with ulcer healing, ulcer recurrence and mortality.

**Results:** Between 2001 and 2012 there were 8028 incident cases of diabetic foot ulcers among 2937 people. There has been no change in age at presentation (mean 68.6 years, median 70 years) or the proportion of patients that were male (59.4%). 2.4% of incident ulcers were deep enough to involve the bone, 24% were accompanied by cellulitis and 32.7% were in people with peripheral vascular disease. The proportion of people with a previously healed foot ulcer reduced from 67.2% in 2001 to 44.6% in 2012 ( $p < 0.005$ ). Median time to healing was 79 days (IQR 21–320 days). The proportion of ulcers that healed within 90 days declined from 61.1% in 2011 to 32.1% in 2012 ( $p < 0.005$ ). Men (OR 0.868 95% CI 0.773–0.975) and older people (OR 1.005 95% CI 1.001–1.009 per additional year) were less likely to heal within 90 days. Having peripheral vascular disease (OR 0.750, 95% CI 0.660–0.853), cellulitis (OR 0.840, 95% CI 0.736–0.960), an ulcer to the bone (OR 0.461, 95% CI 0.303–0.702) were significantly associated with a lower chance of the incident ulcer healing within 90 days whilst having a previously healed ulcer increased the chance of healing (OR 1.529, 95% CI 1.364–1.714). Of the people presenting with a foot ulcer in 2010 8.8% died within six months, 15.5% died within one year and 24.6% had died after two years. Being male (OR 1.246, 95% CI 1.002–1.549), older (OR 1.064, 95% CI 1.054–1.075 per additional year), having peripheral vascular disease (OR 2.410, 95% CI 1.949–2.978) or a rear-foot ulcer (OR 1.907, 95% CI 1.520–2.392) were associated with significantly higher mortality six months after presentation. These factors are also predictors of longer term mortality in this group.

**Conclusion:** The demographic characteristics of people presenting with incident diabetic foot ulcer have not changed since the turn of the century. Outcomes remain very poor with the majority of ulcers unhealed at 90 days. One in four people presenting with foot ulcers died within two years; this short term mortality is very high especially in those with co-existent peripheral vascular disease which more than doubles the risk of dying.

### 1148

#### Identification of factors contributing to failure of ambulatory negative pressure wound therapy in patients with diabetic foot

R. Bem, A. Jirkovska, M. Dubska, V. Fejfarova, V. Woskova, A. Nemcova, L. Rezaninova, J. Skibova;

Diabetes Centre, Institute for Clinical and Experimental Medicine, Prague, Czech Republic.

**Background and aims:** Previous studies showed that negative pressure wound therapy (NPWT) is an effective method for the treatment of patients with diabetic foot. Indication criteria of this treatment based on patient and wound characteristics are not clear verified. The aim of our study was to assess the effect of ambulatory NPWT on diabetic foot healing and identify factors contributing to failure of this method.

**Materials and methods:** 148 patients with diabetic foot hospitalized in our Diabetes Department were treated by NPWT between May 2003 and October 2013. 60 patients continued with NPWT on ambulatory basis and were enrolled in the present study. The changes of dressing were done in our foot clinic 2–3 times per week. The median length of NPWT was 23 days

(7–98). The success of NPWT was defined as a complete wound healing during 6 months follow-up; the unsuccess as a premature termination of NPWT (worsening of the wound/no effect), non-healing, major amputation or intolerance of the treatment by patient during 6 month follow-up. In all patients, factors which could influence wound healing were evaluated: age, type of diabetes, duration of diabetes, diabetes control ( $HbA_{1c}$ ), presence of infection, ischemia, Charcot foot, renal failure and other comorbidities, but also local factors (wound localization, size, exposed bone etc.). Uni- and multivariate analyses were used to identification of factors contributing to failure of ambulatory NPWT.

**Results:** During follow-up period, 47/60 (78.3%) patients were completely healed after ambulatory NPWT, in 13/60 (21.7%) patients was not NPWT successful. In univariate analysis, the unsuccess of NPWT was influenced especially by poor diabetes control ( $HbA_{1c}$  in unsuccess vs. success;  $77.2 \pm 19$  vs.  $62.5 \pm 18.6$  mmol/mol;  $p = 0.01$ ). Potential factors of NPWT failure should be also exposed bone in the wound (76.9% of patients with unsuccess vs. 46.8% with success;  $p = 0.1$ ) and haemodialysis (23.1% vs. 4.2%;  $p = 0.1$  resp.). There were no significant differences in other factors assessed in univariate analysis. Logistic regression showed that  $HbA_{1c}$  (OR 1.05; 95% CI 1.01–1.09;  $p = 0.01$ ), haemodialysis (18; 1.6–208.3;  $p = 0.02$ ) and exposed bone (7.8; 1.3–48.1;  $p = 0.03$ ) were significant factors for failure of ambulatory NPWT, other followed factors were not significant.

**Conclusion:** Ambulatory NPWT was effective in majority of patients, but poor diabetes control, haemodialysis or exposed bone in the wound may contribute to the failure of this method. These results showed that patients with diabetic foot treated by ambulatory NPWT require precise follow-up focused on diabetes control and it is necessary to consider the indication in patients on haemodialysis and with exposed bone in the wound.

### 1149

#### Arterial stiffness influence outcome of chronic diabetic foot ulcers in patients with type 2 diabetes

D.-H. Cho, J.-O. Chung, D.-J. Chung, M.-Y. Chung;

Department of Endocrinology and Metabolism, Chonnam National University Hospital, Gwangju, Republic of Korea.

**Background and aims:** Chronic diabetic foot ulcers are estimated to occur in 15% of all patients with diabetes and precede 84% of all diabetes-related lower-leg amputations. The pathophysiology of chronic diabetic foot ulcers still incompletely understood, but both micro- and macroangiopathy strongly contribute to the development and delayed healing of diabetic wounds. Pulse wave velocity (PWV) is a method to estimate arterial stiffness and predicts cardiovascular morbidity and mortality. Several studies demonstrated that pulse wave velocity is a sensitive predictor for peripheral artery disease and cerebrovascular disease among diabetic patients. The objective of this study was to determine whether arterial stiffness index [brachial-ankle pulse wave velocity (baPWV)] can influence outcome of chronic diabetic foot ulcers in patients with type 2 diabetes.

**Materials and methods:** We recruited a total of 102 type 2 diabetic patients (63 men and 39 women) with chronic nonhealing diabetic foot ulcers with Wagner grade 1 or 2 ulcers that are  $\geq 2$  cm in largest diameter at diagnosis for more than 1-month duration. The age was  $65.2 \pm 16.4$  years, and the diabetes duration was  $18.4 \pm 16.0$  years. Anthropometric, clinical, and laboratory data were measured. All patients were seen bi-weekly for debridement, offloading, and other treatments during the initial 8 weeks. The PWV was measured between the brachial and ankle regions (baPWV), and the baPWV was measured in all patients using a waveform analyzer.

**Results:** At 8 weeks, 49 of the 102 ulcers had completely healed. The patients were assigned into healed group ( $n = 49$ ) or unhealed group ( $n = 53$ ) according to clinical outcome of ulcer healing at 8 weeks. There were not significantly different in age, duration of diabetes,  $HbA_{1c}$ , or initial wound size in diameter of the ulcer between the healed and unhealed groups. The healing time of foot ulcers in healed group was  $5.4 \pm 2.8$  weeks (range 2.8–8.0). The baPWV was significantly ( $P < 0.05$ ) higher in the unhealed group ( $1773 \pm 279$  cm/s) as compared with the healed group ( $1547 \pm 340$  cm/s). ABI or TBI was not significantly different between unhealed and healed group. Age ( $r = 0.463$ ;  $p < 0.01$ ), duration of diabetes ( $r = 0.425$ ;  $p < 0.05$ ), ankle-brachial index (ABI) ( $r = -0.349$ ;  $p < 0.05$ ) and toe-brachial index (TBI) ( $r = -0.264$ ;  $p < 0.05$ ) were significantly correlated with baPWV. But BMI, lipid profiles,  $HbA_{1c}$ , and systolic and diastolic BP were not correlated with baPWV. Univariate analysis revealed that baPWV was significantly correlated with healing rate of diabetic ulcers ( $r = 0.321$ ,  $p < 0.05$ ) and duration of diabetes ( $r = 0.412$ ,  $p < 0.01$ ).

**Conclusion:** These findings indicate that baPWV is closely associated with the healing time of diabetic ulcers. We suggest that the measurement of systemic arterial stiffness may help to identify ulcers at risk of poor healing in chronic diabetic foot ulcers in patients with type 2 diabetes.

## 1150

### The association between Neuropad testing with foot ulceration in diabetes

N. Tentolouris<sup>1</sup>, N. Papanas<sup>2</sup>, G. Panagoulas<sup>1</sup>, D.S. Tesic<sup>3</sup>, Z. Kamenov<sup>4</sup>, C. Manes<sup>5</sup>, S. Bousboulas<sup>6</sup>, E. Jude<sup>7</sup>;

<sup>1</sup>1st Department of Propaedeutic and Internal Medicine, Athens University Medical School, Laiko General Hospital, <sup>2</sup>2nd Department of Internal Medicine, Democritus University of Thrace, Alexandroupolis, Greece, <sup>3</sup>Medical Faculty, University of Kragujevac, Serbia, <sup>4</sup>Medical University, Sofia, Bulgaria, <sup>5</sup>Diabetes Centre, General Hospital Papageorgiou, Thessaloniki, <sup>6</sup>3rd Department of Internal Medicine and Diabetes Centre, General Hospital of Nikaia Agios Panteleimon, Piraeus, Greece, <sup>7</sup>Diabetes Centre, Tameside General Hospital, UK.

**Background and aims:** Foot ulceration in patients with diabetes is a serious complication associated with increased morbidity, mortality and healthcare cost and is the main cause of amputation. The prevalence of foot ulcers is 4% to 10%, and the annual population-based incidence is 1.0% to 4.1%. Prevention of foot ulceration and consecutively amputation begins with identification of those at risk. Well-established risk factors for foot ulceration are previous foot ulceration and lower extremity amputation, long duration of diabetes, poor glycaemic control, severity of diabetic neuropathy, foot deformities and visual impairment. Cross-sectional data have shown that dryness of the skin of the feet assessed by either sympathetic skin response or Neuropad testing has been associated with foot ulceration in patients with diabetes. In addition, Neuropad testing has a high performance for the diagnosis of diabetic peripheral neuropathy and is proper for self-testing. The aim of the present prospective multicenter study was to examine the association between Neuropad testing with foot ulceration in patients with diabetes.

**Materials and methods:** A total of 308 patients with diabetes (155 females and 153 males; 280 with type 2 diabetes; mean age  $62.8 \pm 11.3$  years; mean diabetes duration  $12.4 \pm 9.7$  years) with no history of foot ulceration were recruited in the study from the year 2005 until the year 2012. At baseline participants were evaluated for neuropathy status using the neuropathy disability score (NDS). Patients with NDS 0-2 were considered as having no neuropathy, those with NDS 3-5 as having mild neuropathy and those with NDS  $\geq 6$  as having severe neuropathy. In addition Neuropad testing was performed and the results were evaluated as normal or abnormal based on complete colour change of the test after 10 min of application.

**Results:** At baseline, 148 patients (48.1%) did not have neuropathy, 82 (26.6%) had mild neuropathy and 78 (25.3%) had severe neuropathy. Neuropad testing was normal in 128 (41.6%) and abnormal in 180 (58.4%) patients. The mean follow-up was  $5.5 \pm 2.5$  years. During this time, 55 (17.9%) patients developed foot ulcers. At baseline, patients who developed foot ulcers were older ( $p=0.03$ ) and had longer diabetes duration ( $p=0.01$ ). After adjustment for age, gender and duration of diabetes, abnormal Neuropad testing at baseline was associated with increased odds (OR, 95% confidence intervals) for foot ulceration [4.2 (1.8-9.8)]. Similarly, the adjusted OR of NDS $\geq 6$  vs. NDS $<6$  for foot ulceration was 8.5 (3.3-21.7). The OR for foot ulceration was not increased significantly ( $p=0.09$ ) in those having mild neuropathy (NDS 3-5) vs. those having no neuropathy.

**Conclusion:** These prospective demonstrate that abnormal Neuropad testing is associated with a 4-fold higher risk for foot ulceration. Neuropad testing can be included in the screening tests for the prevention of foot ulceration in patients with diabetes.

### Measurement of TcPO<sub>2</sub>, toe pressures and laser Doppler flow reveals hitherto undiagnosed subclinical ischaemia in patients with palpable pedal pulses and foot ulceration

C.A. Manu, V. Morris, P. Vas, M. Simmggen, M.E. Edmonds; Diabetic Foot Clinic, King's College Hospital, London, UK.

**Background and aims:** Patients presenting with a diabetic foot ulcer should be assessed and treated urgently as a "foot attack". However, their clinical vas-

cular assessment is often limited to palpation of pulses and measurement of Ankle Brachial Pressure Index (ABPI). The aim of this study was to investigate the contribution of a full assessment of the macro- and microcirculation in patients with foot ulceration.

**Materials and methods:** Consecutive patients with ulceration in one or both limbs underwent measurement of ABPI, Toe Blood Pressure Index (TBPI), TcPO<sub>2</sub> in both feet, at supine and at 30° elevation and simultaneously in forearm, and forefoot laser Doppler flowmetry, in perfusion units (PU), at baseline and with heat provocation. All measurements were carried out within 35min. Results are reported as mean $\pm$ SD.

**Results:** There were 53 limbs in 27 patients, age  $57\pm 9.8$  yrs, 93% males, 86% with type 2 diabetes and 66% of limbs were ulcerated; 40 limbs had palpable pedal pulses (Group 1) and 13 limbs had a known diagnosis of ischemia (Group 2). Unexpectedly 58% of group 1 had evidence of ischemia (we called Group 1a) as denoted by a low TBPI of  $\leq 0.7$  (mean  $0.5\pm 0.1$ ), compared with the remaining patients (Group 1b), with normal TBPI (mean  $1.0\pm 0.2$ ) [ $p=0.001$ ]. Doppler flow increment on heating was less in Group 1a,  $12\pm 9$  to  $52$  PU compared with Group 1b,  $12\pm 4$  to  $68$  PU [ $p=0.03$ ]. However, there was no significant difference between Group 1a and 1b as regards ABPI,  $1.1\pm 0.2$  vs  $1.2\pm 0.2$  [ $p=0.053$ ] nor TcPO<sub>2</sub> at supine,  $52\pm 11$  vs  $55\pm 8$ mmHg [ $p=0.55$ ]. However, foot elevation identified 10% in group 1b with a  $\geq 15$ mmHg drop in TcPO<sub>2</sub> despite their normal TBPI. As expected, in group 2 (known diagnosis of ischaemia), mean TBPI was  $0.5\pm 0.3$ , baseline TcPO<sub>2</sub>  $39\pm 20$ mmHg. There was no difference in proportion of ulcers across all groups,  $p=0.79$ .

**Conclusion:** We have identified a subgroup of patients with palpable pulses that have a low TBPI and a reduced heating response to Doppler flowmetry but a preserved tcpO<sub>2</sub> at baseline. This subgroup is distinct both from patients with palpable pulses and normal TBPI who have a normal TcPO<sub>2</sub> and heat response and also distinct from patients with known ischaemia in whom all these parameters are abnormal. This demonstrates that it is essential for all patients to have a thorough examination of both macro- and micro circulation on presentation to the multidisciplinary team with a foot attack.

### Extent of disagreement and difference between tissue and swab samples from infected diabetic foot ulcers: the CODIFI Study

A. Nelson<sup>1</sup>, M. Backhose<sup>2</sup>, A. Wright-Hughes<sup>2</sup>, M. Bhogal<sup>2</sup>, S. Brown<sup>2</sup>, J. Nixon<sup>2</sup>, B. Lipsky<sup>3</sup>;

<sup>1</sup>Healthcare, <sup>2</sup>Medicine, University of Leeds, <sup>3</sup>University of Oxford, UK.

**Background and aims:** A common complication of diabetic foot ulceration is a wound infection. Treatment with antibiotics is usually started immediately as spreading infection can lead to amputation. At the same time, however, a sample is usually taken for microbiologists to advice on the types of organisms in the wound, and what antibiotics they are sensitive to. Clinical practice guidelines state that tissue samples are the best way to collect samples of wound bacteria for the microbiological analysis, but wound swabs are commonly used. The CODIFI (concordance in diabetic foot infection) study set out to determine whether the results from wound swab and tissue samples taken from the same ulcer 'agree' with each other.

**Materials and methods:** Consenting patients with an infected diabetic foot ulcer had both swab and tissue samples taken from their ulcer for microbiological analysis (plating and culture). Agreement was assessed between techniques based upon the reported presence of 'likely pathogens'. We reported overall prevalence, Kappa statistic, and McNemar's test to investigate patterns of disagreement

**Results:** We recruited 401 patients from 25 centres (2011 - 2013). They had a median age of 63 years; 79% were male; 85.5% had type 2 diabetes; 27.5% presented with a recurrent ulcer; and 45.5% had a neuro-ischaemic ulcer, 50.5% neuropathic ulceration, and 3.5% ischaemic ulceration. Swab and tissue reports were available for 395 patients. We found many 'likely pathogens' - the most prevalent were Gram Positive Cocci (70.4%), Gram Negative Bacilli (36.5%), Staphylococcus Aureus (35.7%), Anaerobic Cocci (20.5%), Coagulase-Negative Staphylococcus (12.2%), Gram Positive Bacilli (11.1%), Streptococcus (16.7%), Enterococcus (14.9%), Corynebacterium (9.4%), Pseudomonas (8.6%), and Methicillin-resistant S. Aureus (MRSA, 8.1%). With the exception of Staphylococcus Aureus, MRSA and Pseudomonas (for which identical discordance was observed), each isolate was reported in significantly more tissue samples than the swab ( $p$ -value  $< 0.05$ ) by between 3.3% (Streptococcus) and 13.4% (Gram Positive Cocci).

**Conclusion:** Overall, significantly more isolates are reported from tissue samples than swab samples in patients with infected diabetic foot ulcers. This has potential implications for choice of sampling technique in practice.

### Conservative management of neuropathic heel ulceration with calcaneal osteomyelitis and avulsion fracture in a cohort with diabetic foot disease

R. Fikri<sup>1</sup>, V. Bravis<sup>1</sup>, W.M. Gedroyc<sup>2</sup>, P. Rosenfeld<sup>3</sup>, R.A. Gibbs<sup>4</sup>, D.G. Samarasinghe<sup>5</sup>, N. Oliver<sup>1</sup>, J. Valabhji<sup>1</sup>;

<sup>1</sup>Department of Endocrinology, Diabetes and Metabolism, <sup>2</sup>Department of Radiology, <sup>3</sup>Department of Orthopaedics, <sup>4</sup>Department of Vascular Surgery, <sup>5</sup>Department of Microbiology, Imperial College Healthcare NHS Trust, London, UK.

**Background and aims:** The complex of neuropathic heel ulceration, calcaneal osteomyelitis (OM) and calcaneal fracture in people with diabetes is rare and challenging to manage, especially when complicated by tendon avulsion. We describe 4 patients in whom a conservative non-operative approach resulted in limb salvage.

**Materials and methods:** All patients were managed in the multidisciplinary diabetic foot clinic. Specialist input was provided by diabetologists, podiatrists, radiologists, microbiologist, vascular surgeons, orthopaedic surgeons, neurologist and orthotists. Multidisciplinary management included, where appropriate, antibiotics, wound debridement, vascular intervention, vacuum pump therapy and heel offloading. Patients were closely monitored clinically and radiologically for wound healing, resolution of OM and preservation of ankle function.

**Results:** Four patients were included. Their demographics and management are summarised in table 1. Two subjects had multidrug resistant organisms identified. Resolution of complex heel ulceration with calcaneal fracture and tendon avulsion is ongoing with 9 (6-11) months of follow up to date and a similar duration of antibiotics (9 (8-9) months). Vascular surgical intervention was required in 2 out of 4 subjects and adjunctive vacuum pump dressings were used in all subjects. Ankle function was at least partially preserved in all subjects.

**Conclusion:** This is the first description of a cohort of patients with diabetes, heel ulceration and calcaneal OM complicated by an avulsion fracture managed conservatively. Vacuum pump therapy was applied, not only to soft tissue, but also to bone, with progressive wound healing. Despite tendon avulsion, 3 of 4 patients have preserved ankle function and there were no minor or major amputations. Conservative management so far has been successful despite the presence of multiple resistant organisms in 2 of the 4 subjects. This complex can occur following an ulcer or trauma, requires prolonged therapy and has serious physical, psychosocial and biomechanical implications. There is no consensus on conservative or surgical management and functional limb salvage is often unachievable resulting in a major amputation. Whilst this is a small case series, this challenging diabetes foot problem is too rare to examine by randomised controlled trial. These 4 cases, managed successfully by a highly skilled multidisciplinary team provide a template for management.

### The efficacy of removable offloading devices to heal plantar foot ulcers in diabetic patients

J.J. Van Netten<sup>1</sup>, J.G. Van Baal<sup>1</sup>, A. Kottink<sup>1</sup>, M. Hutten<sup>1</sup>, E. Manning<sup>1</sup>, M. Spraul<sup>2</sup>, S.A. Bus<sup>1,3</sup>;

<sup>1</sup>Department of Surgery, Hospital Group Twente, Almelo, Netherlands,

<sup>2</sup>Matias Spital, Rheine, Germany, <sup>3</sup>Academic Medical Center, Amsterdam, Netherlands.

**Background and aims:** Adequate offloading is required for healing neuropathic plantar foot ulcers in patients with diabetes. Guidelines recommend non-removable offloading as primary treatment for these ulcers. However, in clinical practice removable offloading devices are more commonly used, mainly for practical reasons. The aim of this study was to assess the efficacy of three commonly used removable offloading devices on success in healing of plantar neuropathic foot ulcers in diabetes.

**Materials and methods:** A total 60 diabetic patients (48 male, mean age 62.5 years, 87% type 2) with a neuropathic non-infected, non-ischemic plantar foot ulcer were randomized to one of three treatment modalities: a bivalved total contact cast (BTCC), a Mabal Cast shoe (MABAL), or a forefoot offloading shoe (FOS). Patients were followed until healing or until 20 weeks, whichever came first. Primary outcomes were percentage healing in 12 and 20 weeks time.

**Results:** Foot ulcers were located at the hallux (n=24), first metatarsal head (n=21), other metatarsal heads (n=13) and toes (n=2). Forty-nine of the 60 foot ulcers were classified as small (< 2 cm<sup>2</sup>), 11 as large (> 2 cm<sup>2</sup>). Healing rates within 12 and 20 weeks according to intention-to-treat were 60% and 63% for BTCC, 60% and 83% for MABAL, and 70% and 80% for FOS (non-significant between conditions, p=0.703 and p=0.305 for 12 and 20 weeks respectively). Per protocol healing rates were 57% and 69% for BTCC, 67% and 87% for MABAL, and 77% and 88% for FOS (non-significant between conditions, p=0.519 and p=0.374 for 12 and 20 weeks respectively).

**Conclusion:** Healing rates were not significantly different between the three removable devices, but the off-the-shelf FOS condition showed higher healing percentages than the two casting conditions at 12 weeks. Healing rates for the BTCC were substantially lower than previously found for non-removable total contact casts (~90% healing rates), while healing rates for the other two devices are comparable for those previously found for similar removable offloading devices. A lack of forced adherence is suggested to be an explanatory factor in lower healing rates found compared to non-removable offloading, which stresses the importance of continuous pressure relief in ulcer healing. *Supported by: Interreg III 2\_EUR\_II\_2=60*

#### Ophthalmic biomarkers of diabetic neuropathy: does neural dysfunction precede vascular changes?

M. Tavakoli, M. Ferdousi, I.N. Petropoulos, H. Fadavi, A. Marshall, A.J.M. Boulton, R.A. Malik; University of Manchester, UK.

**Background and aims:** To evaluate structural- functional changes in the neural level of retina and cornea in type 1 diabetic (T1DM) patients without clinical evidence of retinopathy.

**Materials and methods:** 30 T1DM patients (Age: 48±2 yrs; Duration diabetes: 28±3 yrs, HbA1c: 7.6±0.5 %) with no evidence of retinopathy and 15 aged matched healthy controls underwent detailed neurological (including Neuropathy Deficit Score (NDS)) and ophthalmic assessment including measurements of global and sectorial retinal nerve fibre layer (RNFL) thickness using Spectral Domain OCT (SD-OCT) (SPECTRALIS, Heidelberg Engineering) and retinal ganglion layer function (Flicker-Defined-Form (fdf)) using Heidelberg High Edge Perimetry (HEP). Corneal nerve fibre length (CNFL) and density (CNFD) were assessed using a corneal confocal microscope (Heidelberg HRT III) and corneal sensitivity was quantified using non- contact corneal aesthesiometer (NCCA).

**Results:** There was a significant reduction in the global and sectorial RNFL ( $P=0.01$ ) in diabetic patients compared to controls which correlated with the severity of peripheral neuropathy measured by NDS ( $r=-0.403$ ,  $P=0.01$ ). fdf ( $P=0.01$ ), CNFD ( $P=0.01$ ), CNFL ( $P=0.01$ ) and corneal sensitivity ( $P=0.01$ ) were significantly reduced in T1DM compared to control subjects and they were significantly correlated with NDS. A greater proportion of T1DM patients showed abnormal retinal structure (RNFL-61%) and function (fdf-52%) compared to corneal structure (CNFD-32%) and function (NCCA-20%).

**Conclusion:** Changes at the level of nerve fibre layers were observed in both the retina and cornea. However, the prevalence of abnormality was higher at the retina but the severity was more pronounced in the cornea especially in those patients without neuropathy. The results of this preliminary study suggest that structural changes in the cornea (Peripheral nerves) and in the retina (central nervous system) may occur in parallel and are correlated with functional changes.

### 1156

#### Early detection of neurodegenerative changes in diabetes: systematic review and meta-analysis

E.E.B. De Clerck<sup>1</sup>, J.S.A. Schouten<sup>1</sup>, T.T.J. Berendschot<sup>1</sup>, R.M.M. Nuijts<sup>1</sup>, H.J.M. Beckers<sup>1</sup>, M.T. Schram<sup>2</sup>, C.D.A. Stehouwer<sup>2</sup>, C.A.B. Webers<sup>1</sup>; <sup>1</sup>Ophthalmology, <sup>2</sup>Internal Medicine and Cardiovascular Research Institute Maastricht (CARIM), Maastricht University Medical Centre, Netherlands.

**Background and aims:** The onset of diabetic neuropathy is difficult to detect by electrophysiology. The earliest damage occurs in the small nerve fibers. These fibers can be evaluated by thermal and pain perception, which have limited reproducibility, and by skin biopsy, which is invasive. A more reliable and feasible approach could be the imaging and quantification of neurodegenerative changes in the diabetic eye. Aims: To systematically assess ocular neurodegenerative changes in adults with type 1 or type 2 diabetes, their relationship with diabetic retinopathy and neuropathy, and whether these changes are already present in an early stage of diabetes.

**Materials and methods:** This meta-analysis was conducted according to the PRISMA statement and the Cochrane collaboration. The databases searched were MEDLINE, the Cochrane Controlled Trials Register and EMBASE (1968-2013). Language restrictions were English, French, German or Dutch. Only studies of neurodegenerative changes in the retina, the optic nerve head or the cornea in adults (>18 years) with type 1 or type 2 diabetes mellitus were included. One author reviewed studies for inclusion, quality and risk of bias. The second author checked the extracted data.

**Results:** 41 out of 4051 articles were included (3043 diabetic and 2021 non-diabetic individuals). 35 neurodegenerative parameters were analyzed. Compared with non-diabetic individuals, diabetic patients with any level of severity of diabetic retinopathy, had a mean reduction in thickness of at least 2 µm in 5 retinal layers: the mean ganglion cell/inner plexiform layer in the peripheral area and the inner plexiform layer, the ganglion cell layer, the mean

outer nuclear layer/inner segments and the mean ganglion cell/inner plexiform layer thickness in the pericentral area of the macula. In the optic nerve head, the highest reduction was observed for the superior retinal nerve fiber layer thickness (superior RNFL: -7.98 µm, 95% CI -12.46 to -3.50). In the cornea, the nerve branch density (NBD) and the nerve fiber density (NFD) were lower by 12.80/mm<sup>2</sup> and 7.45/mm<sup>2</sup>, respectively (95% CI -14.56 to -11.04 and -9.88 to -5.01). In patients without diabetic retinopathy the pericentral outer nuclear layer and inner segment were reduced by 2.45 µm (95% CI -4.76 to -0.14). In the optic nerve head the superior and mean RNFL thickness were decreased by 3.24 and 2.37 µm respectively (95% CI -7.31 to 0.83 and -7.32 to 2.59). In the cornea the NBD (-7.77/mm<sup>2</sup>, 95% CI -12.20 to -3.34) and the NFD (-3.57/mm<sup>2</sup>, 95% CI -7.12 to -0.02) were lower. In patients with any severity of diabetic polyneuropathy, the NBD and the NFD of the cornea were decreased by 20.84/mm<sup>2</sup> (95% CI -23.92 to -17.77) and 16.32/mm<sup>2</sup> (95% CI -19.26 to -13.37). Ocular changes were already present in patients without diabetic polyneuropathy (NBD: -9.99/mm<sup>2</sup>, 95% CI -15.26 to -4.72; NFD: -7.80/mm<sup>2</sup>, 95% CI -12.32 to -3.28).

**Conclusion:** This systematic review establishes a correlation between ocular neurodegenerative changes and diabetes. Structural changes are already present in diabetic individuals without diabetic retinopathy or neuropathy. Imaging and quantification of ocular neuronal tissues gives the opportunity to study diabetic neuronal changes and to early detect diabetic neuropathy.

### 1157

#### An evaluation of different methods of normalising fovea thickness measurements from optical coherence tomography instruments

K.M. Gooding<sup>1,2</sup>, A.C. Shore<sup>1,2</sup>, R. Ling<sup>3</sup>, E. Agardh<sup>4</sup>; <sup>1</sup>Diabetes and Vascular Medicine, University of Exeter Medical School, <sup>2</sup>NIHR Exeter Clinical Research Facility, Royal Devon and Exeter NHS Foundation Trust, <sup>3</sup>West of England Eye Unit, Royal Devon and Exeter NHS Foundation Trust, Exeter, UK, <sup>4</sup>Department of Clinical Sciences, Ophthalmology, Lund University, Malmo, Sweden.

**Background and aims:** The assessment of macular thickness by optical coherence tomography (OCT) is routinely used in clinical practice. However, interpretation is hampered by the lack of a universal clinical scale, partly due to variations in the segmental algorithms between devices. For example the Stratus, Cirrus and Topcon OCTs all measure thickness to different depths: inner/outer photoreceptors interface, mid and inner limit of the retinal pigment epithelium respectively; resulting in a systematic difference when comparing measurements between devices. Previous work have proposed the logarithmic transformation of normalised data, and then utilising step changes to define clinically significant changes. Using this approach fovea data has been normalised to fovea thickness as measured by Stratus (200µm) and mid-range normal fovea thickness as measured by spectral domain (SD) OCTs (250µm) in healthy eyes. Utilising these normalisation values may still result in a systematic difference when comparing measurements from different devices. Alternative approaches are to either customise the normalisation factor to each device or to normalise data to a 'gold standard' before log transformation. As part of the SUMMIT consortium this study aims to explore different normalisation procedures for combining data from different OCT devices.

**Materials and methods:** 43 individuals were recruited (11 controls, 32 with diabetes: 14, 15, 5 with no retinopathy, non- and proliferative retinopathy respectively). Macular thickness was assessed in all participants on both Cirrus and Topcon-1000 OCT devices (512x128 scanning protocol). Raw data comparisons demonstrated that, as expected, Topcon measurements were consistently lower than with the Cirrus in all quadrants (mean (SD) difference: 7.9(0.5)%,  $p<0.001$  paired t-tests). Fovea data was log<sub>10</sub> transformed following normalisation by expected normal fovea thickness by 1) Stratus (200µm); 2) mid-range SD-OCTs (250µm); 3) customised to device (based on literature: Cirrus: 270µm, Topcon: 230µm); 4) Topcon measurements normalised to Cirrus based on raw data (8% increase). Transformed data was then examined using Bland-Altman plots and limits of agreement.

**Results:** Normalising Topcon fovea measurements to Cirrus measurements successfully eliminated the systematic difference between devices. The limits of agreement for this data before and after log transformation are -16 to 17µm and -0.025 to 0.027 respectively. Similar trends were observed in all macular regions. A systematic difference was observed with the other fovea normalisation approaches.

**Conclusion:** This study suggests that systematic differences in macular thickness measured by different OCT devices may be eliminated; however, limits of agreement and methods of normalisation need to be considered.

**Longitudinal association of retinopathy and glucose metabolism in a Japanese population**T. Nakagami<sup>1</sup>, K. Takahashi<sup>1</sup>, C. Suto<sup>2</sup>, A. Hirose<sup>1</sup>, Y. Uchigata<sup>1</sup>;<sup>1</sup>Diabetes Center, Tokyo Women's Medical University, Tokyo,<sup>2</sup>Department of Ophthalmology, Saitama-ken Saiseikai Kurihashi Hospital, Kuki City, Japan.

**Background and aims:** The epidemiological data for diabetic retinopathy have been extensively analyzed, however, limited studies have assessed the development of retinopathy across different glucose levels ranging from normal glucose tolerance to diabetes. Some studies have reported that retinopathy increased the risk of vascular disease and incident diabetes. Here, we assess the 6-year incidence for retinopathy across different glucose categories and the association of retinal signs detected at baseline with development of diabetes in a Japanese population.

**Materials and methods:** Subjects were 3,580 among 5,200 health check-up examinees (2,353 men, mean age: 51±8 years old) who underwent the test of non-mydratric 45° digital fundus photography. The retinal and glucose status were followed up for 6 years in 181 and 3,399 individuals, with and without retinopathy, respectively, at baseline (mean follow up: 5.7 years). Individuals were classified into five categories according to fasting plasma glucose (FPG) (<90, 90–97, 98–125, ≥126 mg/dL, known diabetes) or HbA1c (<5.38, 5.38–5.67, 5.68–6.49, ≥6.50%, known diabetes) at baseline, and the incidence of retinopathy was calculated in each category. Multivariable logistic regression analysis to examine the effects of the presence of retinopathy as well as FPG or HbA1c at baseline on incident diabetes was performed.

**Results:** 1) Of 3,194 non-diabetes and 287 diabetes without retinopathy at baseline, 1,926 were followed (follow-up rate: 55.3%). The incidence of retinopathy was 2.5% (48/1,926) during 6 years and increased with deteriorating glucose category evaluated by HbA1c (P=0.005): 1.5, 2.3, 3.0, 4.4, and 6.6%, but not by FPG (p=0.08). The significant positive relationship between incident retinopathy and HbA1c category remained after adjusting for age (p=0.021). 2) The incidence of diabetes during 6 years was 4.4% (91/2,050) and 12.0% (10/83), respectively, among those with and without retinopathy at baseline. Multivariable logistic regression analysis showed that retinopathy at baseline as well as FPG or HbA1c, BMI, and SBP at baseline were significantly and independently associated with incident diabetes during 6 years. Adjusted odds ratios associated with the presence of retinopathy at baseline for incident diabetes during 6 years were 2.43 (95% Confidence Intervals: 1.05–5.65) and 2.95 (1.32–6.51) in the models including HbA1c and FPG at baseline, respectively, as independent variables.

**Conclusion:** The incidence of retinopathy during 6 years of follow-up was 2.5% in a Japanese population, and it increased with deterioration of glucose categories based on HbA1c. Non-diabetic individuals with retinopathy at baseline had a more than 2-fold higher risk of developing diabetes within 6 years than those without retinopathy. Our result suggests the importance of retinal signs as a preclinical marker of diabetes risk in the future.

**Diabetic retinopathy prevalence in patients with type 2 diabetes not performing regular eye examination**

N. Szyłło, M. Gilewska, M. Pawłowski, J. Loba, L. Czupryniak; Internal Medicine and Diabetology, Medical University of Lodz, Poland.

**Background and aims:** Regular eye examination is crucial in preventing diabetic retinopathy. As recommended, patients with type 2 diabetes should have an initial eye examination by an ophthalmologist at or shortly after diabetes diagnosis, and then have it performed on annual basis. However, a significant number of patients do not comply with this recommendations and fail to perform regular eye examination. The aim of this study was to evaluate the frequency of retinal abnormalities in patients with type 2 diabetes who have not had eye exam performed for at least three years.

**Materials and methods:** The study group consisted of 674 patients with type 2 diabetes for more than 5 years and had not their eyes examined for at least three years, which meant missing two annual eye exams. All patients underwent eye fundus examination by an experienced ophthalmologist. Moreover, 103 patients completed a questionnaire containing questions related to the reasons for not reporting for ophthalmologic examinations.

**Results:** The reasons for not reporting to the regular eye exams was the lack of awareness of eye examination importance (37%), lack of time (26%), lack of referral letter (21%). There were no differences between the treatment groups in the incidence of hypertension or smoking. 303 (45%) patients were treated with insulin only, while 212 (31.4%) were taking insulin and oral drugs.

**Conclusion:** Diabetic retinopathy was found in a significant number of the patients who failed to show up for their annual eye exam, with the duration of diabetes as the main risk factor. Regrettably, despite long duration of the disease a significant proportion of patients are not aware of the need for regular eye examination. This finding calls for more intensive education regarding eye complications in the wide range of type 2 diabetes patients.

NPDR – non-proliferative diabetic retinopathy

## 1160

**Validation of a simple stratification algorithm for progression to sight threatening diabetic retinopathy**

S.J. Aldington, I.M. Stratton, P.H. Scanlon;

Dept. Ophthalmology/Diabetic Eye Screening, Gloucestershire Hospitals NHS Foundation Trust, Gloucester, UK.

**Background and aims:** Diabetic retinopathy (DR) is a microvascular complication of diabetes and can lead to vision loss and blindness. Annual screening with 2-field digital retinal imaging after mydriasis is recommended by the UK National Screening Committee. This is becoming difficult to achieve because of resource limitations and increasing numbers of people with diabetes. We have previously published a risk stratification model based on the results of 2 consecutive screening episodes. We know that grading protocols differ between screening programmes and rates of DR are affected by duration of diabetes, ethnicity, deprivation and diabetic control, hence validation of the model is required in screening programmes to assess whether the stratification tool could be used more widely. Here we aim to validate this stratification in independent samples.

**Materials and methods:** Data were obtained from 2 English screening programmes. Patients free of sight threatening DR (STDR) at each of two successive screening episodes were categorised by the presence of DR in neither, one or both eyes at each screening. Using this risk categorisation the proportion with progression to STDR in each of 9 groups was calculated using Kaplan Meier estimation.

**Results:** The programmes had 24,509 and 32,987 people respectively who had been screened at least three times with no STDR at either of the first two episodes. There were few non White Caucasian patients in the first programme but 30% of those in the second programme were of African or Afro-Caribbean ethnicity. In the first programme by 4 years from the second baseline screening 9.5% of patients had been found to have STDR. In the highest risk group of 1838 people (7.5% of total) (those with mild NPDR in both eyes on each of two occasions) 44.0% had been found to have STDR by 4 years, in the middle risk group (n=1055, 4.3%) (those with mild NPDR in one eyes on each of two occasions) 11.3% had progressed and in the lowest risk group (n=15826 64.6%) (those with no DR in both eyes on each of two occasions) 3.7% had progressed by 4 years. The c- statistic was 0.76. In the second programme, by 4 years from the second baseline screening 12.1% of patients had been found to have STDR. In the highest risk group of 1669 people (6.5% of total) (those with mild NPDR in both eyes on each of two occasions) 54.0% had been found to have STDR by 4 years, in the middle risk group (n=1201, 4.7%) (those with mild NPDR in one eyes on each of two occasions) 19.5% had progressed and in the lowest risk group (n=16570 64.5%) (those with no DR in both eyes on each of two occasions) 4.5% had progressed by 4 years. The c- statistic was 0.80.

**Conclusion:** Within each of these two programmes the stratification enables categorisation of patients into those with very low of progression to STDR and those at high risk. This information could be used to inform decisions about screening intervals.

Time to referable DR from background or no DR

**Male sex, blood pressure and heart rate are associated with the risk of diabetic retinopathy in normoalbuminuric type 1 patients**

M. Tomić<sup>1</sup>, T. Bulum<sup>1</sup>, K. Blaslov<sup>1</sup>, S. Ljubić<sup>1</sup>, S. Kaštelan<sup>2</sup>, L. Smirčić-Duvnjak<sup>1</sup>;

<sup>1</sup>Vuk Vrhovac University Clinic Merkur Clinical Hospital,

<sup>2</sup>Dubrava Clinical Hospital, Zagreb, Croatia.

**Background and aims:** The pathogenesis and the onset of diabetic retinopathy (DR) are still insufficiently understood. It is presumed that retinopathy and nephropathy occur simultaneously and that the severity of retinopathy equals that of renal disease in diabetes. The aim of this study was to assess the prevalence of retinopathy in normoalbuminuric type 1 diabetic patients and evaluate the risk factors for its development and progression in these patients.

**Materials and methods:** A total of 223 normoalbuminuric type 1 diabetic patients (116 male / 107 female) with normal renal function (glomerular filtration rate  $\geq 60$  ml/min/1.73m<sup>2</sup>) were included in this study and followed for 48 months. Basic and anthropometric parameters assessed were sex, age, diabetes duration and body mass index (BMI). Glycated haemoglobin (HbA1c), HDL and LDL cholesterol, triglycerides and serum creatinine were determined using routine laboratory methods. Glomerular filtration rate (GFR) was estimated using CKD-EPI formula. Urinary albumin excretion rate (UAE) was measured from at least two 24-hr urine samples and determined as the mean of 24-hr urine collections. Blood pressure was measured with a mercury sphygmomanometer and resting heart rate using a standard 12-lead ECG, after a 10-minute resting period. Ophthalmologic examination included binocular indirect slit lamp fundoscopy and color fundus photography after mydriasis of two fields (macular field, disc/nasal field) of both eyes according to the EURODIAB retinal photography methodology. Possible risk factors for the development and progression of DR were examined in backward stepwise Cox's multiple regression analysis.

**Results:** Patients were  $38.2 \pm 10.3$  years old with mean diabetes duration of  $17.2 \pm 9.1$  years. Mean/median values of BMI ( $24$  ( $18 - 37$ ) kg/m<sup>2</sup>), HDL cholesterol ( $1.7 \pm 0.4$  mmol/L), triglycerides ( $1.02 \pm 0.6$  mmol/L), systolic ( $120$  ( $80 - 180$ ) mmHg) and diastolic blood pressure ( $80$  ( $60 - 110$ ) mmHg), serum creatinine ( $70.1 \pm 12.2$   $\mu$ mol/L), UAE ( $9.8$  ( $1.3 - 29.0$ ) mg/24h) and eGFR ( $106.2 \pm 15.1$  ml/min/1.73m<sup>2</sup>) were within normal range for diabetic patients, whereas HbA1c ( $7.0 \pm 1.4$  %) and LDL cholesterol ( $2.8 \pm 0.8$  mmol/L) were slightly elevated. At baseline, 156 (70%) patients had no retinopathy and 67 (30%) had nonproliferative diabetic retinopathy (NPDR). After 48 months, 24 patients (10.7%) developed NPDR or progressed to proliferative diabetic retinopathy (PDR). From the 156 patients with no retinopathy at the beginning of the study 15 (9.6%) progressed to NPDR, while from the 67 patients with NPDR at the beginning of the study 9 (13.4%) progressed to PDR. Male sex (HR 2.9, CI 1.04-8.3,  $p=0.04$ ), systolic blood pressure (HR 1.03, CI 1.01-1.06,  $p=0.02$ ), UAE (HR 1.14, CI 1.06-1.23,  $p=0.001$ ) and resting heart rate (HR 1.03, CI 1.01-1.07,  $p=0.03$ ) were significantly associated with the development and progression of retinopathy.

**Conclusion:** The results of this study suggest that diabetic retinopathy may develop and progress in type 1 diabetic patients even without a coexisting renal disease. This points to the need for close monitoring of normoalbumi-

nuric type 1 diabetic patients aimed at early detecting, preventing or limiting the progression of retinopathy, especially in men with higher UAE, systolic blood pressure and higher resting heart rate.

## 1162

**Incidence of severe diabetic retinopathy and all-cause mortality among migrants in Denmark**

J. Oya, M.E. Jørgensen, B. Carstensen, G.S. Andersen;

Clinical Epidemiology, Steno Diabetes Center, Gentofte, Denmark.

**Background and aims:** Global migration has been increasing and it has been reported that migrants from non-European countries are usually diagnosed with diabetes more commonly and at younger age than European counterparts. Consequently, they may have higher rates of diabetic complications and death. Diabetic retinopathy (DR) is a common microvascular complication of diabetes and may progress to proliferative retinopathy and macular oedema if exposure of hyperglycemia and hypertension prolongs. Reports from UK and US showed that African and Asian migrants had higher prevalence of DR and especially sight-threatening retinopathy, than UK and US born people with diabetes. It has been considered that the difference probably reflects worse glucose and blood pressure control, lower frequency of eye examination and genetic background. However, longitudinal data on incidence of DR using nationwide data among migrants are lacking.

**Materials and methods:** Nationwide clinical data from the Danish Diabetes Database for Adults (Dansk Voksne Diabetes Database) on >17 years old diabetes patients followed since 2005 was linked through the personal ID number with data from the National Patient Register for identification of retinopathy diagnoses, the Cause of Death Register for information on deaths and the Central Personal Register for information on country of origin. We classified patients according to country of origin into six groups: Denmark, other Europe, Sub Saharan Africa, Middle East (includes North Africa), Asia and America (includes Oceania). From 73,572 patients with complete information, follow-up of 56,148 patients (mean age  $58 \pm 15$  years, duration of diabetes  $8.6 \pm 9.3$  years) and free from severe DR at baseline were analysed. We estimated event rates and hazard ratios (HR) for incidence of severe retinopathy and all-cause mortality between geographical regions.

**Results:** At baseline, median age, duration of diabetes and systolic blood pressure were lower and median HbA1c was higher in migrants from Sub Saharan Africa, Middle East and Asia compared to diabetes patients of Danish origin. During 215,565 person-year of follow-up, 6,348 patients suffered an incident of severe DR and 2,400 patients died. Compared to Danish borns, migrants from Middle East and Asia had higher risk of severe retinopathy (HR, 1.15 [95% confidence interval (CI) 1.04-1.27] and 1.24 [1.03-1.49], respectively) after adjustment for age, sex, type of clinic, body mass index, smoking status, and diabetes type, duration and control. The associations remained after further adjustment for blood pressure and lipids. Mortality rates were lower among those with other European, Sub Saharan, Middle Eastern, Asian or American origin compared to Danish borns after adjustment for age and sex (HR; 0.71, 0.26, 0.51, 0.55 and 0.52, all significant except America).

**Conclusion:** Migrants with diabetes from the Middle East and Asia showed higher risk of incidence of severe DR compared to Danish borns, but substantially lower mortality rates.

## PS 102 Mechanisms of microangiopathy: experimental

1163

### Topical administration of a GLP-1 agonist prevents retinal neurodegeneration in experimental diabetes

R. Simó<sup>1,2</sup>, P. Bogdanov<sup>1,2</sup>, L. Corraliza<sup>1,2</sup>, C. Solà<sup>1</sup>, C. Hernández<sup>1,2</sup>;  
<sup>1</sup>Diabetes and Metabolism Research Unit, Institut de Recerca Hospital Universitari Vall d'Hebron, <sup>2</sup>CIBERDEM, Barcelona, Spain.

**Background and aims:** Retinal neurodegeneration is an early event in the pathogenesis of diabetic retinopathy (DR). Therefore, treatments aimed at preventing or arresting retinal neurodegeneration has been recently proposed as a new strategy to reduce the incidence and progression of DR. There is evidence that glucagon-like peptide-1 (GLP-1) exerts a neuroprotective effect in the central nervous system but there is scarce information on this issue in the retina. The aim of the study was to explore the effectiveness of a GLP-1 analogue (liraglutide) administered topically (eye-drops) in preventing retinal neurodegeneration in db/db mice, an experimental model of type 2 diabetes.

**Materials and methods:** For this purpose we evaluated a total of 24 diabetic mice (db/db) aged 8 weeks that were randomly assigned to daily oral treatment with liraglutide (6 mg/ml) (n=12) or vehicle (n=12) for two weeks. Twelve non-diabetic mice (db/+) were used as control group. Retinal neurodegeneration was evaluated by measuring glial activation (immunofluorescence and Western blot) and apoptosis (TUNEL, cell count in ganglion cell layer). Functional abnormalities were assessed by electroretinography (ERG). **Results:** We observed that diabetic mice presented significantly higher glial activation and apoptosis than age-matched non-diabetic mice. The diabetic mice treated with eye drops of GLP-1 analogue presented a significant decrease of both glial activation and rate of apoptosis than diabetic mice treated with vehicle. Furthermore, a significant improvement of ERG parameters was observed.

**Conclusion:** Topical administration of a GLP-1 analogue prevents retinal neurodegeneration induced by diabetes. Our findings open up a new pharmacological strategy targeted to early stages of DR.

### Early-outgrowth bone marrow cells protect the retina of experimental model of type 2 diabetes by improving SIRT-1 signalling

D.A. Duarte<sup>1</sup>, K.C. Silva<sup>1</sup>, A. Papadimitriou<sup>1</sup>, M.A.B. Rosales<sup>1</sup>, E.B.M. Peixoto<sup>1</sup>, R.E. Gilbert<sup>2</sup>, J.B. Lopes de Faria<sup>1</sup>, J.M. Lopes de Faria<sup>1</sup>;  
<sup>1</sup>Faculty of Medicine, State University of Campinas, Brazil,  
<sup>2</sup>Keenan Research Centre of the Li Ka Shing Knowledge Institute, University of Toronto, Canada.

**Background and aims:** Cellular therapy has been studied in cardiovascular disease but has rarely been investigated in eye diseases. Sirtuins (SIRT1), a family of deacetylases, is thought to be sensitive to oxidative stress. This study hypothesized that cell therapy using early outgrowth cells (EOC) could protect the diabetic retina through antioxidant means, thus improving the SIRT1 pathway. This study investigated the possible therapeutic effects of cells derived from healthy (db/m) and diabetic (db/db) animals on diabetic retinopathy (DR).

**Materials and methods:** Mice aged 8-weeks and db/db were randomized to receive a unique intravenous injection of PBS or 0.5 × 10<sup>5</sup> db/m EOCs or 0.5 × 10<sup>5</sup> db/db EOCs. Four weeks later, the animals were euthanized and the eyes enucleated. For in vitro study, an EOCs-conditioned medium (EOC-CM) was generated from db/m and db/db EOCs cultures. The rat Müller cells (rMCs) were exposed for 24 h to normal (NG), high glucose (HG) combined, or with neither db/m nor db/db EOC-CMs.

**Results:** In diabetic rats, there was an increase of DR and oxidative damage markers accompanied by an increase in NOX4 expression leading to detriment of SIRT1 protein. This was followed by lysine-310-p65-NFκB acetylation. The treatment with cells from db/m significantly reduced this damage, but the treatment with cells from db/db mice fully restored these alterations to normal levels. The rMCs exposed to HG displayed GFAP and VEGF expression upregulation accompanied by an increase in NOX4 expression, ROS levels and acetyl-lysine-310-p65-NFκB. Protein expression and activity of

SIRT1 were markedly reduced in diabetic milieu conditions. The treatment with both EOC-CMs prevented all these abnormalities, but db/db EOC-CM resulted in full restoration to NG conditions. The presence of EX-527, a SIRT1-specific blocker, or siRNA SIRT1 abolished the observed effects in both treatments.

**Conclusion:** This study demonstrates that the endocrine capacity of EOCs is effective in improving the retinal SIRT1 pathway, thus protecting the retina from diabetic milieu insult. This is one evidence that regenerative therapy for DR using EOCs or its released factors could be a promising tool for patients with diabetic eye disease.

### Attenuation of reactive gliosis in retinas by PARP-1 inhibitors treatment under diabetes in rats

M. Guzyk, A. Tykhomyrov, T. Kuchmerovska;  
 Palladin Institute of Biochemistry, Kiev, Ukraine.

**Background and aims:** Diabetic retinopathy (DR) is a multifactorial disease, and persistent hyperglycemia appears to be a major contributor to its development. Gliosis is a hallmark of retinas neurodegeneration. The exact molecular mechanisms which contribute to development of diabetes-induced retinas neuropathy are not completely understood. The study was aimed to estimate the Poly(ADP-ribose)ylation and reactive gliosis under DR and effect of Poly(ADP-ribose) polymerase-1 (PARP-1) inhibitors, 3-aminobenzamide (3-AB) and nicotinamide (NAM) on these processes.

**Materials and methods:** All studies were carried out after 10 weeks of diabetes (streptozotocin, 70 mg/kg of body weight, i. p.) in male Wistar rats treated 2 weeks with or without 3-AB (30 mg/kg/day, i. p.) and NAM (100 mg/kg/day, i. p.). The proteins content was assessed by Western blot and immunohistochemically.

**Results:** The levels of glial fibrillary acidic protein (GFAP) were significantly increased in retinas at diabetes as result of glial reactivity. In addition, expression of immunoreactive products of GFAP degradation (lower molecular weight polypeptides, in the range from 47 to 37 kDa), another representative indicator of reactive gliosis, was observed. Marked reduction of GFAP levels was seen in retinas of diabetic rats treated with 3-AB or NAM, though content of retinas GFAP did not reached to the control. Noteworthy, 3-AB and NAM administration completely prevented increase in GFAP degradation. Increased GFAP immunoreactivity was observed in retinas sections of diabetic rats compared with control, which is in parallel with data obtained by Western blot. Immunohistochemically, supplementation of diabetic rats with PARP inhibitors counteracted glial activation in retinas. Intensity of glial response appeared to be correlated directly with PARP-1 activation. Western blot analysis demonstrated significant upregulation of PARP-1 expression by about 1.5 in diabetic retinas compared to nondiabetic group. At the same time PARP-1 fragmentation was exacerbated more than 2-fold in diabetic rats as compared to control. PARP-1 inhibitors administration to diabetic rats normalized PARP-1 expression in retinas. However, effect of NAM was more profound than 3-AB not only on protein expression but also on protection of PARP-1 from its fragmentation due to its antioxidant property and improving of proinsulin biosynthesis through increase of NAD level that is responsible for the cellular ATP which is necessary for glycolysis and mitochondrial respiration. Poly(ADP-ribosyl)ated proteins (pADPs) were detected primarily in range from 72 to 130 kDa of the retinas protein spectrum, with several minor bands at 17 to 55 kDa. Both 72 to 130 kDa and 26 to 37 kDa pADPs expression was increased in diabetic rats as compared to control and was essentially prevented by 3-AB and NAM treatment.

**Conclusion:** Thus, PARP-1 inhibitors can be potential drugs for treatment of DR through improvement of PARP-1 fragmentation and modulation of reactive gliosis that maintain homeostasis and normal neuronal function in retinas under diabetes.

## 1166

**p62 is not only a marker of autophagy but also a possible target against retinal Müller cells apoptosis under diabetic milieu conditions**

C. Montemurro, V.H. de Oliveira Amancio, D. Andreazzi Duarte, A. Papadimitriou, J.B. Lopes de Faria, J. Mendoza Lopes de Faria; Faculty of Medical Sciences, University of Campinas (Unicamp), Renal Pathophysiology Laboratory, Investigation on Complications of Diabetes, Brazil.

**Background and aims:** Inhibition of autophagy, a catabolic process by which cells degrade intracellular components inside lysosomes, induces degenerative changes in mammalian tissues that resemble those associated with aging, and was described to be altered in retinal cells under diabetic conditions. Apoptosis, or programmed cell death, appears to play an important role in the pathogenesis of diabetic complications. The aim of this study was to investigate the interaction between autophagy and apoptosis of retinal Müller cells under diabetic conditions *in vitro*.

**Materials and methods:** Rat Müller cells (rMCs) were cultured in normal glucose (NG; 5.5 mM), high glucose (HG; 30 mM) and under oxidative stress conditions ( $H_2O_2$ ; 1 mM) for 24, 48, 72h, with and without N-Acetyl Cysteine (NAC), autophagosome formation inhibitor, 3-Methyladenine (3MA; 1mM) and PERK inhibitor 1, GSK 2606414. The markers of autophagosome formation, Beclin1, and autophagosome-lysosome fusion, p62, were measured by Western blot (WB). Intracellular reactive oxygen species (ROS) were evaluated by 2'-7'-dichlorofluorescein (DCFH(2)) assay and apoptosis was assessed by TUNEL and extrinsic apoptotic pathway by caspase 8 activity.

**Results:** In rMCs, HG and  $H_2O_2$  increased Beclin1 and p62 levels ( $p < 0.05$ ) as well as the rate of cellular apoptosis ( $p < 0.05$ ) in a time independent manner, and increased activity of caspase 8 ( $p < 0.05$ ). Whereas 3MA decreased the expression of Beclin1 under HG, it increased further p62 levels, caspase 8 activation and cellular apoptosis ( $p < 0.05$ ). The presence of GSK 2606414, an indirect inhibitor of phospho-eif2 $\alpha$ , an endoplasmic reticulum (ER) stress marker, decreased the activation of caspase 8 ( $p < 0.05$ ). NAC was able to prevent the increase of intracellular ROS ( $p < 0.05$ ) and reversed the increments of Beclin1 and p62 expressions, caspase 8 activity and cellular apoptosis ( $p < 0.05$ ).

**Conclusion:** Cells exposed to diabetic conditions displayed an alteration of autophagic flux as demonstrated by increased levels of Beclin1 and p62. The increases in p62 levels suggest a defective clearance of autophagosome by lysosome fusion. The accumulation of p62 levels cause activation of caspase 8 leading to retinal Müller apoptosis. The modulation of p62 levels could be a possible target to prevent retinal Müller cells apoptosis under diabetic conditions.

**The association between Bsm1/Apa1 polymorphisms in the vitamin D receptor gene and complications of type 2 diabetes in the Korean population**

T. Oh<sup>1</sup>, H.-J. Jeon<sup>1</sup>, H.-J. Choi<sup>1</sup>, Y.-H. Lee<sup>2</sup>;

<sup>1</sup>Internal Medicine, <sup>2</sup>Biochemistry, Chungbuk National University, Cheongju, Republic of Korea.

**Background and aims:** Type 2 diabetes is one of the most common disease in with devastating complications. However, genetic susceptibility of diabetic complications has not been clarified. The vitamin D endocrine system is related with calcification and lipolysis, insulin secretion, and may be associated with many complicated disease including diabetes and cardiovascular disease. Recent studies reported that single nucleotide polymorphisms (SNP) of vitamin D receptor (VDR) gene were associated with diabetic complications.

**Materials and methods:** We evaluated the association of VDR SNPs (*BsmI* and *ApaI*) with diabetic complications in 537 type 2 diabetic patients. PCR-restriction fragment length polymorphism was used to test the genotype and allele frequency of BsmI (rs1544410; BB, Bb, bb) and ApaI (rs7975232; AA, Aa, aa) polymorphisms.

**Results:** Patients with B allele (BB or Bb) was significantly associated with lower risk of severe retinopathy (severe nonproliferative diabetic retinopathy or proliferative retinopathy) (7.4%; 5/68) compared with patients without B allele (bb) (17.3%; 81/469) (Odds Ratio=2.63,  $P=0.037$ ). This association was significant after adjusting for age, sex and BMI ( $P=0.044$ ) in logistic regression analysis. In Kaplan-Meier survival analysis, there was a trend of lower risk of severe retinopathy among patients with B allele (BB or Bb) compared

with patients without B allele (bb) ( $P=0.091$ ). Regarding coronary artery disease, patients with B allele (BB or Bb) had significantly higher risk of developing myocardial infarction compared with patients without B allele (bb) ( $P=0.049$ ). No significant association was observed regarding ApaI SNP.

**Conclusion:** Our findings suggest that BsmI SNP in VDR gene is associated with lower risk of severe retinopathy and higher risk of coronary artery disease in type 2 diabetic patients. BsmI genotype could be used as a susceptibility marker to predict the risk of diabetes complications.

## 1168

**Pro-angiogenic and anti-angiogenic microRNAs expression on endothelial progenitor cells from type 1 diabetic patients with and without diabetic retinopathy**

N. García de la Torre<sup>1</sup>, R. Fernández<sup>1</sup>, R. Gómez<sup>1</sup>, A. Barabash<sup>1</sup>, M. Fuentes<sup>2</sup>, I. Runkle<sup>1</sup>, M. Roldán<sup>3</sup>, A.L. Calle<sup>1</sup>;

<sup>1</sup>Endocrinology Department, <sup>2</sup>Preventive Medicine Department,

<sup>3</sup>Ophthalmology Department, Hospital Clínico San Carlos, Madrid, Spain.

**Background and aims:** Endothelial progenitor cells (EPCs) are recognized as a key cell responsible for healthy maintenance of the vasculature, including the retina. Recently, microRNAs (miRs) have emerged as critical regulators of signalling pathways in multiple cell types including endothelial cells. miR-221 and miR-222 are highly expressed in vascular endothelial cells where they exert anti-proliferation, anti-migration and pro-apoptosis effects. miR-126 has been identified as pro-angiogenic and increases colony formation, proliferation, and migration of EPCs. The expression of miRs in EPCs from patients with type 1 diabetes mellitus (DM1) and its relation with different stages of diabetic retinopathy (DR) has not been reported to date. In addition, there is evidence that triglyceride lowering drugs such as fenofibrate can reduce progression of DR, but the mechanisms implicated remain unknown. Therefore, the aim of the present study was to analyze the expression of miR-222, miR-221, and miR-126 in circulating EPC from patients with DM1 with and without DR.

**Materials and methods:** Patients with DM1 without overt macrovascular disease, were recruited from January 2012 to December 2013. 33 DM1 patients with DR, 30 DM1 patients without DR, and 29 non-diabetic controls were included. Venous blood was collected for EPC colony culture and for flow cytometry analysis. Total RNA was extracted and purified and real-time qPCR was performed to analyse miRs expression after 7 days of EPC culture. Relative changes in miRs expression were analyzed with the 2<sup>-</sup>(delta delta c(T)) method. Non-parametric methods were used to compare differences between groups.

**Results:** There was no significant difference in age and gender distribution between patients and controls. Patients with DR were significantly older than those without DR ( $48.18 \pm 10.33$  vs  $40.8 \pm 11.104$ ,  $p=0.009$ ) and had longer duration of diabetes ( $34 [24-39]$  vs  $17 [10.75-22.5]$  years,  $p < 0.0001$ ). Circulating EPC number was reduced in DM1 patients compared to controls ( $p=0.006$ ) but was not significantly different in DM1 patients with and without DR. miR-126 and miR-221 expression was significantly higher in DM1 compared to controls ( $p=0.024$  in both cases). In addition, miR-221 was significantly higher in patients with DR than in those without DR ( $p=0.046$ ). However, differences between non proliferative and proliferative DR were not significant ( $p=0.08$ ). We did not find any relationship between miRs expression and duration of diabetes, HbA1c, fasting glucose, albumin excretion ratio, or total, HDL and LDL cholesterol. There was a positive correlation between miR-126 and miR-221 expression and triglyceride concentration (Rho 0.266,  $p=0.044$  and Rho 0.413,  $p=0.01$ , respectively). We found, also, a positive correlation between circulating EPC number and total and LDL cholesterol concentrations (Rho 0.306,  $p=0.019$  and Rho 0.321,  $p=0.013$ , respectively).

**Conclusion:** Circulating EPC number is reduced in DM1 patients compared to controls. miR-221 expression is significantly higher in DM1 patients compared to controls and in patients with DR than in those without DR. In addition there is a positive correlation between miR-221 expression and triglyceride concentration.

**Thiamine metabolism abnormalities contribute to the progression of diabetic nephropathy**

K. Kankova<sup>1</sup>, K. Kuricova<sup>1</sup>, V. Dvorakova<sup>1</sup>, L. Pácal<sup>1</sup>, Z. Marcanova<sup>1</sup>, J. Svojanovsky<sup>2</sup>, J. Olsofsky<sup>2</sup>, J. Belobradkova<sup>3</sup>, J. Rehorova<sup>3</sup>;

<sup>1</sup>Dept. of Pathophysiology, Masaryk University, <sup>2</sup>Dept. of Internal Medicine, St. Anne University Hospital, <sup>3</sup>Dept. of Gastroenterology, Faculty Hospital Brno-Bohunice, Brno, Czech Republic.

**Background and aims:** Pentose phosphate pathway (PPP) represents potentially protective pathway in hyperglycaemia since it can process glycolytic intermediates and thus decrease production of reactive dicarbonyls (methylglyoxal) and reactive oxygen species in mitochondria. Transketolase (TKT) is the rate-limiting enzyme of non-oxidative branch of PPP whose activity depends on thiamine diphosphate (TDP) - an active form of thiamine (vit. B1) - as a cofactor. Thiamine supplementation was shown to prevent development and progression of diabetic nephropathy (DN) in animal model of diabetes. Thiamine is delivered to the cell via specific thiamine transporters 1 (encoded by SLC19A2) and 2 (SLC19A3) and phosphorylated by thiamine pyrophosphokinase (TPK). We have previously shown that plasma levels of thiamine are dominantly influenced by GFR, however increasing plasma thiamine in subjects with decreased renal function are not paralleled by increase of intracellular TDP. The aim of the current study was to analyse relationship between plasma and erythrocyte parameters reflecting the thiamine status and progression of DN, cardiovascular morbidity and mortality. Additionally, since genetic variability in SLC19A2 and SLC19A3 loci may potentially affect activity of thiamine transport, common SNPs in those genes were detected and tested for their contribution to the progression of DN.

**Materials and methods:** Prospective observational cohort study comprised a total of 273 type 2 diabetics with variable stage of DN at baseline followed for a median of 39 [IQR 21 - 59] months. Following end-points were considered: (1) progression of DN by stage, (2) major cardiovascular event (MCVE, non-fatal and fatal myocardial infarction or stroke, limb amputation, revascularisation) and (3) all-cause mortality. Plasma and erythrocyte TDP was detected using HPLC. TKT activity was determined by kinetic method. Genotyping of 6 SNPs (3 in the SLC19A2 locus (rs1983546, rs7522245, rs6656822) and 3 in the SLC19A3 locus (rs13025803, rs4973216, rs7567984)) was performed by RT-PCR. Time-to-event analysis was carried out to ascertain contribution of thiamine, TDP and SNPs to studied end-points.

**Results:** Cumulative incidence of DN progression was 22.9%, CVE 8.2%, and ACM 19.8%. Significant differences in DN progression and all-cause mortality were ascertained for plasma TDP tertile groups (both  $P < 0.001$ ) and for erythrocyte TKT activity for the latter end-point ( $P = 0.01$ ). In all cases the highest tertiles were associated with the worst survival rate while the lowest tertile of erythrocyte TDP/plasma TDP was associated with the lowest survival rate ( $P = 0.01$ ). No significant effects were ascertained for any of the studied SNPs and the three end-points (all  $P > 0.05$ ).

**Conclusion:** Our results indicate that abnormalities of thiamine metabolism induced by diabetes, especially intracellular deficit of active TKT cofactor and impaired activity of TKT contribute to the progression of diabetes-associated morbidity or mortality. Elucidation of molecular mechanisms responsible for decreased intracellular availability of TDP is warranted.

<sup>6</sup>Glycation & Diabetes, Mater Medical Research Institute, South Brisbane, Australia.

**Background and aims:** Diabetic nephropathy (DN) is the major cause of end stage renal disease in the Western world. Defects in mitochondrial bioenergetics are evident in DN and are thought to initiate renal impairment. Accumulation of fragmented mitochondria are found in the renal cortex in experimental diabetes, suggesting that in tandem with a shift in dynamics, mitochondrial clearance mechanisms may be impaired. The process of mi-

tophagy is the selective targeting of damaged or dysfunctional mitochondria to autophagosomes for degradation through the autophagy pathway. Here, we aimed to determine if there was an impairment in mitophagy and changes in mitochondrial dynamics in the kidney in DN.

**Materials and methods:** Markers of mitophagy and mitochondrial dynamics were followed in the renal cortex from mice rendered diabetic with the beta cell toxin streptozotocin (STZ). Tissue from the renal cortex was studied by western immunoblot for changes in mitophagy and mitochondrial dynamics changes, while mitochondrial bioenergetics were performed to measure mitochondrial function. Electron microscopy was also undertaken to follow changes in mitochondrial morphology, between control and diabetic populations. Human renal biopsies, taken from both type 1 and control patients (taken from kidney donor patients) were studied by electron microscopy for evidence of changes in mitochondrial morphology and autophagy/mitophagy.

**Results:** Bioenergetics were impaired in mitochondria isolated from renal cortex, with a decline in ATP content, increased reactive oxygen species and depolarisation of the inner mitochondrial membrane. Increased recruitment of Drp-1 to mitochondria was observed in diabetes, with a 3-fold increase in Drp-1 translocating to mitochondria ( $n = 6$ ,  $P < 0.05$ ), indicating a shift towards mitochondrial fission. Electron microscopy imaging revealed mitochondrial fragmentation in the proximal tubule epithelial cells (PTECs). Mitophagy impairment was seen with a decrease in autophagic flux (decline in LC3-II), with a 2-fold decrease ( $n = 6$ ,  $P < 0.05$ ) in renal cortical cell lysates, coupled with a decline in Parkin translocation to mitochondria (approximate 2-fold decrease,  $n = 6$ ,  $P < 0.05$ ) and an approximate 10-fold decrease of p62 within mitochondrial fractions ( $n = 6$ ,  $P < 0.05$ ). Importantly, these data correlate with findings from renal biopsies of patients with DN that show striking changes in morphology of mitochondria residing within PTECs manifesting as a greater percentage of fragmented mitochondria (3-fold increase,  $n = 6$ ,  $P < 0.0001$ ), indicative of a shift towards fission.

**Conclusion:** These data demonstrate that in chronic hyperglycaemia, mitochondria undergo fission, however, there is a defect in mitophagy, leading to reduced mitochondrial turnover and accumulation of dysfunctional mitochondria. A better understanding of the cellular and molecular events that govern mitophagy and dynamics in DN may lead to improved therapeutic strategies.

### Nrf2 overexpression inhibits mechanical stretch-induced fibronectin expression

L. Gnudi, A.A. Hayward, S. Duggan, K.L. Price, J. Pan, C. Dessapt, R.C.M. Siow, G.E. Mann;

Cardiovascular Division, King's College London, London, UK.

**Background and aims:** Mesangial cells are a primary target for haemodynamic perturbations in hypertensive glomerulopathies (e.g. diabetes). Oxidative stress plays a central role in the pathogenesis of diabetic microvascular complications, and the transcription factor Nuclear factor (erythroid-derived 2)-like 2 (Nrf2) has been proposed as a central player in the cellular antioxidant response. The aim of this study was to evaluate, in cultured human mesangial cells (HMCs), the role of Nrf2 in the stretch-mediated antioxidant response and fibronectin secretion.

**Materials and methods:** HMCs were exposed to 10% average elongation (S) or static conditions (NS) up to 48h. Cellular superoxide was assessed with Cytochrome-C reduction assay, while mitochondrial superoxide was investigated using MitoSOX Red. Protein and mRNA expression were assessed respectively with western immunoblotting and real time PCR after normalisation against housekeeping genes. Fibronectin secretion was assessed by ELISA and normalised against cell number.

**Results:** S increased superoxide production ( $p=0.01$ ), which was paralleled by an upregulation of the antioxidant enzyme heme oxygenase-1 (HO-1) both at the mRNA and protein level ( $p=0.01$ ). The increase in superoxide was not accompanied by an increase in p22phox, p67phox or Nox4 mRNA expression, whilst mRNA expression of gamma-glutamyl cysteine ligase catalytic subunit was upregulated ( $p=0.05$ ), but not mRNA levels for NAD(P)H quinone oxidoreductase-1 or glutathione peroxidase. Stretch-mediated increase in superoxide production was significantly inhibited by the NADPH-oxidase inhibitors apocynin (10 mM) and diphenyleneiodonium (100 mM), and by the antioxidant rotenone (25nM), suggesting a mitochondrial origin of oxidative stress in stretched cells. Inhibition of stretch-mediated superoxide production was paralleled by absent stretch-induced HO-1 protein upregulation. Transfection of HMCs with dominant negative Nrf2 resulted in inhibition of stretch-induced HO-1 upregulation ( $p=0.05$ ), but had no effect on basal and stretch-induced (24 and 48h) fibronectin secretion when compared to control (GFP-transfected) cells. Conversely overexpression of wild type Nrf2 resulted in a significant HO-1 up regulation ( $p=0.01$ ), which was paralleled by a reduction in both basal and stretch-induced fibronectin ( $p<0.01$ ).

**Conclusion:** Mechanical stretch-mediated superoxide production in HMCs is paralleled by an upregulation of HO-1. Nrf2 plays a role in stretch-mediated HO-1 upregulation. Overexpression of Nrf2 (and parallel HO-1 upregulation) is sufficient to prevent basal and stretch-induced fibronectin secretion in HMCs in vitro.

### Development of impaired renal function in pre-diabetic mice overexpressing SREBP-1c

K. Kaul<sup>1,2</sup>, T. Jelenik<sup>1,2</sup>, I. Rokitta<sup>1,2</sup>, J. Kotzka<sup>3,2</sup>, M. Roden<sup>1,4</sup>,

<sup>1</sup>Institute of Clinical Diabetology, <sup>2</sup>German Center for Diabetes Research,

<sup>3</sup>Institute for Biochemistry and Pathobiochemistry,

<sup>4</sup>Department of Endocrinology and Diabetology, Heinrich-Heine University, Düsseldorf, Germany.

**Background and aims:** Microalbuminuria associates with insulin resistance even in humans without overt type 2 diabetes. However, development of albuminuria and altered renal function remains inadequately understood in the context of insulin resistance. Here, we examined a specific model of insulin resistance with partial lipodystrophy and ectopic lipid deposition. Transgenic aP2-SREBP-1c mice overexpress sterol regulatory element binding protein 1c (SREBP-1c) in adipose tissue, and are hyperinsulinemic and insulin resistant based on hyperinsulinemic-euglycemic clamps, when compared to C57BL/6 mice serving as controls.

**Materials and methods:** Urinary albumin-to-creatinine ratio was measured by ELISA. Kidneys from sacrificed mice were weighed and homogenized for assessing lipid peroxidation by thiobarbituric acid (TBARS).

**Results:** The aP2-SREBP-1c mice had 2.5-fold higher urinary albumin-to-creatinine ratio than control mice ( $15.8\pm 4.5$   $\mu\text{g}$  albumin/ $\mu\text{g}$  creatinine vs.  $6.2\pm 0.8$   $\mu\text{g}$  albumin/ $\mu\text{g}$  creatinine,  $P<0.01$ ,  $n=6$ ). The transgenic mice showed higher kidney weight as compared to controls ( $394\pm 13$  mg vs.  $299.9\pm 13$  mg,  $P<0.01$ ,  $n=6$ ) indicating renal hypertrophy. Similarly, kidney-to-body weight ratio was also higher in the transgenic mice ( $1.22\pm 0.01\%$  vs.  $1.12\pm 0.03\%$ ,  $P<0.01$ ,  $n=6$ ). In kidney homogenates of transgenic mice, TBARS were almost twice compared to controls ( $0.61\pm 0.08$   $\mu\text{mol}/\text{mg}$  protein vs.  $0.32\pm 0.02$   $\mu\text{mol}/\text{mg}$  protein,  $P<0.05$ ,  $n=6$ ).

**Conclusion:** In conclusion, insulin resistant but nondiabetic aP2-SREBP-1c transgenic mice display impaired renal function and increased lipid peroxidation suggesting an oxidative stress response. The aP2-SREBP-1c transgenic mice may therefore serve as a novel rodent model of pre-diabetic kidney disease.

1173

### Inactivation of Wnt pathway and interaction of GSK3 $\beta$ with p53 contribute to podocyte apoptosis in diabetes mellitus and are prevented by treatment with green tea

A. Papadimitriou, E. M.P. Prado, C. Montemurro, D. A.T. Teixeira,

J. M. Lopes de Faria, J. B. Lopes de Faria;

Renal Pathophysiology Laboratory, Investigation on Complications of Diabetes, Faculty of Medical Science, Campinas, Sao Paulo, Brazil.

**Background and aims:** In diabetes mellitus (DM) podocyte apoptosis contributes to albuminuria and renal disease progression. Green tea (GT) reduced albuminuria in diabetic rats by an unknown mechanism. The mechanism of podocyte apoptosis in DM is not well understood. Wnt pathway is a key signaling in integrating cell adhesion, motility, cell death and differentiation in podocytes, and GSK3 $\beta$  plays a crucial role in this pathway. Activated GSK3 $\beta$  is known to promote p53-mediated increases in apoptotic signaling, by functional interaction GSK3 $\beta$ -p53 after camptothycin-DNA damage, in human neuroblastoma and lung carcinoma cells. The contribution of the interaction GSK3 $\beta$ -p53 leading to podocyte apoptosis under DM is not known. Aims of the present study were to assess the contribution of Wnt pathway, principally by the interaction of GSK3 $\beta$  with p53 in podocyte apoptosis and the effects of GT in these abnormalities.

**Materials and methods:** For in vitro studies, immortalized mouse podocytes (iMPs) were cultured in normal glucose (NG; 5.5 mM) and high glucose (HG; 30 mM) with or without GSK3 $\beta$  blocker (BIO), p-LRP6 blocker (DKK-1), siRNA for LRP6. We also tested if GT activates Wnt. Apoptosis was assessed by caspase-3 activity and TUNEL. GSK3 $\beta$ -p53 interaction, and GSK3 $\beta$  and p-53 relations with Wnt components were done by immunoprecipitation (IP). In vitro filtration barrier integrity was done by albumin influx assay. For in vivo studies, diabetic 12 week-old spontaneously hypertensive rats (SHR) received or not daily GT treatment (1.7g/Kg body weight/day). After 12 weeks of treatment, albuminuria was quantified by ELISA kit. Nephron, Wnt pathway components (p-LRP6 and GSK3- $\beta$  (p-Ser9) and p-p53 levels were measured by immunofluorescence and Western blot (WB). Podocyte foot processes were assessed by electron microscopy.

**Results:** In iMPs, HG inactivated Wnt by reducing p-LRP6 and WNT-1 component expression ( $p<0.0001$ ). Consequently, GSK3- $\beta$  was activated ( $p=0.003$ ) and GSK3 $\beta$ -p53 interaction led to rise in apoptosis and albumin permeability flux, all of which were ameliorated by GT. NG treatments with Wnt blockers, such as: BIO, DKK-1 and siRNA LRP-6 had the same effects as HG. In the rats, systolic blood pressure did not differ among the groups. Body weight was less and glycemia was greater in diabetic rats (treated or not with GT). In diabetic animals, rise in albuminuria ( $p=0.0083$ ) was in parallel with reduction of nephrin ( $p=0.0002$ ) and synaptopodin ( $p=0.038$ ), and increased in podocyte foot process effacement and in p-p53 level ( $p=0.011$ ). All these parameters were prevented by GT ( $p<0.0001$ ;  $p=0.0016$ ;  $p=0.003$ , respectively). p-LRP6 and pGSK3 $\beta$  levels were reduced in diabetic rats ( $p=0.044$  and  $p=0.0002$ , respectively) and they were all reversed by GT ( $p=0.05$  and  $p=0.006$ , respectively). IPs showed a decrease in synaptopodin-LRP6 ( $p=0.048$ ) and synaptopodin-GSK3 $\beta$  ( $p=0.0008$ ) interactions in diabetic animals, suggesting blockade of podocyte Wnt pathway, in vivo. GT reestablished these interactions. ( $p=0.0004$  and  $p<0.0001$ , respectively).

**Conclusion:** In summary, podocyte Wnt blockade leads to high GSK3 $\beta$ -p53 interaction promoting podocyte apoptosis under diabetic conditions. Activation of Wnt pathway and inactivation of GSK3 $\beta$ -p53 may be important strategies to prevent podocyte apoptosis in diabetes mellitus.

**Global toll-like receptor 4 knockout attenuates features of diabetic nephropathy**I. Jialal<sup>1</sup>, S. Devaraj<sup>2</sup>;<sup>1</sup>Internal Medicine, UC Davis Medical Center, Sacramento,<sup>2</sup>Pathology, Baylor College of Medicine, Houston, USA.

**Background and aims:** Type 1 Diabetes Mellitus (T1DM) is a pro-inflammatory state with increased Toll-like receptor (TLR) activity. Inflammation is crucial in diabetic vascular complications including diabetic nephropathy (DN). We tested the effect of a global deficiency of TLR4 on renal inflammation, fibrosis and podocytopeny.

**Materials and methods:** Streptozotocin (STZ) was used to induce diabetes in wildtype (WT) and TLR4-knockout (TLR4KO) mice. Control (C) and diabetic groups (STZ-WT and STZ-TLR4KO) mice were euthanized at 17 weeks and plasma and kidneys collected.

**Results:** Compared to C, the STZ-WT group had significantly increased macrophage and TLR4 immunostaining in the kidney, significant increases in MyD88, Interferon Regulatory Factor 3, Nuclear Factor Kappa B activity, Tumor Necrosis Factor Alpha, Interleukin 6, and MCP-1 protein levels; all these parameters were significantly decreased in the STZ-TLR4KO compared to STZ-WT mice. Compared to C, there were significant increases in fibrosis markers including Collagen 4, Laminin and Transforming Growth Factor Beta in STZ-WT which were significantly decreased in the STZ-TLR4KO versus the STZ-WT. Podocyte numbers and podocin protein were decreased in the STZ-WT versus C and these were increased in the STZ-TLR4KO mice.

**Conclusion:** In conclusion, a global genetic deficiency of TLR4 also ameliorates renal inflammation, fibrosis and podocytopeny and could be important in DN.

## 1175

**Alkalinization attenuates diabetes-induced albuminuria and glomerular injury through reduced oxidative stress**T. Senmaru<sup>1</sup>, M. Fukui<sup>1</sup>, M. Tanaka<sup>1</sup>, H. Okada<sup>2,1</sup>, T. Fukuda<sup>1</sup>, K. Mitsuhashi<sup>1</sup>, N. Kitagawa<sup>1</sup>, T. Kimura<sup>1</sup>, Y. Hashimoto<sup>1</sup>, N. Nakanishi<sup>1</sup>, M. Yamazaki<sup>1</sup>, G. Hasegawa<sup>2,1</sup>, N. Nakamura<sup>1</sup>;<sup>1</sup>Department of Endocrinology and Metabolism, Kyoto Prefectural University of Medicine Graduate School of Medical Science,<sup>2</sup>Division of Metabolism, Nephrology and Rheumatology, Japanese Red Cross Kyoto Daini Hospital, Japan.

**Background and aims:** Patients with diabetes frequently have chronic metabolic acidosis. Metabolic acidosis traditionally defined as a decrease in blood bicarbonate (HCO<sub>3</sub><sup>-</sup>) concentration contributes to the progression of diabetic nephropathy, leading to end-stage renal failure. However, it is not well known whether alkalinization could prevent the progression of diabetic nephropathy, and if so, its mechanism has not been elucidated. In this study, we investigated the effects of alkalinization by potassium-sodium citrate on the pathogenesis and progression of diabetic nephropathy.

**Materials and methods:** Diabetes was induced using streptozotocin in male C57BL/6 (WT) mice at 7 weeks of age. Diabetic mice were divided into two groups: alkalinization (Alkali+) and non-alkalinization (Alkali-). Alkali+ was allowed free access to water containing potassium-sodium citrate (0.2% potassium citrate and sodium citrate hydrate) for 16 weeks.

**Results:** Blood HCO<sub>3</sub><sup>-</sup> concentration is higher in Alkali+ than in Alkali- (25.1 ± 1.8 vs. 19.5 ± 1.5 mmol/L, p < 0.05). Urinary albumin excretion was decreased in Alkali+ compared to Alkali- (45.6 ± 7.1 vs. 99.8 ± 14.1 µg/day, p < 0.05). Diabetic mice exhibited glomerular hypertrophy and mesangial expansion as compared with WT mice. Histological and morphometric analysis of periodic acid-Schiff stained sections revealed that an increase of mesangial area was milder in Alkali+ than in Alkali- (26.2 ± 1.1 vs. 36.5 ± 1.0 %, p < 0.0001). In addition, the number of podocytes and the number of apoptosis cells was decreased in Alkali+ compared to Alkali-. On the other hand, alkalinization did not affect tubulointerstitial fibrosis (Sirius red stain). The degree of oxidative stress assessed by 4-hydroxynonenal (4HNE) immunostaining in the glomerular area was decreased in Alkali+ compared to Alkali-. Similar to the degree of 4HNE expression, the mRNA expression of p67-phox was decreased in Alkali+ compared to Alkali-. Furthermore, the mRNA expression of TGF-β and vascular endothelial growth factor was down-regulated in Alkali+. It is conceivable that the decreased expression of

these fibrogenic cytokine contributes to the prevention of advanced glomerular injury in Alkali+.

**Conclusion:** These results indicate that alkalinization attenuates diabetes-induced albuminuria and glomerular injury. Reduction of oxidative stress may be mainly involved in these changes. Alkalinization could be a useful treatment for the progression of diabetic nephropathy.

## 1176

**Zinc exerts anti-fibrotic action by inhibiting TGF-beta1-induced type I collagen and fibronectin in human renal proximal tubular cells**

Y. Takiyama, M. Maeda, K.K. Atageldiyeva, T. Yanagimachi, J. Honjo, Y. Fujita, Y. Makino, M. Haneda;

Department of Medicine, Asahikawa Medical University, Japan.

**Background and aims:** Hyperglycemia, chronic hypoxia and TGF-β1 contribute to the development of diabetic nephropathy. The aim of this study is to investigate whether novel key factors contribute to the pathophysiological mechanism of diabetic nephropathy.

**Materials and methods:** We analyzed microarray data using Affymetrix GeneChip (Rat Gene 1.0 ST Array) with microdissected juxtamedullary proximal tubules in a rat model of type 2 diabetes, Zucker Diabetic Fatty (ZDF) rats. Then, we studied the regulation of the expression of the candidate using human renal proximal tubular epithelial cells (HRPTECs).

**Results:** A total of 27,342 transcripts were analyzed, among them, 47 were upregulated (>2.0-fold) in the ZDF rat compared with the lean control rat. One of them which were upregulated in diabetic renal tubules was metallothionein(MT)-1. MT is a cysteine-rich protein with low molecular weight, and act as an antioxidant against the toxicity of metals, ischemia, and ROS. MT originally has a pivotal role in the regulation of the metabolism of zinc. Previous studies reported that diabetic patients showed decreased plasma level of zinc, and zinc might be involved in diabetic nephropathy. Therefore, to explore the interaction of MT and zinc in diabetic nephropathy, we next studied the regulation of MT expression, and the effects of zinc on MT expression. High glucose (25.5 mM) failed to affect MT-1 mRNA expression in HRPTECs, and insulin (100 nM) significantly enhanced MT-1 mRNA levels. Hypoxia (1% O<sub>2</sub>) slightly increased MT-1 mRNA levels. 2.5 ng/ml TGF-β1 significantly decreased MT-1 mRNA levels compared to that of the control (0.62 ± 0.16 vs. control, p < 0.05). This inhibitory effect of TGF-β1 was not affected by the pretreatment of the inhibitors for ERK (PD98059) and JNK (SP600125) pathways, respectively. In contrast, the p38MAPK inhibitor (SB203580) apparently diminished the inhibitory effect of TGF-β1 on MT-1 mRNA. Unexpectedly, TGF-β1 increased another isoform of MT, MT-2 mRNA (1.86 ± 0.49 vs. control, p < 0.05), and the stimulatory effects of TGF-β1 on MT2 was inhibited by ERK inhibitor. On the other hand, zinc at 100 µM concentration remarkably increased MT-1 mRNA (17.3 ± 7.83 vs. control, p < 0.05), and restored the inhibitory effect of TGF-β1 on MT-1 mRNA in a dose-dependent manner (0~100 µM). Similarly, zinc augmented MT-2 expression in a dose-dependent manner, and 100 µM zinc significantly increased MT-2 mRNA (7.00 ± 2.76 vs. control, p < 0.05). TGF-β1 is known to be a profibrotic molecule which promotes renal fibrosis in diabetic nephropathy. Accordingly, 2.5 ng/ml TGF-β1 significantly increased mRNA levels of type I collagen (7.07 ± 1.48 vs. control, p < 0.05) and fibronectin (3.00 ± 0.88 vs. control, p < 0.05) in HRPTECs. Intriguingly, 75 µM zinc significantly suppressed TGF-β1-induced type I collagen mRNA down to 61% (p < 0.05), and 50 µM zinc also decreased TGF-β1-induced fibronectin-1 mRNA down to 65% (p < 0.05) of those in TGF-β1 alone treatment, respectively.

**Conclusion:** In conclusion, the current study showed that MT may be dysregulated in diabetic nephropathy, and suggesting that zinc might have the potential therapeutic effects in diabetic nephropathy by anti-TGF-β1 action and via the induction of antioxidant MTs.

## 1177

**Protective effects of adiponectin on uncoupling of glomerular VEGF-NO axis in type 2 diabetic rats**N. Huang<sup>1</sup>, F. Han<sup>2</sup>, J. Zhao<sup>1</sup>, N. Hou<sup>1</sup>, X. Liu<sup>1</sup>, X. Sun<sup>1</sup>;<sup>1</sup>Department of Endocrinology, <sup>2</sup>Department of Pathology, Affiliated Hospital of Weifang Medical University, China.

**Background and aims:** The uncoupling of glomerular vascular endothelial growth factor (VEGF) - nitric oxide (NO) axis is an important mechanism of early diabetic nephropathy. We aimed to determine whether adiponectin

could reduce microalbuminuria and provide renal protective effects by improving endothelial dysfunction and uncoupling of glomerular VEGF-NO axis in streptozotocin-induced type 2 diabetic rats.

**Materials and methods:** Wistar rats were randomly divided into a normal control (NC) group, a diabetic nephropathy (DN) group induced by high-fat feeding and streptozotocin, diabetic rats injected with adenovirus-expressed adiponectin AD-AdipoQ-IRES-EGFP (AD-AdipoQ, DA group), and diabetic rats injected with AD-IRES-EGFP (AD-IRES, DI group). Blood and urine samples were collected. Endothelium-dependent vasodilatation (EDV) of the aorta was measured. Renal tissues were collected for CD34 immunohistochemistry. Glomerular NO and VEGF levels were measured by the Griess reaction and western blot testing, respectively.

**Results:** STZ-injected rats in the DN group had severe hyperglycemia and high levels of insulin ( $P < 0.01$ ). This was reduced by intravenous injections of AD-AdipoQ (glucose,  $11.3 \pm 5.5$  mmol/L vs  $21.2 \pm 3.3$  mmol/L; insulin,  $16.70 \pm 2.40$  uU/ml vs  $20.91 \pm 2.78$  uU/ml,  $P < 0.01$ ). Serum hs-CRP and MDA levels increased and serum adiponectin levels decreased significantly in the DN group compared with the NC group ( $P < 0.01$ ). Intravenous injections of AD-AdipoQ reduced serum hs-CRP and MDA levels and increased serum adiponectin levels in diabetic rats (hs-CRP,  $1.85 \pm 0.56$  mg/L vs  $3.13 \pm 0.38$  mg/L; MDA  $2.44 \pm 0.28$  umol/L vs  $4.80 \pm 0.59$  umol/L; adiponectin,  $273.50 \pm 21.20$  ug/L vs  $94.97 \pm 25.12$  ug/L,  $P < 0.01$ ). Albumin-to-creatinine (ACR) was significantly higher in rats in the DN group than those of the NC group [ $180.35$  ( $113.54$ – $233.29$ ) mg/g vs  $13.15$  ( $8.93$ – $17.95$ ) mg/g,  $P < 0.01$ ]. Injections of AD-AdipoQ significantly reduced the ACR in diabetic rats. [ $72.0$  ( $46.18$ – $99.41$ ) mg/g vs  $180.35$  ( $113.54$ – $233.29$ ) mg/g,  $P < 0.01$ ], indicating an improvement of early diabetic nephropathy. Severe EDV impairment was observed in the DN group, which was improved by AD-AdipoQ. CD34 expression in the glomeruli was also enhanced in diabetic rats, indicating increased proliferation of glomerular endothelial cells [mean optical density (IOD/area):  $0.145 \pm 0.015$  vs  $0.073 \pm 0.007$ ,  $P < 0.05$ ]. However, treatment with AD-AdipoQ partly improved the increased proliferation of endothelial cells in glomeruli (IOD/area:  $0.113 \pm 0.012$  vs  $0.145 \pm 0.015$ ,  $P < 0.05$ ). Diabetic rats showed increased glomerular VEGF levels and reduced NO levels ( $P < 0.05$ ). This uncoupling of the VEGF-NO axis was partially improved by AD-AdipoQ ( $P < 0.05$ ). There were no significant differences in these parameters between the DN and DI groups ( $P > 0.05$ ).

**Conclusion:** Adiponectin reduces the degree of microalbuminuria and has renal-protective effects by improving endothelial dysfunction and uncoupling the glomerular VEGF-NO axis in early diabetic nephropathy.

### Heat shock proteins role in the biochemical and molecular interplay leading to diabetic nephropathy

A.I. Serban<sup>1</sup>, L. Stanca<sup>1</sup>, O.I. Geicu<sup>1,2</sup>, F. Barbuceanu<sup>1</sup>, A. Dinischiotu<sup>2</sup>; <sup>1</sup>Preclinical Sciences, University of Agricultural Science and Veterinary Medicine, <sup>2</sup>Biochemistry and Molecular Biology, University of Bucharest, Faculty of Biology, Bucharest, Romania.

**Background and aims:** Heat shock protein (Hsp) expression is correlated with oxidative stress, yet few studies focus on Hsp's modulation in diabetes. The objective of this study was to highlight the link between Hsp levels and the biochemical changes leading to diabetic nephropathy, using the human embryonic kidney cells HEK293.

**Materials and methods:** Cells were treated for 12, 24 and 48 h with 200 µg/ml glycated-bovine serum albumin (AGE-BSA) or BSA. Reduced glutathione (GSH), advanced glycation lipid products (ALEs) levels and enzyme activities were evaluated by spectrophotometric methods. Superoxide dismutase (SOD) was also assessed by zymography. The receptor for advanced glycation end products (RAGE), Hsp 27, 60 and 70 expressions were evaluated by western immunoblotting and real-time PCR.

**Results:** AGE-BSA induced a time dependent RAGE upregulation. Maximal increases of gene expression by 2.25 fold and protein expression by 2.01 fold were registered after 48 h. Increased expression of RAGE has been documented in chronic renal disease and diabetic complications. Probably the up-regulated RAGE stimulated pro-inflammatory signaling and reactive oxygen species (ROS) production. Increased ROS contribute to GSH depletion by 70 % after 48 h, which hinders the cellular antioxidative and anti-AGE activities. SOD activity upregulated with AGE-BSA exposure time and increased by 33 % after 48 h. Zymogram analysis revealed a similar pattern. Cu/Zn-SOD had the most important contribution for the SOD activity after 12 h of exposure.

Probably the initial superoxide anion source is not mitochondrial but cytosolic, although later, Mn-SOD increased, indicating mitochondrial damage. After 24 h and 48 h, ALEs arose by 1.75 and 2.29 fold, suggesting oxidative damage is amassed with time. Catalase activity increased over 200 % after 12 h of AGE exposure and remained over 50 % higher than controls later on. This early increase denotes the presence of high hydrogen peroxide amounts, probably generated by NADPH oxidase rather than SOD activity. AGE exposure boosted glutathione peroxidase activity by 50 % after 48 h. This enzyme could be involved in the detoxification of lipid hydroperoxides that are most abundant after 48 h. Glutathione reductase and glucose 6-phosphate dehydrogenase upregulated by 35 % after 48 h. These enzymes are sensitive to ROS, and probably their increase was supported by Hsp70 activity. Hsp 70 gene and protein expressions augmented in a time dependent manner, increasing by 2.07 and 2.78 fold after 48 h. Hsp 70 expression seems a reliable indicator of the biochemical alterations described mainly by the increase of RAGE, ROS and ALE. Hsp 27 gene and protein expressions increased after 12 h of treatment by 1.93 and 1.52 fold, but decrease to 0.45 and respectively 0.16 fold after 48 h. Hsp 60 analysis revealed a similar profile. Hsp 27 and 60 decrease after 48 h suggests the possibility of pro-apoptotic pathways activation. **Conclusion:** ROS induced by AGE - RAGE activation employ antioxidative mechanisms, which are themselves susceptible to oxidative damage. Although Hsps protective roles can improve some of the AGE-induced effects, therapeutic approaches based on Hsp overexpression must take great care not to target anti-apoptotic Hsps, because inhibiting AGE-promoted apoptosis could invoke cancerous transformation.

### Lentiviral vector-mediated FoxO1 overexpression inhibits extracellular matrix protein secretion under high glucose conditions in mesangial cells

F. Guo, G. Qin, Q. Wang, Y. Zhou, L. Wu, X. Ma, F. Huang; Division of Endocrinology, The First Affiliated Hospital of Zhengzhou University, China.

**Background and aims:** The excessive accumulation of ECM proteins in the mesangium of glomerulus results in glomerulosclerosis and contributes to the genesis and development of diabetic nephropathy (DN). The bioactivity of Forkhead transcription factor O1 (FoxO1) is attenuated in renal cortex under high glucose conditions, which may be associated with the progression of DN. High glucose conditions also upregulate the expression level of ECM proteins by activating the transforming growth factor  $\beta$  (TGF- $\beta$ )/Smad pathway in MCs. The study is designed to investigate whether FoxO1 is involved in the redundant secretion of extracellular matrix (ECM) proteins in mesangial cells (MCs) under high glucose conditions.

**Materials and methods:** Constitutively active FoxO1 recombinant lentiviral vectors (LV-CA-FoxO1) and GFP lentiviral vectors (LV-NC-GFP) were constructed. MCs were transfected with either LV-CA-FoxO1 or LV-NC-GFP cultured in high glucose medium (25 mmol/L), compared with untransfected cells cultured in high or normal glucose medium (5.6 mmol/L). Functional analysis was performed by real-time PCR, western blotting, immunofluorescence and flow cytometry to evaluate the expressions of FoxO1, ECM components and TGF- $\beta$  signaling pathways.

**Results:** High glucose conditions increased p-FoxO1 protein levels and the ratio of p-FoxO1/FoxO1, thereby attenuating bioactivity of endogenous FoxO1, which was accompanied by marked increases in the expression of ECM components, including FN and Col I. High glucose conditions also activated TGF- $\beta$ -mediated pathways by elevating the latent and mature protein levels of TGF- $\beta$ 1, in accordance with the increase of TGF- $\beta$ 1 mRNA levels. The expressions of TGF- $\beta$ R1 and TGF- $\beta$ R2 as well as the expression and phosphorylation of Smad3 were both increased under high glucose conditions, thereby promoting signal transduction of TGF- $\beta$ -mediated pathways. Immunofluorescence analysis indicated that high glucose conditions increased p-Smad3 staining in the nucleus, consistent with an overall increase in p-Smad3 expression. By contrast, FoxO1 expression markedly increased and the ratio of p-FoxO1/FoxO1 decreased after LV-CA-FoxO1 transfection, accompanied by reductions of FN and Col I mRNA levels. The mRNA level of TGF- $\beta$ 1 as well as its latent and mature protein levels both reduced with overexpression of transfected CA-FoxO1, while TGF- $\beta$ R1 and TGF- $\beta$ R2 levels decreased simultaneously. Although mRNA and protein levels of Smad3 remained unchanged after transfection, the phosphorylation of p-Smad3 was blocked and the ratio of p-Smad3/Smad3 declined to the level of which under normal glucose conditions. In addition, overexpression of CA-FoxO1 attenu-

ated nuclear staining of p-Smad3, in concert with faintly observed immunofluorescence in the cytoplasm, indicating lower basal expression of p-Smad levels and diminished transcriptional activity.

**Conclusion:** High glucose conditions increased the expression of fibronectin and collagen I by activating TGF- $\beta$ /Smad3 pathway in mesangial cells, while lentiviral vector-mediated overexpression of constitutively active FoxO1 blocked this effect by suppressing the activation and signaling of the TGF- $\beta$ /Smad3 pathway. FoxO1 may play a vital role in attenuating ECM protein secretion and alleviating the pathological changes associated with diabetic nephropathy.

## 1180

### The experimental study of the effects of FoxO1 on the podocyte injury in diabetic rats

G. Qin, Y. Zhang, Q. Wang, Y. Zhou, X. Ma;  
The First Affiliated Hospital of Zhengzhou, China.

**Background and aims:** Diabetic nephropathy (DN) is the chief reason for end-stage renal disease (ESRD). The podocyte injury of DN is often characterized by foot process fusion and effacement, podocytes getting smaller, negative charge becoming less, and podocytes detaching from glomerular basement membrane (GBM) and discharging in the urine. Nowadays, the importance of podocyte injury in pathogenesis of DN and the occurrence of proteinuria and glomerular sclerosis has been gradually acknowledged. We have previously demonstrated that the activity of forkhead transcription factor O1 (FoxO1) was decreased in the renal cortex of DN rats, and discovered that compared with DN rats without treatment, the expression of FoxO1 phosphorylation was reduced, the activity of FoxO1 was increased and the podocyte injury was improved in the renal cortex of DN rats with treatment. So it is inferred that the activity of FoxO1 may affect the podocyte injury in DN rats. Our study was performed to investigate the effects of FoxO1 on the podocyte injury in diabetic rats.

**Materials and methods:** Streptozotocin-induced diabetic rats were divided into three groups: diabetic rats (group d), rats transfected with empty lentiviral vectors (DM plus LV-empty-FoxO1 group, served as group a) and rats which were transfected with constitutively active FoxO1 recombinant lentiviral vectors (DM plus LV-CA-FoxO1 group, served as group b). The rats which received an injection of diluent buffer served as normal control (group c). 2,4,8 weeks after the infection, the levels of urine albumin, blood glucose, blood urea nitrogen and serum creatinine were measured. Real-time PCR and Western blotting were performed to measure the mRNA and protein expressions of FoxO1, podocalyxin, nephrin, desmin, COL4A3, COL4A5 and FoxO1 phosphorylation (p-FoxO1) level of renal cortex in rats. Moreover, light microscope and electron microscope were used to observe the structure changes of glomerulus and podocytes.

**Results:** Compared with group a and d, in group b, there was a significant increase in the mRNA and protein expressions of FoxO1, and a distinctly decrease in the levels of urine albumin, blood urea nitrogen and serum creatinine of rats (except ones in two weeks) (all  $p < 0.05$ , F values at the end of 8 weeks were 44001.312, 1557.130, 126.153, 498.800, 186.960, respectively), the mRNA and protein expressions of podocalyxin and nephrin all increased (all  $p < 0.05$ , F values of mRNA at the end of 8 weeks were 199.813, 116.899, respectively; F values of protein at the end of 8 weeks were 344.917, 353.486, respectively), the mRNA and protein expressions of COL4A3, COL4A5 and desmin all decreased (all  $p < 0.05$ , F values of mRNA at the end of 8 weeks were 665.64, 784.015, 579.257, respectively; F values of protein at the end of 8 weeks were 91.121, 122.954, 266.640, respectively), and pathological changes in kidney were also improved.

**Conclusion:** Upregulate the expression of FoxO1 by transfecting with constructed lentiviral vectors can definitely improve the podocyte injury in diabetic rats.

## PS 104 Nephropathy: genes and mechanisms

### 1181

#### Meta-analysis of genome-wide gene expression data from glomeruli in human kidney with diabetic nephropathy

K. Kodama<sup>1</sup>, K. Toda<sup>2</sup>, S. Yamada<sup>2</sup>, A.J. Butte<sup>1</sup>;  
<sup>1</sup>Stanford University, Stanford, USA,  
<sup>2</sup>Kitasato Institute Hospital, Kitasato University, Tokyo, Japan.

**Background and aims:** Genetic association studies have successfully revealed a number of important genes associated with diabetic nephropathy (DN). However, these DN-associated genes do not fully elucidate the mechanisms underlying the progression of the disease. In this report, we attempted to provide an additional catalog of functionally important candidate genes for DN by meta-analyzing genome-wide gene expression data from human glomeruli.

**Materials and methods:** We performed a gene-expression based genome-wide association study (eGWAS; searching for genes repeatedly implicated in functional microarrays) using 67 DN case-control microarrays from glomeruli in human kidney biopsy samples.

**Results:** We identified 429 significantly up-regulated genes and 323 down-regulated genes in DN glomeruli (Fig. 1;  $P < 2.2 \times 10^{-6}$ ). Pathway analysis highlighted the extracellular matrix (ECM) and receptor interaction, natural killer cell mediated cytotoxicity, and toll-like receptor signaling pathway (TLR1, TLR2 and MYD88) in up-regulated genes. Gene Ontology (GO) term analysis revealed the enrichment of “regulation of epithelial cell proliferation” in down-regulated genes. We also found ERBB4 gene was significantly down-regulated in patients with DN, together with the other related genes in ErbB signalling pathway, such as CDKN1B, SOS2, PLCG2 and CAMK2G.

**Conclusion:** Our studies have cataloged multiple gene-expression signatures that may play a role in the pathogenesis of DN or could serve as biomarkers.

**Fig 1** A graphic representation of the meta-analysis of gene expression of human glomeruli from DN compared to normal subjects. Meta-analysis was performed by Storey's Z-method.  $Z > 0$  shows up-regulation, and  $Z < 0$  shows down-regulation compared to healthy control. The red line indicates the genome-wide significant threshold of Z-value ( $= 4.73$ ,  $P$ -value  $= 2.2 \times 10^{-6}$ ). We identified 429 significantly up-regulated genes and 323 down-regulated genes in DN glomeruli ( $P < 2.2 \times 10^{-6}$ )

#### Genome-wide association study identifies novel variants associated with diabetic kidney disease in Chinese

R.C.W. Ma<sup>1</sup>, J.S.K. Ho<sup>1</sup>, Y. Wang<sup>1</sup>, C.H.T. Tam<sup>1</sup>, V.K.L. Lam<sup>1</sup>, G. Jiang<sup>1</sup>, H.M. Lee<sup>1</sup>, A.O.Y. Luk<sup>1</sup>, S.K.W. Tsui<sup>2</sup>, P.C.Y. Tong<sup>1</sup>, C.C. Chow<sup>1</sup>, M.C.Y. Ng<sup>3</sup>, C.C. Szeto<sup>1</sup>, W.Y. So<sup>1</sup>, J.C.N. Chan<sup>1</sup>;

<sup>1</sup>Dept of Medicine and Therapeutics, Chinese University of Hong Kong,

<sup>2</sup>School of Biomedical Sciences, Chinese University of Hong Kong, China,

<sup>3</sup>Centre for Genomics and Personalized Medicine Research, Winston-Salem, USA.

**Background and aims:** Although several genetic variants have been identified to be associated with diabetic nephropathy, few genetic markers have been found to be able to predict development of kidney disease among subjects with type 2 diabetes (T2D). In this study, we utilized prospective samples from the Hong Kong Diabetes Registry to identify genetic predictors of diabetic kidney disease (DKD).

**Materials and methods:** All subjects had T2D and were free of DKD at time of enrolment and DNA collection. We identified 200 subjects who developed incident diabetic kidney disease, defined as T2D with estimated glomerular filtration rate  $< 60$  ml/min per  $1.73$  m<sup>2</sup>, with other causes of renal impairment excluded, during the follow-up period. Two hundred individuals who were age, gender and disease-duration matched who did not develop DKD were

identified from the registry as controls. We performed genome-wide association study using the Illumina 610Quad genotyping array. Validation was performed by de novo genotyping using a MassARRAY platform on additional samples from the Registry.

**Results:** After quality control on the SNP data, we analyzed a total of 446,343 SNPs. We identified 8 genomic regions which showed suggestive association with increased risk or protection against incident diabetic kidney disease ( $p < 1 \times 10^{-5}$ ). De novo genotyping in additional validation samples of 850 incident DKD cases and 3064 controls free of DKD confirmed association of 2 novel variants with incident DKD. Cox regression analysis revealed that individuals who carry 1-2 risk variants at the two loci have increased risk of incident DKD with HR 1.502 (95% CI 1.25-1.81,  $p = 1.58 \times 10^{-5}$ ).

**Conclusion:** We identified 2 novel variants associated with incident diabetic kidney disease in Chinese. Additional replication genotyping and targeted resequencing to identify the causal variants are currently underway.

### Glutathione peroxidase 1 (GPX1) variants, oxidative stress markers, and risk of kidney complications in patients with type 1 diabetes

K. Mohammedi<sup>1,2</sup>, N. Bellili-Muñoz<sup>1</sup>, F. Driss<sup>3</sup>, T. Patente<sup>4</sup>, S. Hadjadj<sup>5,6</sup>, F. Fumeron<sup>1,7</sup>, R. Roussel<sup>1,7</sup>, M. Corrêa-Giannella<sup>4</sup>, M. Marre<sup>1,7</sup>, G. Velho<sup>1</sup>; <sup>1</sup>INSERM, Research Unit 1138, <sup>2</sup>AP - HP, Department of Diabetology, <sup>3</sup>INSERM, Research Unit 773, Paris, France, <sup>4</sup>Laboratório de Endocrinologia Celular e Molecular (LIM-25), Faculdade de Medicina da USP, São Paulo, Brazil, <sup>5</sup>INSERM, Research Unit 1082, Poitiers, <sup>6</sup>Université de Poitiers, UFR de Médecine et Pharmacie, <sup>7</sup>Univ Paris Diderot, Sorbonne Paris Cité, UFR de Médecine, France.

**Background and aims:** Glutathione peroxidase (GPX) is a class of antioxidant enzymes that catalyzes the reduction of hydrogen peroxide to water. GPX1 is the most abundant isoform and is expressed in all kidney cells. Advanced oxidation protein products (AOPP) and 8-iso-prostaglandin (isoprostane) were identified as markers of oxidative stress in patients with kidney disease. We investigated associations of GPX1 genotypes and plasma concentrations of AOPP and isoprostane with kidney complications in type 1 diabetic patients.

**Materials and methods:** Four SNPs in the GPX1 region were genotyped in SURGENE (n=340; 10-year follow-up), GENEDIAB (n=461) and GENESIS (n=498) cohorts of type 1 diabetic patients. Subsets of GENEDIAB (n=237) and GENESIS (n=393) participants were followed-up for 9 and 5 years, respectively. Plasma concentration of AOPP (spectrophotometry assay) and isoprostane (ELISA) were measured at baseline in 436 GENEDIAB participants. Hazard ratios (HR) or odds ratios (OR) were estimated for incidence and prevalence of kidney complications.  $p \leq 0.02$  was significant.

**Results:** In SURGENE, the minor T-allele of rs3448 was associated with the incidence of microalbuminuria (HR 1.97, 95% CI 1.23 - 1.33,  $p = 0.004$ , n=76) and with the progression to a more severe stage of diabetic nephropathy (HR 1.91, 95% CI 1.26 - 3.02,  $p = 0.002$ , n=98). The variant was also associated with lower estimated GFR at baseline ( $78 \pm 5$  TT vs  $93 \pm 3$  TC vs  $87 \pm 3$  ml/min CC, ANCOVA,  $p = 0.003$ ) and with faster decline of eGFR during follow-up ( $-8.49 \pm 2.74$  TT+TC vs  $-5.09 \pm 2.67$  ml/min.year-1 CC,  $p = 0.01$ ; all SURGENE analyses adjusted for sex, age, duration of diabetes, diabetic retinopathy stages, and use of ACE inhibitors). In pooled analyses of GENESIS/GENEDIAB cohorts, the same variant was associated with the prevalence at baseline (OR 2.79, 95% CI 1.16 - 6.20,  $p = 0.01$ , n=82) and the incidence during follow-up of end stage renal disease (ESRD; HR 1.98, 95% CI, 1.38 - 2.92,  $p = 0.0001$ ; n=51, analyses adjusted for the above mentioned covariates plus cohort membership). Association with the incidence of ESRD was also observed for rs9818758 and rs1987628. Plasma AOPP and isoprostane concentrations at baseline were higher in participants who developed ESRD during follow-up as compared to those who did not. The risk T-allele of rs3448 was associated with higher plasma AOPP ( $81 \pm 5$  TT+CT vs  $64 \pm 5$   $\mu\text{mol/l}$  CC,  $p = 0.02$ ) and isoprostane concentration ( $1.85 \pm 0.08$  TT+CT vs  $1.57 \pm 0.08$  ng/ml CC,  $p = 0.005$ ; ANCOVA adjusted for sex, age, duration of diabetes, eGFR and use of ACE inhibitors).

**Conclusion:** The minor T-allele of rs3448 was associated with kidney complications (incidence and progression of microalbuminuria, prevalence and incidence of ESRD, decline of eGFR) in patients with type 1 diabetes. The risk allele was associated with higher plasma concentration of markers of oxidative stress. Our results are consistent with the implication of GPX1 in the mechanism of renal protection against oxidative stress in patients with type 1 diabetes.

## 1184

### Advanced glycation end products disrupt cholesterol feedback regulation in diabetic renal tubules

H. Sun<sup>1</sup>, Y. Yuan<sup>2</sup>, S. Wang<sup>2</sup>, H. Jin<sup>2</sup>, Y. Wang<sup>2</sup>, B. Yang<sup>2</sup>, Z. Sun<sup>2</sup>; <sup>1</sup>Medical School, Southeast University, <sup>2</sup>Department of Endocrinology, Southeast University, Zhongda Hospital, Nanjing, China.

**Background and aims:** Advanced glycation end products (AGEs) cause diabetic renal tubules damage in various ways. The aim of this study is to investigate the lipid-mediated injuries caused by AGEs in HK-2 cells and the renal tubules of type 2 diabetic rats.

**Materials and methods:** For the in vitro study, human renal tubular epithelial cell line (HK-2) was respectively incubated with N $\epsilon$ -(carboxymethyl) lysine (CML, a member of the AGEs family), CML+anti-RAGE (receptor of AGEs), low density lipoprotein (LDL), LDL+CML, LDL+CML+ anti-RAGE for 24h. At in vivo level, animal model was developed by high fat/sucrose diet feeding plus streptozotocin injection. Rats were divided into DM and DM+AG (Aminoguanidine, an inhibitor of AGEs) groups. The effects of cholesterol accumulation were examined by Oil Red O staining and a quantitative intracellular cholesterol assay. Serum CML was determined by HPLC-MS analyzer, and renal CML was measured by immunohistochemical staining. The urine protein and neutrophil gelatinase-associated lipocalin (u-NGAL) were measured by ELISA. The gene transcription and protein translation were analyzed by quantitative RT-PCR and western blot respectively.

**Results:** 1. CML increased Oil Red O staining and intracellular cholesterol ester in the absence or presence of LDL in HK-2 cells. Anti-RAGE reduced the lipid droplets accumulation. A strong staining of Oil Red O was also found in the renal tubules of the diabetic group, but less staining in the AG treated group. 2. CML upregulated both mRNA and protein expression of 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMG-CoAR), LDL receptor (LDLR), sterol regulatory element binding protein-2 (SREBP-2), and SREBP cleavage-activating protein (SCAP), which were inhibited by anti-RAGE. The overexpression of these molecules in the renal of the diabetic rats was also ameliorated by AG treatment. 3. AG reduced serum and renal CML. 4. The increased urine protein and u-NGAL were improved by AG.

**Conclusion:** For the in vitro study, we demonstrated CML increased lipid accumulation in HK-2 cells by disrupting the SCAP-mediated feedback regulation of HMG-CoAR and LDLr. On in vivo level, we also found that reduce of CML improved the disrupted SCAP-mediated feedback regulation in the renal tubules of type 2 diabetic rats. These data suggested that CML caused diabetic tubules injury might be via disturbing the intracellular feedback regulation of cholesterol. Inhibition of CML-induced lipid accumulation might be a potential renoprotective role in the progression of diabetic tubules damage. *Supported by: Natural Science Foundation of China*

### Inflammation and oxidative stress markers related to renal damage due to diabetes mellitus

A.A.F. Oliveira<sup>1</sup>, L.L. Bobadilla<sup>1</sup>, T.F. Oliveira<sup>1</sup>, M.H.G. Medeiros<sup>2</sup>, A.P.M. Loureiro<sup>1</sup>; <sup>1</sup>Department of Clinical and Toxicological Analysis, <sup>2</sup>Department of Biochemistry, University of São Paulo, Brazil.

**Background and aims:** Currently, strategies to monitor renal damage in the course of Diabetes mellitus (DM) are focused on diabetes markers and renal function. Assuming that oxidative stress and inflammation are implicated in the pathophysiology of Diabetic Nephropathy (DN), the aim here was to assess markers of inflammation and oxidative stress in the course of a long-term model of DM and evaluate how different strategies of glycemic control would modulate these markers.

**Materials and methods:** An experimental model of streptozotocin-induced DM in male Wistar rats was employed here. After 12 weeks of diabetes induction, animals were treated with insulin alone or combined with metformin (100 mg/kg) or N-acetylcysteine (750 mg/kg) until a total period of 24 weeks. Non-diabetic or non-treated diabetic animals during 12 and 24 weeks served as control groups. Body weight and blood glucose were monitored weekly. HbA1c, urinary total protein and albumin, plasma IL-6 and TNF- $\alpha$  were assessed after different periods of diabetes. The same cytokines were quantified in renal tissue after 12 or 24 weeks, beyond plasma and kidney malondialdehyde (MDA) by HPLC-DAD.

**Results:** As expected, diabetic animals showed higher glycemic levels, water consumption and urine volume, and reduced weight gain compared

to non-diabetic. HbA1c was increased after 6, 12, 18 and 24 weeks of DM ( $p < 0.0001$ ). Renal function was significantly altered only from 12 weeks of DM, once diabetic animals presented higher proteinuria ( $p = 0.027$ ) and albuminuria ( $p < 0.0001$ ) compared to controls. At the end of 12 or 24 weeks, an enlarged kidney/body weight ratio was observed in non-treated diabetic groups ( $p < 0.0001$ ), indicating renal hypertrophy due to DM. All treatment schemes reverted these alterations after 18 and 24 weeks. In respect to inflammation markers, higher levels of plasmatic IL-6 were found in diabetic rats after 6 ( $p = 0.0015$ ) and 12 weeks ( $p = 0.0019$ ), but not in 18 and 24 weeks, showing this alteration is not persistent. NAC treatment had a pro-inflammatory effect, once a 3 fold increase of plasmatic IL-6 was observed ( $p = 0.0161$ ). No significant alteration of kidney IL-6 and TNF- $\alpha$  or plasmatic TNF- $\alpha$  were detected. On the other hand, local and systemic oxidative stress (MDA quantitation) were found after 12 and 24 weeks of DM ( $p < 0.0001$ ). Insulin alone or combined with metformin recovered this change in plasma and kidney, but NAC led to increased MDA levels, showing a pro-oxidant action ( $p < 0.0001$ ). Good Pearson or Spearman correlations were obtained between plasma MDA and glycaemia ( $r = 0.7554$ ,  $p = 0.0003$ ), HbA1c ( $r = 0.5790$ ,  $p = 0.0149$ ), proteinuria ( $r = 0.7495$ ,  $p = 0.0020$ ), relative kidney/body weight ratio ( $r = 0.6690$ ,  $p = 0.0024$ ) and kidney MDA ( $r = 0.5885$ ,  $p = 0.0102$ ).

**Conclusion:** Overall, therapeutic strategies employed here were capable to control changes related to DM, renal function and oxidative stress. NAC presented an unexpected pro-inflammatory and pro-oxidant effect. MDA can be considered a good oxidative stress biomarker related to renal damage in DM and could be used to improve therapeutic monitoring in DM.

## 1186

### Predominant role of glomerular podocytes in mediating the deleterious effects of CB2 deficiency in experimental diabetic nephropathy

F. Barutta, S. Grimaldi, P. Cavallo Perin, G. Gruden;  
Department of Medical Sciences, University of Turin, Italy.

**Background and aims:** Diabetic nephropathy (DN) is characterised by increased glomerular permeability to proteins and excessive extracellular matrix accumulation in the mesangium, resulting eventually in glomerulosclerosis and progressive renal impairment. A functionally active endocannabinoid system is present within the kidney. The cannabinoid receptor of type 2 (CB2) is expressed by both inflammatory cells and podocytes. CB2 receptor activation has beneficial effects in experimental DN, while CB2 deletion worsens both functional and structural abnormalities of DN confirming a protective role of signalling through CB2. To investigate the relative contributions of podocytes cells and monocytes to the phenotype of diabetic CB2<sup>-/-</sup> mice, we have performed bone marrow (BM) transplantation experiments. **Materials and methods:** Male CB2 knockout (CB2<sup>-/-</sup>) or wild type (CB2<sup>+/+</sup>) mice received bone marrow transplants at age 8 weeks. Twenty-four hours before transplantation, recipient CB2<sup>-/-</sup> and CB2<sup>+/+</sup> mice underwent whole body irradiation with 8 Gy. Post-irradiated CB2<sup>-/-</sup> mice received a BM transplant from CB2<sup>+/+</sup> mice (KO<sup>CWT</sup>;  $n = 15$ ). Post-irradiated CB2<sup>+/+</sup> mice received a BMT from CB2<sup>-/-</sup> mice (WT<sup>CKO</sup>;  $n = 15$ ). 4 weeks after BMT, diabetes was induced in all mice by intraperitoneal injection of streptozotocin (55 mg/kg) in citrate buffer delivered in 5 consecutive days. Control mice were injected with citrate buffer alone. 14 weeks after the induction of diabetes, mice were individually placed in metabolic cages for urine collections and blood samples taken for blood glucose and glycated haemoglobin measurements. Urinary albumin excretion was measured by enzyme-linked immunosorbent assay. Expression of the slit-diaphragm protein, podocin, was assessed by immunofluorescence. Fibronectin mRNA levels were quantitated by real-time PCR on total renal cortex.

**Results:** Diabetes was associated with reduced body weight and elevations in both plasma glucose and glycated haemoglobin levels. BMT did not affect metabolic/physiological parameters in either CB2<sup>+/+</sup> or CB2<sup>-/-</sup> animals. Albuminuria was significantly ( $p < 0.05$ ) increased in the CB2<sup>+/+</sup> diabetic animals [DM:234.0 (200.0-285.9)  $\mu\text{g}/18\text{hrs}$ , geometric mean (25<sup>th</sup>-75<sup>th</sup> percentile)] as compared to the controls [ND:68.1 (64.6-75.3)] and further enhanced by CB2 receptor deletion [DM CB2<sup>-/-</sup>:359.9 (227.9-519.4);  $p < 0.05$  DM CB2<sup>+/+</sup> vs DM CB2<sup>-/-</sup>]. However, albuminuria was similar in diabetic CB2<sup>-/-</sup> and diabetic CB2<sup>-/-</sup> mice transplanted with bone marrow from CB2<sup>+/+</sup> mice [DM-KO<sup>CWT</sup>:376.8 (353.2-368.5)]. Moreover, in diabetic CB2<sup>+/+</sup> animals, transplantation of CB2<sup>-/-</sup> bone marrow did not affect the magnitude of albuminuria [DM-WT<sup>CKO</sup>:236.2 (211.5-257.4)]. In the diabetic mice the increase in albuminuria was paralleled a significant reduction in podocin and this effect was further exacerbated in diabetic mice lacking CB2 receptors. However,

neither transplantation with BM from CB2<sup>+/+</sup> mice in diabetic CB2<sup>-/-</sup> animals, nor transplantation with BM from CB2<sup>-/-</sup> mice into diabetic CB2<sup>+/+</sup> animals altered podocin expression. Similarly, diabetes-induced upregulation of fibronectin expression was further exacerbated in CB2<sup>-/-</sup> mice, but not altered by BMT.

**Conclusion:** These findings demonstrate that in experimental diabetes the BM-derived cells do not play a major role in mediating the deleterious effects of CB2 deficiency and suggests a predominant role of podocytes.

## 1187

### Combinatorial therapy of cilostazol and probucol effectively reduces albuminuria through inhibition of proinflammatory pathways in podocytes

P. He, H. Kawamura, M. Takemoto, K. Kuno, M. Shoji, A. Hattori, M. Yamaga, K. Sakamoto, R. Ishibashi, T. Ishikawa, S. Onishi, Y. Maezawa, H. Tokuyama, K. Kobayashi, K. Yokote;  
Clinical Cell Biology and Medicine, Chiba University Graduate School of Medicine, Japan.

**Background and aims:** Long-lasting inflammation occurring in glomeruli has been proved to be involved in the development of chronic kidney disease such as diabetic nephropathy (DN). The aim of this study is to clarify the mechanism of renoprotective effect of combinatorial therapy of cilostazol (CSZ) and probucol (PBC), both of which exhibit anti-inflammatory properties.

**Materials and methods:** We employed lipopolysaccharide (LPS) induced acute renal inflammation model. In brief, after treatment with CSZ, PBC alone or in combination, mice were intraperitoneally injected with LPS. After 24 h, urinary albumin levels were measured by ELISA and expression of MCP1 in glomeruli was analyzed by immunostaining. In vitro, we treated cultured podocytes with LPS in the presence or absence of CSZ, PBC individually or both and then estimated NF- $\kappa\text{B}$  activation by immunostaining, MAPK phosphorylation by immunoblotting and reactive oxygen species (ROS) production by dihydroethidium staining. Also activation of NADPH oxidase (Nox) and components of Nox family were examined by lucigenin assay and real-time PCR, respectively.

**Results:** In mouse model, CSZ significantly reduced and PBC showed a tendency to decrease LPS-induced albuminuria and the concurrent administration showed a more potent effect. The MCP1 upregulation in glomeruli was suppressed by individual treatment of both drugs and more strongly by the combination. The MCP1 overexpressed by LPS was mainly produced in podocytes among the native cells of glomeruli. And the inhibitory effect of these drugs on MCP1 upregulation was shown in LPS-treated cultured podocytes similar to that in glomeruli. As for molecular mechanism, CSZ suppressed nuclear accumulation of NF- $\kappa\text{B}$  and phosphorylation of p44/42 MAPK induced by LPS. Forskolin, an activator of adenylate cyclase, reduced p44/42 MAPK phosphorylation as well and a specific PKA inhibitor H89 reversed the inhibitory effect of CSZ, indicating CSZ suppresses p44/42 MAPK through cAMP-PKA activation. PBC also reduced LPS-induced nuclear accumulation of NF- $\kappa\text{B}$ , while it failed to suppress p44/42 MAPK phosphorylation. PBC is originally developed as an anti-oxidant and it completely suppressed ROS production in response to LPS in both mouse glomeruli and cultured podocytes. Also, another anti-oxidative agent, NAC inhibited MCP1 upregulation and nuclear accumulation of NF- $\kappa\text{B}$ , indicating that ROS generation is prerequisite for NF- $\kappa\text{B}$  activation and following MCP1 induction. Further, PBC suppressed Nox activity and Nox4 expression, indicating PBC inhibits ROS generation through suppression of Nox4, which in turn lead to suppression of MCP1 upregulation induced by LPS.

**Conclusion:** We found the combination of CSZ and PBC had a strong protective effect on inflammatory renal dysfunction using LPS model. The combined effect of these drugs was due to the fact that CSZ and PBC showed anti-inflammatory effects through inhibition of different pathway, p44/42 MAPK and ROS, respectively. Although further investigations are needed, the combination therapy would hold promise for future refinement of treatment of CKD.

## 1188

**High-fat meals induce systemic cytokine release without evidence of endotoxaemia-mediated cytokine production from circulating monocytes or myeloid dendritic cells**C.L. Fogarty<sup>1</sup>, J.K. Nieminen<sup>2</sup>, L. Peräneva<sup>1</sup>, M.I. Lassenius<sup>1</sup>, C. Forsbloom<sup>1</sup>, P.-H. Groop<sup>1</sup>, O. Vaarala<sup>2</sup>, M. Lehto<sup>1</sup>, FinnDiane Study Group;<sup>1</sup>Folkhälsan Research Center,<sup>2</sup>National Institute for Health and Welfare, Helsinki, Finland.

**Background and aims:** Dietary fat is known to increase circulating levels of bacterial lipopolysaccharide (LPS) and proinflammatory cytokines in healthy subjects. Earlier studies have found increased intestinal permeability in patients with type 1 diabetes (T1D), suggesting that patients may display a more pronounced postprandial increase in circulating proinflammatory TLR4 agonists-LPS and triglycerides. While it has been long known that circulating inflammatory markers are predictors of progressive renal failure, we have recently shown that LPS activity levels are strongly associated with the components of the metabolic syndrome and the development of diabetic nephropathy in patients with T1D. Increased TLR4 responsiveness together with postprandially elevated circulating LPS and triglyceride levels may play a key role in the promotion and progression of inflammation, thereby increasing the risk of developing diabetic complications. The aim of the present study was to investigate the acute effects of two sequential high-fat meals on circulating cytokines and the LPS responsiveness of innate immune cells in the context of T1D. We hypothesized that high-fat diet-induced endotoxaemia would increase cytokine release from peripheral innate immune cells, which could in turn both induce systemic inflammation and modulate TLR4 responsiveness, particularly in patients with T1D.

**Materials and methods:** Eleven patients with T1D and eleven controls received two fatty meals: breakfast (8:00, 65 g fat) and lunch (12:00, 42 g fat). The patients were studied as part of the Finnish Diabetic Nephropathy (FinnDiane) Study. Fasting (8:00) and postprandial (14:00) blood samples were taken and incubated with or without *E. coli* LPS. Cytokine levels in serum, and cytokine responses in monocytes and mDCs were measured using flow cytometry

**Results:** At fasting, diabetic myeloid dendritic cells (mDCs) exhibited higher LPS-induced IL-6 and IL-1 $\beta$  production than controls. Postprandially, patients with T1D and controls showed significant increases in the serum concentrations of eight inflammatory cytokines (IL-6, TNF- $\alpha$ , IL-1 $\beta$ , IFN- $\alpha$ , IL-10, IFN- $\gamma$ , IL-12, and MIP-1 $\beta$ ) without concomitant increase in serum LPS activity. Serum cytokine production was similar in both groups. No postprandial change was seen in the IL-6, TNF- $\alpha$ , or IL-1 $\beta$  production of mDCs or monocytes.

**Conclusion:** Our results show that in whole blood, diabetic dendritic cells are hyperresponsive to *in vitro* LPS stimulation. Furthermore, in patients and controls alike, acute high-fat meals increase circulating cytokines but have no effect on serum LPS activity levels or cytokine production in circulating mDCs or monocytes. Our results suggest that postprandial increases in serum cytokine levels are neither mediated by circulating endotoxins nor the activation of circulating innate immune cells. The production of high-fat meal induced inflammatory markers is conserved between patients and controls and most likely regulated at the tissue level.

**Effects of incretin on human mesangial cells loaded with apo E2 remnant lipoproteins and on nephropathy in diabetic patients**

M. Eto, M. Saito;

Clinical Medicine, Ohu University, Koriyama, Japan.

**Background and aims:** In JDCS (Japan) and UKPDS 74, hypertriglyceridemia was detected as one of the risk factors for diabetic nephropathy. Increased remnant lipoproteins underlie hypertriglyceridemia. We first found that apo E2 is a genetic factor for diabetic nephropathy, and that increase of plasma TG/remnant lipoproteins caused by apo E2 contributes to nephropathy. Remnant lipoproteins are taken up by mesangial cells, and then cause renal damage. The frequency of apo E2 is approx.10% in Japan and western countries. Diabetic nephropathy is characterized by the accumulation of extracellular matrix protein in the glomerular mesangium. Incretin, which is widely used in T2DM patients, reduces plasma TG/remnant lipoproteins as well as glucose. There is little information about the effect of incretin on nephropathy. In the present study we examined the effect of GLP-1 on TGF- $\beta$

and type IV collagen expression in human mesangial cells (HMCs) loaded with apo E2 remnant lipoproteins, and examined whether sitagliptin which increases incretin is effective to improve nephropathy in T2DM patients with apo E2 allele.

**Materials and methods:** Remnant lipoproteins were isolated from plasma of a patient with T2DM and apo E2/2 genotype by ultracentrifugal method. HMCs loaded with remnant lipoproteins were incubated for 24 h with GLP-1 at the concentration of 0, 50, 100 and 500 nmol/L. To evaluate the expression of TGF- $\beta$ , type IV collagen and GLP-1 receptor mRNA in HMCs, RT-PCR procedure was performed. T2DM with apo E3/3 (n=38) and apo E3/2 genotype (n=7) were studied. Patients were treated with sitagliptin over 10 months. HbA1c, plasma TG and remnant cholesterol were compared before and after sitagliptin therapy. Remnant cholesterol was determined as RLP-cholesterol. Urinary albumin-to-creatinine ratio (ACR, normal range <30 mg/g) was measured as a marker of nephropathy.

**Results:** Apo E2 remnant lipoproteins significantly stimulated the expression of TGF- $\beta$  and type IV collagen mRNA in HMCs. GLP-1 significantly suppressed the expression of TGF- $\beta$  and type IV collagen mRNA in HMCs loaded with remnant lipoproteins. GLP-1 significantly stimulated the expression of GLP-1 receptor. In apo E3/3 patients, 10-month therapy with sitagliptin significantly reduced HbA1c (6.6 $\rightarrow$ 6.0%), plasma TG (129 $\rightarrow$ 107mg/dl) and remnant cholesterol (5.5 $\rightarrow$ 3.9mg/dl), and ACR (57.4 $\rightarrow$ 34.1mg/g). In apo E3/2 patients, it reduced HbA1c (6.8 $\rightarrow$ 6.0), plasma TG (173 $\rightarrow$ 119) and remnant cholesterol (8.0 $\rightarrow$ 5.0), and ACR (119.0 $\rightarrow$ 19.2). Reduction in HbA1c from baseline at 10 months was not significantly different between apo E3/3 and apo E3/2 patients, but reduction in plasma TG and remnant cholesterol, and ACR was significantly greater in apo E3/2 patients than in apo E3/3 patients.

**Conclusion:** GLP-1 suppresses the expression of TGF- $\beta$  and type IV collagen in HMCs loaded with apo E2 remnant lipoproteins. Sitagliptin reduced plasma TG/remnant lipoproteins and ACR more greatly in apo E2 T2DM patients. It is suggested that incretin is effective to protect and improve diabetic nephropathy associated with apo E2 through its lowering effect of plasma TG/remnant lipoproteins and/or direct effect on mesangial cells.

## PS 105 Diabetic nephropathy: clinical

### Performance of creatinine and cystatin C based CKD-EPI equations to estimate glomerular filtration rate in type 2 diabetes

A.A. Soares<sup>1</sup>, R. Boff<sup>1</sup>, J.D. Machado<sup>1</sup>, L.S. Rodrigues<sup>1</sup>, E.G. Camargo<sup>1</sup>, J.L. Camargo<sup>2</sup>, S.P. Silveiro<sup>1</sup>;

<sup>1</sup>Universidade Federal do Rio Grande do Sul,

<sup>2</sup>Hospital de Clínicas de Porto Alegre, Brazil.

**Background and aims:** Diabetes kidney disease (DKD) is the worldwide leading cause of end-stage renal disease. Current guidelines recommend annual screening with urinary albumin measurement and estimation of glomerular filtration rate (GFR) by equations. The aim of this study was to evaluate the accuracy of creatinine and cystatin C based Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equations to estimate GFR in patients with type 2 diabetes (DM) as compared to healthy adults.

**Materials and methods:** Cross-sectional study included healthy adults and DM patients with GFR higher than 60 mL/min/1.73 m<sup>2</sup>. GFR was estimated by CKD-EPI creatinine (CKDEPIcreat), CKD-EPI cystatin C (CKDEPIcystC), and CKD-EPI creatinine-cystatin C (CKDEPI-CC) equations in comparison with GFR measured by a reference method (51Cr-EDTA). Each group (DM vs healthy) was stratified according to ages above and below 45 years and analyzed separately. Serum creatinine was measured by Jaffe traceable method (Advia 1800, Siemens Healthcare) and serum cystatin C was evaluated by immunoturbidimetric method (Dako, Cytomation). Accuracy (percentage of estimated GFR within 30% [P30] of measured GFR), bias (mean difference between measured and estimated GFR), and precision (standard deviation of bias) were assessed. Agreement was evaluated according to Bland & Altman analyses.

**Results:** One hundred healthy adult subjects and 84 DM patients, aged 38±14 (18-86) and 59±19 (31-82) years, respectively, were evaluated. Measured 51Cr-EDTA GFR was 112±19 (64-160) and 104±27 (60-184) mL/min/1.73 m<sup>2</sup>, in healthy individuals and in DM patients, respectively. For the healthy group with less than 45 years of age, the measured 51Cr-EDTA GFR was 117±19 and the CKDEPIcreat, CKDEPI-CC and CKDEPIcystC were 117±13, 110±11 and 104±12 mL/min/1.73 m<sup>2</sup>, respectively. Only CKDEPIcreat was in agreement with the reference method (P=0.894). In the DM group, the measured 51Cr-EDTA GFR (126±41 mL/min/1.73 m<sup>2</sup>) was different from all equations: CKDEPIcreat, CKDEPI-CC and CKDEPIcystC equations were, respectively 98±16, 95±16 and 93±18 mL/min/1.73 m<sup>2</sup>. The Figure depicts the GFR mean values as well as the precision (SD) of the older individuals. In this set, the reference GFR method did not agree with any equation, in both groups. In healthy subjects older than 45 years, the accuracy (P30) was 94%, 91% and 85% for CKDEPIcreat, CKDEPI-CC and CKDEPIcystC, respectively. In DM patients older than 45 years, accuracy was 71%, 68% and 55% for CKDEPIcreat, CKDEPI-CC and CKDEPIcystC, respectively.

**Conclusion:** All CKD-EPI equations underestimated GFR in older adults, more markedly in type 2 DM patients. In younger subjects, the creatinine based equation presented the best performance.

Figure – GFR values of individuals  $\geq 45$  years as measured by <sup>51</sup>Cr-EDTA and by the CKD-EPI equations; healthy volunteers (N=34) in panel A and type 2 DM patients (N=79) in panel B.

### Albuminuria predicts progression to end-stage renal disease in diabetic patients

T. Babazono, H. Murata, A. Toyonaga, N. Yoshida, S. Takemura, M. Takagi, N. Yoshida, K. Toya, I. Nyumura, K. Hanai, N. Tanaka, Y. Uchigata; Tokyo Women's Medical University School of Medicine, Tokyo, Japan.

**Background and aims:** Albuminuria in diabetic patients has been repeatedly shown to be a crucial risk factor for renal outcomes; however, previous studies examining these associations were limited to short observational period or surrogate markers including decline in GFR. There are few large cohort studies that observed patients until reaching end-stage renal disease. We conducted this study to clarify the association between albuminuria and hard renal endpoint in diabetic patients.

**Materials and methods:** This was a single-center historical cohort study consisting of adult Japanese diabetic patients who had both serum creatinine concentration and albuminuria data measured within 90 days at our hospital between 1995 and 2012, baseline estimated GFR (eGFR)  $\geq 15$  mL/min/1.73 m<sup>2</sup>, and those who were observed at least 90 days. According to the baseline urinary albumin-to-creatinine ratio (ACR), patients were classified into the following 7 groups; <10, 10 to 29, 30-99, 100-299, 300-999, 1,000-2,999, and  $\geq 3,000$  mg/g (Table). The primary endpoint was decrease in eGFR < 15 mL/min/1.73 m<sup>2</sup>. Cumulative incidence of the primary endpoint was estimated by the Kaplan-Meier method and the statistical differences among groups were examined by the log-rank test. HRs and the corresponding 95% CIs for reaching the endpoint were calculated using the Cox proportional hazard model.

**Results:** A total of 20,884 patients, 8,547 women and 12,337 men, with the mean age of 55 ± 14 (SD) years (range; 20-93 years) were studied; number of patients with the ACR group was listed in Table. During the median follow-up period of 5.6 years (up to 18.1 years), 1,033 patients reached the endpoint. Eighteen-year cumulative incidence of reaching the endpoint in each ACR group was summarized in the Table. Hazard ratio for patients in each ACR group after adjustment for gender, age and eGFR at baseline in reference to those with an ACR < 10 mg/g rose exponentially (Table, each p<0.001).

**Conclusion:** In this long-term large observational cohort study in Japanese diabetic patients, we found that stepwise rise in the risk of reaching ESRD according to increase in albuminuria. Higher levels of albuminuria, even within the normal range, may be associated with increased risk of renal hard endpoint.

| Albuminuria (mg/g creatinine)            | <10   | 10-29 | 30-99 | 100-299 | 300-999 | 1,000-2,999 | $\geq 3,000$ |

### Prevalence of albuminuria in subjects with impaired fasting glucose in Korean population

J. Won<sup>1</sup>, D.-J. Kim<sup>2</sup>, J. Kim<sup>1</sup>, J. Noh<sup>2</sup>, K. Ko<sup>1</sup>, B. Rhee<sup>1</sup>;  
<sup>1</sup>Department of Internal Medicine, Cardiovascular and Metabolic Disease Center, College of Medicine, Inje University, Seoul, <sup>2</sup>Department of Internal Medicine, Cardiovascular and Metabolic Disease Center, College of Medicine, Inje University, Ilsan, Republic of Korea.

**Background and aims:** We tried to assess the prevalence of albuminuria across the fasting plasma glucose (FPG) level including normal fasting glucose (NFG), impaired fasting glucose (IFG), and diabetes

**Materials and methods:** A total of 5,202 subjects who participated in the fifth Korea National Health and Nutrition Examination Survey (KNHANES V-2) were enrolled in this study. And, albumin-creatinine ratio was calculated.

**Results:** We divided subjects into five group according to fasting plasma glucose level of < 5.0 (NGT1, n=1905), 5.0-5.5 (NGT2, n=1784), 5.6-6.0 (IFG1, n=727), 6.1-6.9 (IFG2, n=268), and  $\geq 7.0$  (or diabetes, n=518) mmol/l. 7.6 percent (n=395). The prevalence of albuminuria in each group was 4.1, 6.0, 7.6, 12.3, and 23.4%, respectively, in the five groups (P < 0.01 for the trend). The prevalence of albuminuria in IFG2 was significantly higher than in IFG1 even after adjustment for age, sex, hypertension and obesity. In a multivariate logistic regression, independent associations with albuminuria were age, hypertension, and increasing fasting glucose including IFG2 and diabetes.

**Conclusion:** The current data suggest that prevalence of albuminuria may begin to increase in the higher range of IFG, independent of traditional risk factors.

## 1193

### Arterial stiffness is more associated with albuminuria than decreased glomerular filtration rate in the development of type 2 diabetic nephropathy

Y. Nam<sup>1</sup>, S. Kim<sup>1</sup>, C. Lee<sup>2</sup>, S. Park<sup>1</sup>, J. Kim<sup>1</sup>, W. Kim<sup>1</sup>, Y. Jeon<sup>1</sup>, B. Kim<sup>1</sup>, I. Kim<sup>1</sup>, S. Son<sup>3</sup>;

<sup>1</sup>Department of Internal Medicine, Pusan National University Hospital,

<sup>2</sup>Department of Internal Medicine, Busan St. Mary's Medical Center,

<sup>3</sup>Department of Internal Medicine, Bongseng Memorial Hospital, Busan, Republic of Korea.

**Background and aims:** Arterial stiffness, a clinical atherosclerosis marker, was associated with the progression of chronic kidney disease (CKD) including diabetic nephropathy. Each albuminuria and decline of glomerular function rate (GFR) are being recognized as complementary rather than obligatory markers for diabetic nephropathy. The aim of study was to evaluate the association of arterial stiffness with albuminuria and/or GFR in the development of type 2 diabetic nephropathy.

**Materials and methods:** This study was an analysis from participants of The Relationship between Cardiovascular disease and Brachial-ankle Pulse Wave Velocity in Patients with Type 2 Diabetes (REBOUND) Study, which was a prospective multi-center cohort study recruited from 8 general hospitals in Busan, Korea. Type 2 diabetic patients aged 30 years and more were recruited and measured brachial-ankle pulse wave velocity (baPWV) as noninvasive marker for arterial stiffness. The patients were categorized into 4 groups according to albumin-to-creatinine ratio (ACR, normoalbuminuria and albuminuria) and eGFR (<, ≥ 60 mL/min/1.73 m<sup>2</sup>).

**Results:** A total of 2,613 patients were analyzed for this study. Maximal baPWV was significantly correlated with both ACR ( $r = 0.302$ ,  $P < 0.001$ ) and eGFR ( $r = -0.218$ ,  $P < 0.001$ ) in univariate analysis with whole subjects. After adjusting for age, sex, several significant clinical variables and eGFR, baPWV remained significant association with ACR in multivariate analysis ( $r = 0.226$ ,  $P < 0.001$ ). In patients with eGFR ≥ 60 mL/min/1.73 m<sup>2</sup> ( $n = 2,134$ ), baPWV also showed positive correlations with ACR after adjusting in final model ( $r = 0.219$ ,  $P < 0.001$ ). However, baPWV lost significant correlation with eGFR after adjusting several significant clinical variables. In the patients with eGFR ≥ 60 mL/min/1.73 m<sup>2</sup>, the increased level of baPWV remained significant association with to being albuminuria after adjusting for several clinical factors in multivariate model. In the normoalbuminuric patients ( $n = 1,798$ ), the increased level of baPWV was not associated with decreased eGFR (<60 mL/min/1.73 m<sup>2</sup>, normoalbuminuric CKD) in multivariate model.

**Conclusion:** The results of this study suggest that arterial stiffness is more associated with albuminuria than GFR in development of type 2 diabetic nephropathy. Especially, arterial stiffness is not associated with normoalbuminuric CKD in type 2 diabetic patients.

### Sex difference in coronary artery calcification score and its use as a predictor of progression of diabetic nephropathy

S. Fukushima<sup>1</sup>, A. Hagiwara<sup>1</sup>, T. Haruki<sup>1</sup>, J. Ogino<sup>1</sup>, K. Tajima<sup>1</sup>, C. Yoneda<sup>1</sup>, Y. Suzuki<sup>2</sup>, N. Hashimoto<sup>1</sup>;

<sup>1</sup>Diabetes, Endocrine and metabolic Diseases, Yachiyo Medical Center,

Tokyo Women's Medical University, <sup>2</sup>Diabetes and Metabolic Diseases, Asahi General Hospital, Chiba, Japan.

**Background and aims:** Cardiovascular disease (CVD) is a leading cause of death in type 2 diabetes mellitus (T2DM). The coronary artery calcification score (CACs) is believed to be one of the predictors of CVD. The progression of diabetic nephropathy (DN) leads to an increase in the risk of CVD and mortality. Moreover, it has been reported that progression of DN is strongly associated with macrovascular as well as microvascular complications. In this study, we assessed the relationship between progression of DN and CACS in T2DM patients at baseline and at 5-year follow-up.

**Materials and methods:** A total 103 T2DM patients (71 men, 65 ± 7 years old; 32 women, 67 ± 7 years old) of our medical center, who underwent multidetector CT scan and were assessed for DN each year, were studied. We excluded patients with a serum creatinine (Cr) over 1.0 mg/dl or those

who had iodine sensitivity. Patients were divided into two group based on median CACS derived from the Agatston score. Low CACS were those < 116 and < 65 for men and women, respectively, while high CACS were those ≥ 116 and ≥ 65 for men and women, respectively. The main measured outcome was the progression of DN stage defined by Japan Diabetes Society, American Diabetes Association, or European Association for the Study of Diabetes. Kaplan-Meier method and Cox proportional hazard analysis were performed to examine whether the relationship between CACS and DN progression was different between the sexes.

**Results:** At baseline, the male group with high CACS at baseline had a significantly higher albuminuria (283 ± 70 mg/g · Cr vs. 83 ± 39 mg/g · Cr,  $p = 0.016$ ) and prevalence of diabetic retinopathy (DR, 53.1% vs. 21.9%,  $p = 0.010$ ) than the male group with low CACS. Other baseline parameters (age, duration of DM, BP, HbA<sub>1c</sub>, serum Cr, estimated GFR [eGFR], uric acid, lipid profile, white blood cell count, percentage of current smokers, use of statin, ACE inhibitor or angiotensin II receptor blocker) were not significantly different between the two groups. At baseline, the female group with high CACS were significantly older (70 ± 6 years vs. 64 ± 7 years,  $p = 0.036$ ), had a lower level of eGFR (64.2 ± 10.6 mL/min/1.73<sup>2</sup> vs. 74.0 ± 11.7 mL/min/1.73<sup>2</sup>,  $p = 0.019$ ) and a higher level of Cr (0.70 ± 0.11 mg/dl vs. 0.63 ± 0.09 mg/dl,  $p = 0.041$ ) compared with the female group with low CACS. Other parameters at baseline were not significantly different. At the 5-year follow-up, 52.8% of men in the high CACS group demonstrated progression of DN compared with 22.9% in the low CACS group ( $p = 0.008$ ). In male patients without DR, those in high CACS group also had significantly higher progression of DN than those in the low CACS group (60.0% vs. 20.0%,  $p = 0.007$ ). Patients with DR in the high and low CACS groups did not have a significantly different rate of DN progression (47.1% vs. 14.3%,  $p = 0.145$ ). In women, DN progression was not significantly different between the high and low CACS groups (25.0% vs. 43.7%,  $p = 0.233$ ) and the presence of DR had no effect on DN progression in the high and low CACS groups.

**Conclusion:** In men with T2DM, CACS is a good predictor of DN progression. DN progression was not related to the presence of DR, suggesting that the progression of nephropathy in men may be affected by atherosclerotic factors more than in women.

## 1195

### Bimodal association of incidence and progression of diabetic nephropathy according to pack-years of smoking in type 1 diabetes

M. Feodoroff<sup>1,2</sup>, V. Harjutsalo<sup>1,3</sup>, C. Forsblom<sup>1,2</sup>, P.-H. Groop<sup>1,2</sup>, FinnDiane; <sup>1</sup>Folkhälsan Institute of Genetics, Folkhälsan Research Center, Biomedicum Helsinki, <sup>2</sup>Division of Nephrology, Department of Medicine, Helsinki University Central Hospital, <sup>3</sup>National Institute for Health and Welfare, Diabetes Prevention Unit, Helsinki, Finland.

**Background and aims:** Our preliminary analyses of the relationship between dose of smoking as pack-years (py) and the initiation and progression of diabetic nephropathy (DN) based on the non-linear splines showed a bimodal distribution with the first peak at 10.5 pack-years and the second increase after 30 pack-years. This phenomenon was especially evident in women who progressed from normoalbuminuria to microalbuminuria.

**Materials and methods:** The study included 3,838 patients with type 1 diabetes. At baseline, mean age was 37.7 (IQR 28.8-47.0) years, duration of diabetes 21.4 (12.2-30.9) years, and 51% were males. Patients were followed for 6.3 (4.1-9.1) years. All patients with progressive DN were analyzed together; any progression from normo- to micro-, micro- to macro- or macroalbuminuria to end-stage renal disease. First the potential non-linear relationship between pack-years and progression of DN was modeled by Generalized Additive Models (GAM). The data were further analysed by Kaplan-Meier method and finally by Cox regression models adjusted for age, HbA<sub>1c</sub>, systolic blood pressure (SBP) and triglycerides (TG) and providing hazard ratios (HR). Based on the bimodal distribution found by the GAM-analyses the data were divided into the groups 0-5, 5-8.5, 8.5-12.5 (±2 years around the first peak), 12.5-30 and ≥30 pack-years (when risk started to increase again).

**Results:** There were a total of 438 progressors. Those who had smoked 8.5-12.5 py had a more favorable profile for clinical risk factors than those who had smoked ≥30 py (such as TG, SBP, age, duration of diabetes), although the risk of progression of DN was similar. The 10-year progression risks for the groups (0-5, 5-8.5, 8.5-12.5, 12.5-30 and ≥30 py) were 14.3% (95% CI 12.6-16.0), 22.6% (16.3-28.5), 34.7% (28.6-40.3), 25.8% (21.6-29.8) and 31.6% (24.7-37.8), respectively (Figure). HR was 2.2 (1.5-3.1) for those who had smoked 8.5-12.5 py, while it was 1.7 (1.1-2.7) for those who had smoked ≥30

py compared to those who had smoked 0–5 py. HR was 1.4 (0.9–2.1) and 1.3 (0.9–1.8) for those who had smoked 5–8.5 and 12.5–30 py.

**Conclusion:** Increase in pack-years of smoking is associated with progression of DN, but the relationship is not linear but rather bimodal. We conclude that the first peak might indicate an increased risk of a subset for the patients who are genetically predisposed and the second due to harmful effects of smoking.

### Reduction of microalbuminuria by calcium channel blockers in patients with type 2 diabetes mellitus and hypertension

Y.-C. Hwang<sup>1</sup>, S. Oh<sup>1</sup>, K.-H. Yoon<sup>2</sup>, B. Cha<sup>3</sup>, K.-W. Lee<sup>4</sup>, H. Jang<sup>5</sup>, K. Min<sup>6</sup>, C. Chung<sup>7</sup>, M.-K. Lee<sup>1</sup>;

<sup>1</sup>Samsung Medical Center, Seoul, <sup>2</sup>Seoul St. Mary's Hospital,

<sup>3</sup>Yonsei University College of Medicine, Seoul, <sup>4</sup>Ajou University School of Medicine, Gyeonggi-do, <sup>5</sup>Seoul National University Bundang Hospital, Gyeonggi-do, <sup>6</sup>Eulji General Hospital, Seoul,

<sup>7</sup>Yonsei University Wonju College of Medicine, Republic of Korea.

**Background and aims:** It has been suggested that reno-protective effects are different among calcium channel blockers. The aim of this study was to compare anti-albuminuric effect of different types of calcium channel blockers in patients with type 2 diabetes.

**Materials and methods:** A multicenter, randomized, open label, active-controlled study was conducted in seven hospitals in Korea. Inclusion criteria were age  $\geq 18$  years, hypertension treated with angiotensin receptor blocker or angiotensin-converting enzyme inhibitor, type 2 diabetes with HbA1c  $\leq 8\%$ , and persistent microalbuminuria. A total of 74 patients were randomized into the cilnidipine 10mg group ( $n = 37$ ) or the amlodipine 5mg group ( $n = 37$ ). Patients were assessed at baseline, 12 weeks and 24 weeks after treatment.

**Results:** Compared with cilnidipine group, amlodipine group showed greater diastolic blood pressure reduction at 24 weeks after treatment ( $P=0.03$ ). In the cilnidipine group, urine albumin to creatinine ratio (ACR) was significantly reduced after 12 weeks ( $-53.0 \pm 123.2$  mg/g,  $P<0.01$ ) and 24 weeks ( $-57.3 \pm 106.9$  mg/g,  $P<0.01$ ) treatment. However, amlodipine group did not show any decrease in ACR after 12 weeks or 24 weeks treatment. Cilnidipine group showed significant reduction in ACR compared with amlodipine group after 12 weeks ( $-84.7 \pm 106.8$  mg/g in cilnidipine group and  $-9.5 \pm 79.2$  mg/g in amlodipine group,  $P=0.02$ ) and 24 weeks ( $-84.0 \pm 111.7$  mg/g in cilnidipine group and  $14.6 \pm 119.4$  mg/g in amlodipine group,  $P<0.01$ ) treatment, particularly in patients with long duration of diabetes more than 10 years.

**Conclusion:** Cilnidipine shows greater microalbuminuria reduction than amlodipine in rennin-angiotensin system blocker-treated hypertensive patients with long duration of type 2 diabetes.

### Adherence to medications improves risk reduction of end-stage renal disease in diabetes mellitus

P.-Y. Chang<sup>1</sup>, H.-Y. Chiou<sup>1</sup>, L.-N. Chien<sup>2</sup>, Y.-L. Li<sup>1</sup>, Y.-F. Lin<sup>3</sup>, C.-C. Wang<sup>1</sup>, W.-T. Chiu<sup>4</sup>;

<sup>1</sup>School of Public Health, <sup>2</sup>School of Health Care Administration,

<sup>3</sup>Graduate Institute Clinical Medicine, <sup>4</sup>Graduate Institute of Injury Prevention and Control, Taipei Medical University, Taiwan.

**Background and aims:** Diabetes is a prevalent chronic disease with significant complications. Uncontrolled glycemic is an independent risk factor and results in accelerated progression to end-stage renal disease (ESRD). To our knowledge, there is no study discuss the association between antihyperglycemic medication adherence and subsequent ESRD among individuals with type 2 diabetes. The specific aims of this study was to examine the effect of better adherence to antihyperglycemic therapy on preventing the risk of ESRD among newly diagnosed diabetic patients.

**Materials and methods:** This study used a representative cohort of 1 million people from National Health Insurance Research Database in Taiwan. All subjects aged 20 years or older who have been diagnosed with diabetes mellitus (ICD-9 code: 250.xx) and received newly treated with antihyperglycemic agents were included. Newly treated patients were identified as those patients who had not taken any antihyperglycemic agents before the first date of being diagnosed with diabetes. Adherence was a medication possession ratio (MPR) calculated by the sum of total days' supply of medication dispensed divided by the number of days (365) for each year equal or greater than 80%. ESRD was defined as patients received dialysis claims continuously for three months. Time-dependent medication adherence for estimating the risk of ESRD was applied in the Cox proportional hazard regression model. Covariates included age, gender, hypertension, ischemic heart disease, cerebrovascular disease, congestive heart failure, anemia, urinary tract infection, gout, chronic kidney disease, Charlson comorbidity index, use of statin, number of drugs therapy with hypertension, number of drugs therapy with diabetes and only use of metformin. All the analyses were performed using SAS version 9.3. The study was approved by the TMU-Joint Institutional Review Board.

**Results:** A total of 32,861 newly treated diabetes mellitus patients were enrolled and 327 cases developed ESRD during a mean follow-up of 4.9 years. The mean age was  $56.4 \pm 12.8$  years, and male gender accounted for 53.6%. After adjustment for potential confounders, patients who were nonadherent to diabetes medications were associated with the increased risk of ESRD [hazard ratio (HR) = 1.56, 95% confidence interval (CI): 1.19–2.03]. In addition, results indicated that patients with hypertension (HR = 1.40, 95% CI = [1.04–1.87]), cerebrovascular disease (HR = 1.53, 95% CI = 1.05–2.24), chronic heart failure (HR = 3.89, 95% CI = 2.49–6.05), anemia (HR = 3.51, 95% CI = 2.06–5.97), chronic kidney disease (HR = 11.82, 95% CI = 8.61–16.22), monotherapy with hypertension (HR = 1.52, 95% CI = 1.06–2.17), use two or more therapy with hypertension (HR = 1.68, 95% CI = 1.09–2.59), and use two or more therapy with diabetes (HR = 1.56, 95% CI = 1.18–2.07) have higher risk of developing ESRD compared to their counterparts. However, patients only used metformin within the two year of diabetes diagnosis had lower risk of developing ESRD (HR = 0.23, 95% CI = 0.09–0.58).

**Conclusion:** This study showed nonadherence to antihyperglycemic medications are associated with increased the risk of ESRD among type 2 diabetes patients.

### Effect of glycaemic and serum electrolyte variation on cardiac electrical activity during haemodialysis in people with insulin treated diabetes

N.H. Siddaramaiah<sup>1</sup>, D.K. Tez<sup>2</sup>, N.J. Linker<sup>3</sup>, M. Bilous<sup>1</sup>, S. Winship<sup>1</sup>, S.M. Marshall<sup>4</sup>, R.W. Bilous<sup>1</sup>;

<sup>1</sup>Diabetes care, James Cook University Hospital,

<sup>2</sup>Department of Renal Medicine, James Cook University Hospital,

<sup>3</sup>Department of Cardiology, James Cook University Hospital,

Middlesbrough, <sup>4</sup>Institute of Cellular Medicine, Newcastle upon Tyne, UK.

**Background and aims:** One-year survival for diabetic patients on dialysis is 84.7% in the UK. Cardiovascular deaths account for 22%. Rapid electrolyte shifts, QT dispersion, left ventricular hypertrophy, myocardial structural

and functional abnormalities and sympathetic hyperactivity are potential causative factors. Hypoglycaemia has been linked to sudden death in insulin treated diabetes. To explore the relationships between; 1. glycaemic variation and heart rate, rhythm and QTc interval 4hrs before, during (3 to 4hrs) and 4hrs after haemodialysis (HD) 2. changes in serum electrolyte levels during HD and heart rate, rhythm and QTc interval.

**Materials and methods:** In our ongoing study, we undertook week-long continuous glucose monitoring and Holter monitoring, for 1 to 3 weeks in insulin deficient patients. Serum electrolytes and 12 lead ECGs were obtained at the beginning, middle and end of 3 HD sessions during the 1<sup>st</sup> study week. 10 insulin deficient patients (7 female, mean age 50.6±9.8 yrs) were monitored, during 72 HD sessions.

**Results:** Mean glucose levels during HD were significantly lower than pre-HD (8.4±3.6 vs 11.2±4.5mmol/L,  $p<0.001$ ) and post-HD period (8.3±3.5 vs 12.3±4.7mmol/L,  $p<0.001$ ) on paired samples. There were significant periods of hyperglycaemia (>13.0mmol/L) during pre-HD (68.3±93mins vs 22.8±55mins,  $p<0.005$ ) and also post-HD compared to HD period (89.5±82 vs 19.9±48.6mins,  $p<0.001$ ) on paired samples, with no significant difference between pre and post-HD levels. Hypoglycaemia (<3.5mmol/L) occurred more frequently during HD period, but was not statistically significant. Mean QTc interval was not significantly different between pre-HD and HD (420±20 vs 424±19ms,  $p=0.2$ ), but was significantly prolonged during post-HD compared to pre-HD period (427±17 vs 420±20ms,  $p<0.05$ ) on paired samples. Multiple short episodes of asymptomatic tachy- and brady-arrhythmias were noted in 6 out of 10 patients, including atrial tachycardia, non-sustained ventricular tachycardia, sinus bradycardia, ventricular bigeminy/trigeminy & junctional rhythm. Mean post-HD serum electrolytes were significantly lower than pre-HD levels (n=30): potassium (K<sup>+</sup>) 3.3±0.3 vs 4.4±0.8 mmol/L ( $p<0.001$ ), magnesium (Mg<sup>2+</sup>) 0.78±0.07 vs 0.9±0.16mmol/L ( $p<0.001$ ) corrected calcium (Ca<sup>2+</sup>) 2.21±0.07 vs 2.27±0.14 mmol/L ( $p<0.05$ ) A significant drop in K<sup>+</sup> and Mg<sup>2+</sup> levels occurred in both first and second half of HD sessions. Ca<sup>2+</sup> levels dropped significantly in first but not in second half of HD session. Post-HD QTc interval was significantly prolonged compared to pre-HD ECG (500±56 vs 471±44 ms,  $p<0.005$ ). The significant prolongation occurred during second half of the HD session.

**Conclusion:** Glycaemic variation on HD days shows a 'U' shaped pattern with glucose levels being low during HD. There is significant prolongation of QTc interval during HD and subsequent period, which could be related to a drop in serum electrolyte levels. Potentially life threatening episodes of arrhythmias occur frequently in these patients. Larger study is required to understand the pathophysiological basis of these arrhythmias and their relation to glycaemia and electrolyte changes.

### Improving quality: chronic kidney disease in diabetes

N. Milne;

Northenden Group Practice, Manchester, UK.

**Background and aims:** Implementation of a continuous audit tool to facilitate focused review and optimal medicines management of those persons with diabetes and chronic kidney disease (CKD) stage 3 and above within the primary care setting. A significant event review within a general practice highlighted that when there is a decline in renal function outside a patient's formal diabetes review, medication adjustment is not always undertaken. A need was identified for the development of an audit tool to facilitate the continuous and focused review of CKD stage 3 and above within the practice diabetes population which in addition, would also enhance appropriate medicines management and safe prescribing.

**Materials and methods:** An automated weekly search engine using the practice information technology system was established to identify and invite in patients within three population sub groups (estimated glomerular filtration rates (ml/min/1.73m<sup>2</sup>) 46-60, 31-45, and <30), who were failing to meet practice established protocol targets to include optimal medication.

**Results:** Within the practice diabetes population of 616 patients, the prevalence of CKD stage 3 and above was 22% which equated to 135 patients. During the first six months, eight patients (6%) required adjustment of their diabetes medication therapy and four patients (3%) required alternative medication to their non-steroidal anti-inflammatory drugs. This demonstrated a move to enhanced medicines optimisation and safety. Other clinical interventions that are widely accepted as effective in delaying the onset or progression of CKD were also measured. Those patients without a recorded HbA1c fell from 8% to 3% and at the end of the six months all patients with

a HbA1c over 54mmol/mol had a review plan. Those without a blood pressure measurement fell from 3% to 2%. Patients who were not prescribed an angiotensin-converting enzyme inhibitor or angiotensin-II receptor antagonist where there was no contraindication, lowered from 6% to 1%. Those patients without a measurement of micro albuminuria rose from 12% to 13% thus highlighting an area for improvement. Three patients were identified as requiring referral to secondary care.

**Conclusion:** Against the background of an ever changing diabetes population and newer therapies, this audit tool, in combination with focused review, is effective in reducing variation and in improving quality of patient care. In addition, it affords timely intervention to ensure appropriate and safe medicines management within this complex patient population. It is hoped that the impacts will be increasingly evident over time, in terms of reduced patient mortality and morbidity.

## PS 106 Clinical: hypertension in diabetes

### 1200

#### Is home blood pressure reporting in patients with type 2 diabetes reliable?

S. Majima<sup>1</sup>, M. Fukui<sup>1</sup>, S. Matsumoto<sup>1</sup>, E. Ushigome<sup>1</sup>, K. Matsushita<sup>1</sup>, H. Iwase<sup>1</sup>, T. Senmaru<sup>1</sup>, M. Hamaguchi<sup>1</sup>, M. Asano<sup>1</sup>, M. Yamazaki<sup>1</sup>, G. Hasegawa<sup>2,1</sup>, N. Nakamura<sup>1</sup>;

<sup>1</sup>Department of Endocrinology and Metabolism, Kyoto Prefectural University of Medicine, Graduate School of Medical Science,

<sup>2</sup>Division of Metabolism, Nephrology and Rheumatology, Japanese Red Cross Kyoto Daini Hospital, Japan.

**Background and aims:** Hypertension, as well as hyperglycemia, is well known as an important risk of cardiovascular and renal disease in patients with type 2 diabetes. Home blood pressure (HBP) monitoring is a valuable tool in the management of hypertension. To our knowledge no study has investigated the reliability of HBP measurements in patients with type 2 diabetes. The aim of this study was to evaluate the reliability of HBP reporting and determine the factors that affected it in patients with type 2 diabetes.

**Materials and methods:** A cross-sectional study was conducted in 280 consecutive patients with type 2 diabetes recruited from the outpatient clinic at our university. Patients were requested to measure triplicate morning and evening HBP using a digital automatic BP monitor and to record these measurements in a logbook over a 2-week period. The patients were not informed of the storage function of their BP monitor.

**Results:** Among a total of 280 patients, 155 (55.4%) were taking antihypertensive medication. The concordance rate between the self-reported data in the logbook and the stored data in the monitor was 78.6%. Although 65 of the patients (23.2%) had 100% “concordant data” that were matched the stored data in the monitor and 144 (51.4%) had more than 90% concordant data, 44 (15.7%) had 50% or less concordant data. The self-reported data were significantly lower than the stored data (mean of morning systolic BP:  $129.8 \pm 15.8$  vs.  $130.6 \pm 16.2$  mmHg,  $p < 0.0001$ ). In addition, logbook BP was less variable than monitor BP (SD of morning systolic BP:  $7.9 \pm 3.2$  vs.  $9.8 \pm 3.5$  mmHg,  $p < 0.0001$ ). The most frequent erroneous data (55.8%) were “selected data” that were randomly selected from multiple measurements in the monitor, the second most erroneous (23.3%) were “fictional data” that could not be found in the monitor, and the third most erroneous (11.6%) were “shifted data” that were stored in the monitor on another day but for the same time. The concordance rate correlated significantly with HbA1c ( $r = -0.127$ ,  $p = 0.0333$ ), HDL cholesterol ( $r = 0.131$ ,  $p = 0.0286$ ), triglycerides ( $r = -0.121$ ,  $p = 0.0429$ ), mean of morning systolic monitor BP ( $r = -0.121$ ,  $p = 0.0443$ ), mean of evening diastolic monitor BP ( $r = -0.127$ ,  $p = 0.0386$ ) and SD of morning systolic monitor BP ( $r = -0.129$ ,  $p = 0.0310$ ). Multiple regression analysis indicated that the independent explanatory variables concerning the concordance rate were HbA1c ( $\beta = -0.156$ ,  $p = 0.0149$ ) and current smoking ( $\beta = -0.165$ ,  $p = 0.0184$ ). Urinary albumin excretion also correlated with the SD of morning systolic BP in the monitor, but not with that in the logbook.

**Conclusion:** Patients with type 2 diabetes sometimes report erroneous HBP, especially those with poor glycemic control or a smoking habit. As a result of this inaccurate reporting, HBP control obtained from logbooks may appear better than that obtained from a monitor. A device capable of automatically saving BP data may be helpful for obtaining accurate measurements of HBP that will assist in providing optimal treatment for hypertensive patients with type 2 diabetes.

#### Predictive value of markers of vascular damage for renal outcome in type 2 diabetes and essential hypertension

R. Bruno<sup>1</sup>, A. Salvati<sup>2</sup>, K. Raimo<sup>2</sup>, M. Barzacchi<sup>2</sup>, E. Vitolo<sup>2</sup>, L. Ghiadoni<sup>2</sup>, A. Solini<sup>2</sup>;

<sup>1</sup>Institute of Clinical Physiology, CNR Pisa, <sup>2</sup>Dept of Clinical and Experimental Medicine, University of Pisa, Italy.

**Background and aims:** We have shown that renal vasodilating response to nitrates (dynamic renal resistive index, DRIN) is an early vascular alterations of type 2 diabetes (T2DM) and essential hypertension (EH) already present in normoalbuminuric individuals. In this study we prospectively evaluated

whether this parameter and other markers of systemic vascular damage are able to predict microalbuminuria (MA) onset and renal function decline in these patients.

**Materials and methods:** We studied 65 individuals (27 T2DM and 38 EH) following them prospectively. Renal resistive index (RI), DRIN (% change in RI after glyceryl trinitrate, GTN 25 µg sl), endothelium-dependent (flow-mediated-dilation - FMD) and independent (response to GTN) vasodilation in the brachial artery, carotid-femoral pulse wave velocity (PWV), and augmentation index (AIx) were assessed. At the follow-up visit, MA onset was defined with urinary albumin-creatinine ratio (UACR) >30 mg/g; any reduction in estimated glomerular filtration rate (eGFR, CKD-EPI formula) was also considered as an endpoint.

**Results:** All patients were treatment-naïve at enrollment, whereas at the follow-up visit 62% were taking antihypertensive drugs and 37% were treated with anti-hyperglycemic agents. After a follow-up period of  $4.1 \pm 0.6$  years, mean eGFR (CKD-EPI) decreased from  $89.0 \pm 14.4$  to  $86.4 \pm 13.0$  ml/min/1.73m<sup>2</sup>, whereas UACR increased from 5 (0-29) to 9 (0-47) mg/g. According to our definition, 19 individuals developed MA and 10 a reduction in eGFR. At enrollment, patients who would develop MA tended to be older ( $60.4 \pm 9.3$  vs  $53.8 \pm 10.4$  years,  $p = 0.07$ ) and carrying more frequently diabetes than their counterparts. Among vascular parameters, RI ( $0.63 \pm 0.04$  vs  $0.59 \pm 0.06$ ,  $p = 0.04$ ), DRIN ( $-6.4 \pm 8.9$  vs  $-10.2 \pm 6.3$  %,  $p = 0.09$ ) and PWV ( $9.5 \pm 1.3$  vs  $7.9 \pm 1.5$  m/s,  $p = 0.003$ ), were worse at baseline in those who would develop MA during follow-up. Conversely, AIx ( $24 \pm 11$  vs  $22 \pm 13$  %,  $p = 0.93$ ), FMD ( $3.9 \pm 1.9$  vs  $5.6 \pm 3.9$  %,  $p = 0.27$ ) and GTN ( $5.1 \pm 2.8$  vs  $5.6 \pm 3.4$  %,  $p = 0.85$ ) were similar in the two groups. In T2DM patients there was a significant increase ( $p < 0.05$ ) in RI (from  $0.65 \pm 0.05$  to  $0.68 \pm 0.04$ ) and PWV (from  $8.7 \pm 2.1$  to  $10.2 \pm 2.0$  m/s) during follow-up, while both were unchanged in EH patients (RI from  $0.56 \pm 0.03$  to  $0.59 \pm 0.06$ , PWV from  $7.9 \pm 1.5$  to  $8.3 \pm 1.7$  m/s). DRIN was not significantly modified during follow up. In T2DM, at enrollment DRIN ( $-2.2 \pm 7.0$  vs  $-7.5 \pm 4.4$  %,  $p = 0.03$ ), but not RI ( $0.65 \pm 0.4$  vs  $0.65 \pm 0.05$ ,  $p = 0.63$ ) or PWV ( $10.0 \pm 1.6$  vs  $8.3 \pm 2.4$  m/s,  $p = 0.14$ ), was significantly worse in patients who would develop MA, whereas in the EH group RI ( $0.60 \pm 0.03$  vs  $0.57 \pm 0.04$ ,  $p = 0.04$ ) and PWV ( $8.7 \pm 0.7$  vs  $7.8 \pm 1.0$  m/s,  $p = 0.03$ ), but not DRIN ( $-11.6 \pm 6.9$  % vs  $-12.9 \pm 7.6$  %,  $p = 0.62$ ), were altered in patients developing MA. At baseline, patient with reduction in eGFR were older and tended to have higher RI. Considering only T2DM patients, none of the explored vascular parameters were associated with reduction in eGFR.

**Conclusion:** These preliminary results suggest that some parameters of vascular damage like RI, PWV and DRIN are able to predict MA onset in EH and in T2DM, respectively. These markers of vascular damage might be useful in elucidating pathophysiology of renal damage and in predicting its development during the course of these chronic diseases.

### 1202

#### Annual deterioration of renal function in hypertensive patients with diabetes vs without diabetes

J. Polonia<sup>1</sup>, M. Monte<sup>1</sup>, J. Silva<sup>2</sup>, S. Bertoquini<sup>1</sup>;

<sup>1</sup>Medicina e Cintesis, Faculdade Medicina do Porto,

<sup>2</sup>Unidade Hipertensao, Hospital Pedro Hispano, Matosinhos, Portugal.

**Background and aims:** Chronic renal disease (CKD) complicates hypertension and diabetes. Knowledge of the deterioration rate of CKD may anticipate adjustment of therapies with predominant renal elimination. We aim to evaluate the rate of annual deterioration of renal function in a large cohort of hypertensive patients either with diabetes (DM) and without it (non-DM) followed for 5 years in a reference out-patient hospital clinic of hypertension, and to relate it with BP and glycemic control.

**Materials and methods:** Out of a total of 1924 patients, 1023 patients (594 non-DM and 429 DM, 53% female, ageing  $62.1 \pm 10.2$  years) were evaluated during the last 5 years for the annual evolution of renal function (MDRD) ambulatory 24-h blood pressure (ABP, SpaceLabs 90207) and metabolic parameters, corresponding to the analysis of 2378 patients-years.

**Results:** DM and non-DM did not differ for age ( $60.9 \pm 10.1$  v  $62.8 \pm 10.5$  years), mean 24h BP levels ( $134/86 \pm 12/10$  v  $136/87 \pm 11/11$ , nighttime  $123/74 \pm 16/10$  v  $122/73 \pm 15/10$  mm Hg), albuminuria ( $145 \pm 430$  vs  $130 \pm 370$  mg/24h) and body mass index ( $28 \pm 6$  v  $29 \pm 8$  kg/m<sup>2</sup>). DM v non-DM showed a higher (qui square  $p < 0.01$ ) prevalence of stage 3 CKD (24.2% v 18.1%, GFR 30-59 mL/min/1.73m<sup>2</sup>), stage 4 (5.4% v 2.7%, GFR 15- 29) and stage 5 (0.8% v 0.5%, GFR 8.0 %). Each year net GFR was reduced by  $3.3 \pm 8.2$  in DM vs  $2.4 \pm 7.7$  mL/min/1.73m<sup>2</sup> in non-DM ( $p = 0.12$ , ns). In multivariate analysis, age, nighttime BP, the use of double inhibition of renin angiotensin system and HbA1C  $\geq 8.0$  % in DM were independent factors associated

with the deterioration of GFR. Also in average 16.2% of DM and 13.1% on non-DM moved each year towards the next and more severe stage of CKD ( $p=0.051$ ). For initial GFR  $\geq 90$  mL/min/1.73m<sup>2</sup>, 24% of DM and 18% of non-DM showed a reduction per year  $\leq 10\%$  of the previous GFR value (qui square,  $p=0.049$ ).

**Conclusion:** A progressive deterioration of renal function for each next year is frequent in diabetics and non-diabetics with hypertension. Beyond ageing, renal deterioration may be particularly dependent on BP control particularly at nighttime, on certain therapies and on highly abnormal glucose control.

## 1203

### A systematic review and meta-analysis of the effects of diuretics and beta-blockers on glycaemic control in diabetes mellitus

J.A. Hirst, A.J. Farmer, B.G. Feakins, J.K. Aronson, R.J. Stevens; Department of Primary Care Health Sciences, University of Oxford, UK.

**Background and aims:** Although there are reports that beta-adrenoceptor antagonists (beta-blockers) and diuretics can affect glycaemic control in people with diabetes mellitus, there is little information on how blood glucose concentrations are likely to change and by how much.

**Materials and methods:** We systematically reviewed the published literature to identify randomised controlled trials (RCTs) in which glycaemic control was studied in people with diabetes mellitus taking either beta-blockers or diuretics. We pooled end-point data on HbA1c and fasting blood glucose (FBG) concentrations using inverse variance fixed effects meta-analysis.

**Results:** We retrieved 3864 papers and found 10 studies (15 comparisons involving 1889 participants) of beta-blockers and 11 studies (12 comparisons involving 312 participants) of diuretics to include in the meta-analysis. One study included comparisons of both beta-blockers and diuretics, giving a total of 20 included trials. Beta-blockers increased fasting blood glucose concentrations by a mean of 0.64 mmol/l (95% CI 0.24 to 1.03) and HbA1c by 0.75% (95% CI 0.30 to 1.20), corresponding to 8.2 mmol/mol (95% CI 3.3 to 13.1) compared with placebo. Three trials (four comparisons) that studied the beta-blocker propranolol showed a larger increase in FBG concentrations than three trials that used other beta-blockers (1.26 mmol/l, 95% CI 0.62 to 1.89 compared with 0.25 mmol/l, 95% CI -0.25 to 0.76). Diuretics increased FBG by 0.96 mmol/l (95% CI 0.29 to 1.63) compared with placebo and HbA1c by 0.24% (95% CI -0.17 to 0.65), corresponding to 2.6 mmol/mol (95% CI -1.9 to 7.1) compared with placebo. The four trials (5 comparisons) that studied thiazide diuretics gave a larger increase in FBG levels than three trials that used non-thiazide diuretics (1.69 mmol/mol, 95% CI 0.69 to 2.69, and 0.36 mmol/mol, 95% CI -0.55 to 1.27 respectively), but when tested using meta-regression this difference was not significant ( $p=0.101$ ). There were no significant differences in the numbers of hypoglycaemic events or other adverse events between beta-blockers and placebo in three trials.

**Conclusion:** In this synthesis of data we have quantified the effect of two commonly used types of antihypertensive medications on glycaemic control in diabetes. Both medication types increase fasting blood glucose and HbA1c concentrations in patients with diabetes by moderate but clinically significant amounts. Among beta-blockers, propranolol has the biggest effect, but there have been too few studies to allow a full analysis of other beta-blockers. These data will inform the monitoring and use of beta-blockers and diuretics in patients with diabetes.

### Renoprotective effect of ACE-I and ARB in combination with hydrochlorothiazide in hypertensive type 2 diabetic patients

N. Akbarova, N. Rakhimova, B.D. Babadjanov, B. Djanabaev, B. Ikramova; Public Center of Purulent Surgery and Diabetes Complications, Tashkent Medical Academy, Uzbekistan.

**Background and aims:** To compare the effects on albumin excretion rate (AER) of two combined preparations: ramipril/hydrochlorothiazide (Ram/htz) and valsartan/hydrochlorothiazide (Val/htz)

**Materials and methods:** This is a 12 months randomized parallel group study. 130 patients with hypertension (140 mmHg  $\leq$  SBP  $<$  180 mmHg and DBP  $<$  110), controlled Type 2 diabetes and albuminuria  $\geq 20$  and  $<$  500  $\mu$ g/min were randomized to Ram/htz (group 1, n=61) or to Val/htz (group 2, n=69). A dose up-titration from Ram 2.5/htz 12.5 mg up to Ram 5/htz 25 mg or from Val 80/htz 12.5 mg up to Val 160/htz 12.5 mg was allowed up to W12 to achieve blood pressure (BP) targets of SBP  $<$  140 mmHg and DBP  $<$  90 mmHg. The mean urinary albumin excretion was evaluated on overnight urine collections. All patients completed 12 months of follow-up. Following parameters were measured: blood pressure (BP), BMI and HbA1c

**Results:** 130 patients in 2 groups were similar in terms of sex, age (58.2 vs 58.4), diabetes duration (10.8 vs 11.1), BMI, BP (systolic 156 vs 155.8 mmHg, diastolic 93.3 vs 92.8 mmHg), HbA1c (7.9 vs 8.0 %), cholesterol, creatinine and smoking habits. At the end of 1 year period: systolic BP 156  $\pm$  11.2 mmHg vs 142  $\pm$  12.5 for group 1 ( $p < 0.01$ ) and 155.8  $\pm$  11.1 mmHg vs 143  $\pm$  14.2 mmHg for group 2 ( $p < 0.01$ ) and diastolic blood pressure 93.3  $\pm$  6 mmHg vs 84.5  $\pm$  9.2 mmHg for group 1 ( $p < 0.01$ ) and 92.8  $\pm$  6.9 mmHg vs 85.0  $\pm$  7.6 mmHg for group 2 ( $p < 0.01$ ). Pre and post treatment AER were 75.3  $\pm$  25.5  $\mu$ g/min vs 48.5  $\pm$  21  $\mu$ g/min ( $p < 0.01$ ) for group 1 and 76.1  $\pm$  26.1  $\mu$ g/min vs 49.0  $\pm$  23.4  $\mu$ g/min ( $p < 0.01$ ) for group 2. The other parameters remained unchanged in both groups

**Conclusion:** Treatment with such combined preparations as ramipril/hydrochlorothiazide and valsartan/hydrochlorothiazide were equally effective in reducing AER as well as hypertension in hypertensive type 2 diabetic patients

## 1205

### Effect of weight loss on abnormal 24-h blood pressure patterns and endothelial function in hypertensive obese patients with and without type 2 diabetes

L. Flores<sup>1</sup>, M. Careaga<sup>1</sup>, I. Patrascioiu<sup>1</sup>, I. Nuñez<sup>2</sup>, L. Rodríguez<sup>1</sup>, E. Esmatjes<sup>3</sup>, J. Vidal<sup>1</sup>;

<sup>1</sup>Endocrinology and Nutrition, Hospital Clinic, <sup>2</sup>Diagnostic Imaging Center, Hospital Clinic, <sup>3</sup>Diabetes Unit, Hospital Clinic, Barcelona, Spain.

**Background and aims:** Nocturnal hypertension [HT, night systolic blood pressure (SBP)  $>$  120/70 mmHg), non-dipper status (nocturnal BP fall  $<$  10% of daytime values), high pulse pressure (PP, difference between 24-h SBP and DBP readings) and endothelial dysfunction are associated with an increased risk of cardiovascular disease. Our aim was to compare the 1-year effect of significant weight loss on abnormal 24-h BP patterns (nocturnal HT, PP and non-dipper status) and endothelial function in severely obese hypertensive patients with and without type 2 diabetes mellitus (DM).

**Materials and methods:** Patients with documented HT undergoing bariatric surgery (BS) were studied and evaluated before BS and 12 months post-operatively. Antihypertensive treatment was withdrawn one week before each evaluation. Anthropometric data were collected, BP (24-h ambulatory BP measurement) was measured and endothelial function was determined by endothelial-dependent flow-mediated vasodilatation (FMD) of the brachial artery.

**Results:** Thirty-three patients [12 with DM and 21 patients without DM] were studied. DM remission was observed in 75% and HT remission was observed in 67% and 86% of patients with and without DM. The table below shows the main results obtained.

**Conclusion:** In patients with HT surgery-induced weight loss was associated with a sizeable decline in BP with a high HT remission range. After weight loss patients with DM maintain a high prevalence of abnormal 24-h BP patterns and continue to have a high cardiovascular risk. In addition, endothelial function did not improve.

#### Associations of visceral fat area and HOMA-R with both diabetes mellitus and hypertension in a health checkup programme: NingenDock H. Hirose<sup>1,2</sup>, M. Takayama<sup>2</sup>, Y. Iwao<sup>2</sup>, H. Kawabe<sup>1</sup>, Y. Sugino<sup>2</sup>;

<sup>1</sup>Health Center,

<sup>2</sup>Center for Preventive Medicine, Keio University Hospital, Tokyo, Japan.

**Background and aims:** Although the visceral fat area (VFA) value and homeostasis model assessment insulin resistance index (HOMA-R) in patients with metabolic syndrome (MetS) or type 2 diabetes mellitus (DM) are known to be higher, the relationship of VFA and HOMA-R with hypertension (HT) remains unclear. In the present study, we investigated the relationship of blood pressure status with VFA, subcutaneous fat area (SFA), HOMA-R, and insulin secretion capacity (HOMA-β) in male subjects during an annual health check-up program.

**Materials and methods:** A total of 1737 Japanese male subjects, aged 45-74 years, who underwent the whole body health check-up program 'Ningen-Dock' between August 2012 and October 2013 were enrolled in this study. Informed consent was obtained from each subject, and 9 subjects were excluded owing to predetermined exclusion criteria. The subjects were divided into 4 groups according to glucose tolerance status: normal glucose tolerance (NGT), preDM, DM, and DM with medication (DM+Tx), and blood pressure status: normotensive (NT), high normal (HN), HT, and HT with medication (HT+Tx). Both VFA and SFA were measured at the umbilical level using computed tomography.

**Results:** VFA (mean±SD) in the PreDM (n=425), DM (n=120), and DM+Tx (n=175) groups were significantly higher than that of the NGT (n=1008) group (117±43, 133±54, and 124±54 vs. 101±44cm<sup>2</sup>, F=31.6 and P< 0.0001 by ANOVA). Furthermore, the VFA of the HN (n=231), HT (n=202), and HT+Tx (n=517) groups were significantly higher than that of the NT (n=778) group (109±43, 118±46, and 128±49 vs. 95±42cm<sup>2</sup>, F=58.8 and P< 0.0001). The HOMA-R (median [Q1-Q3]) of the HN, HT, and HT+Tx groups were also significantly higher than that of NT group (1.4 [1.0-1.9], 1.5 [1.0-2.1] and 1.6 [1.1-2.7] vs. 1.2 [0.8-1.8], F=38.0 and P< 0.0001). Multiple logistic regression (MLR) analysis of DM as a dependent variable revealed that low HOMA-β, high HOMA-R, age, VFA, and smoking were relevant. Moreover, MLR analysis of HT as a dependent variable revealed that age, VFA, alcohol consumption (more than 20g ethanol/day), BMI, and HOMA-R were relevant (Table 1).

**Conclusion:** These results suggest that VFA and HOMA-R correlate with HT, as well as type 2 DM and MetS, in Japanese male subjects aged 45-74 years.

**Table 1. Multiple logistic regression analysis of hypertension as a dependent variable in 1728 male subjects, aged 45 to 74 years**

#### Endoscopic, duodenal-jejunal bypass liner in obese patients with or without type 2 diabetes lowers incidence of metabolic syndrome and improves cardiovascular risk

R. Chilton<sup>1</sup>, D. Kim<sup>2</sup>, E.G.H. de Moura<sup>3</sup>, A. Liao<sup>4</sup>, J.-C. Tetreault<sup>4</sup>,

E. Chiquette<sup>4</sup>, A. Escalona<sup>5</sup>;

<sup>1</sup>University of Texas Health Science Center at San Antonio, San Antonio,

<sup>2</sup>MetaCon, Inc, La Jolla, USA, <sup>3</sup>University of Sao Paulo Medical School,

Brazil, <sup>4</sup>GI Dynamics, Lexington, USA, <sup>5</sup>Catolica University, Santiago, Chile.

**Background and aims:** The endoscopically delivered duodenal-jejunal bypass liner (DJBL) exhibits robust metabolic effects in obese subjects with or without type 2 diabetes (T2D). Several clinical studies have been conducted in development of the DJBL. We report metabolic and cardiovascular (CV) effects of DJBL in obese subjects with or without T2D across 2 uncontrolled clinical studies.

**Materials and methods:** Forty subjects completed the intended 12 month treatment period (baseline mean ± SEM: age 44.5 ± 1.85 yr, BMI 45.2 ± 1.09 kg/m<sup>2</sup>, A1C 8.6 ± 0.48% and 6.2 ± 0.26% in subjects with [n=13] and without [n=27] T2D, respectively, 77.5 % females). Most common co-morbid conditions were hypertension (47.5%), GERD/Gastritis (12.5% each), and hyperlipidemia (10.0%).

**Results:** At baseline 35/40 ( 87.5%) subject had metabolic syndrome (as defined by ATPIII criteria) and, using the FraminghamBMI, Framingham Lipid, and UKPDS CV risk engine models, the 10-year CV risk was determined to be 11.9 ± 2.09%, 9.0 ± 1.52%, and 5.9 ± 0.93%, respectively. After 12 months of intended implant time, the overall cohort lost 18.6 % in total body weight on average and 17.7 cm from the waist. Additionally, systolic BP dropped by -7.6 mmHg, LDL-cholesterol decreased by 0.6 mmol/L, and A1c reduction of 2.1 % in the diabetic subgroup. The improvement in CV risk factors translated to a 20-32% reduction in 10-year CV risk (see table) and a 37% decreased in subjects meeting the metabolic syndrome criteria, (20/40 subjects (p<0.001). Analysis of concomitant medications during the 12 month period showed trends for dose reductions or discontinuation of glucose, BP, and lipid-lowering agents in 87% of subjects. Adverse events were mostly of gastrointestinal nature, mild or moderate in severity, and tended to diminish in frequency in the weeks after initial device implantation.

**Conclusion:** In 40 obese subjects with or without T2D who completed 12 months of DJBL implantation, clinically meaningful improvements in prevalence of metabolic syndrome and 10-year CV risk level regardless of the model used. The device appears to be generally safe and well-tolerated. This non-surgical approach warrants further characterization as an important treatment option to improve CV risk in obese patients with or without T2D.

| Risk Engine      | Baseline* (%) | 12 Months* (%) | % Change*    | P-value |

## PS 107 Predicting complications I

### 1208

#### Multifactorial risk factor control in clinical practice and risk of cardiovascular disease in type 2 diabetes: report from the Swedish national diabetes register

K. Eeg-Olofsson<sup>1</sup>, S. Gudbjörnsdóttir<sup>1,2</sup>, B. Eliasson<sup>1</sup>, B. Zethelius<sup>3,4</sup>, A.-M. Svensson<sup>2</sup>, J. Cederholm<sup>3</sup>;

<sup>1</sup>University of Gothenburg, <sup>2</sup>Centre of Registers in Region Västra Götaland, Göteborg, <sup>3</sup>Uppsala University, <sup>4</sup>Medical Products Agency, Uppsala, Sweden.

**Background and aims:** Cardiovascular complications are still the major cause of morbidity and mortality in patients with type 2 diabetes (T2D). To lower this risk, guidelines advocate multifactorial risk factor control with focus on glucose control, blood pressure (BP) and blood lipids levels. The aim of this observational study was to assess the effect of change in these risk factors on risk for cardiovascular disease (CVD) and mortality in T2D, also in a subgroup with albuminuria.

**Materials and methods:** 47,020 T2D patients from the Swedish National Diabetes Register, aged 30–70 years, were followed from baseline visits 2003–2006 until 31 Dec 2009, mean follow-up 5.7 years. In all, mean age 60±8 years and diabetes duration 7±6 years. Reference group (n=13,005) with stable values or increase in HbA1c, systolic BP (SBP) and the ratio non-HDL-to-HDL-cholesterol (non-HDL:HDL) during the study period was compared with seven groups (n=3766 to n=6509) of decrease in either each or in combinations of these risk factors. The reference group with stable or increasing risk factor values had mean HbA1c increasing from 52 to 57 mmol/mol, mean SBP increasing from 135 to 141 mmHg, and mean non-HDL:HDL increasing from 2.9 to 3.3. Groups with decrease in HbA1c showed decrease from mean 60 to 52 mmol/mol, with decrease in SBP showed decrease from 146 to 130 mmHg and with decrease in non-HDL:HDL had decrease from 3.3 to 2.5.

**Results:** Compared with reference group hazard ratios (HR) with 95% confidence intervals at Cox regression for fatal/nonfatal CVD were 0.45 (0.40–0.52) with decrease in HbA1c only, 0.31 (0.27–0.36) with non-HDL:HDL, 0.27 (0.23–0.31) with SBP, 0.25 (0.22–0.29)–0.36 (0.31–0.41) with decrease in two of three risk factors combined, and 0.24 (0.21–0.28) with all three risk factors decreasing, all p<0.001. Corresponding HR for total mortality were 0.36 with HbA1c decrease only, 0.23 with non-HDL:HDL, 0.27 with SBP, 0.23–0.36 with decrease in two risk factors, and finally 0.29 with all three risk factors decreasing, p<0.001 after adjusting for clinical characteristics, CVD risk factors, treatments and a history of CVD. Similar results were found in a subgroup of 10,004 patients with albuminuria at baseline, HRs for fatal/nonfatal CVD 0.27–0.49 with decrease in one, 0.26–0.36 with decrease in two risk factors, and 0.23 with all three risk factors decreasing, all p<0.001, while corresponding HR for total mortality were 0.22–0.31, 0.19–0.30, and 0.25, p<0.001.

**Conclusion:** Successful risk factor control in patients with T2D in clinical practice with reductions in HbA1c, blood pressure and blood lipids was associated with 55–76% lower risk for CVD and 36–77% lower risk for total mortality.

### 1209

#### Depressive symptoms predict incident stroke independent from low physical activity in older patients: the Japanese elderly diabetes intervention trial (J-EDIT)

A. Araki<sup>1</sup>, Y. Tamura<sup>1</sup>, Y. Chiba<sup>1</sup>, T. Shinozaki<sup>2</sup>, S. Iimuro<sup>2</sup>, Y. Ohashi<sup>2</sup>, H. Ito<sup>1</sup>, the Japanese Elderly Diabetes Intervention Trial Study Group;

<sup>1</sup>Diabetes, Metabolism, and Endocrinology, Tokyo Metropolitan Geriatric Hospital, <sup>2</sup>Biostatistics, School of Public Health, University of Tokyo, Japan.

**Background and aims:** Although recent remarkable advances in treatment of diabetes have been made, conventional risk factors cannot fully explain the increased risk of stroke in older patients with diabetes mellitus. Psychological factors and physical inactivity have been considered to be one of new potential risk factors for micro- and macrovascular complications in diabetes mellitus. Diabetes mellitus is more likely to have depressive symptoms, which lead to low physical activity. In contrast, physical inactivity is associated with depression. The aim of the study is to examine whether depressive symptoms predict incident stroke independent from conventional risk factors and low physical activity in a 5-year follow-up study of elderly patients with diabetes mellitus.

**Materials and methods:** The Japanese Elderly Diabetes Intervention Study (J-EDIT) is a randomized, controlled, multi-centre, prospective intervention trial using a total of 1173 older patients (aged≥65 years) with type 2 diabetes mellitus from 39 institutions. Nine hundred and seven patients were used for analysis after excluding 110 patients who were dropped out very early or had missing data about depressive symptoms at baseline. Mean age was 71.8 years. Depressive symptoms were evaluated using a short form of the Geriatric Depression Scale (GDS-15, 15 items). Physical activities were assessed using the Baecke questionnaire. Cox regression analysis was performed to examine the independent association between depressive symptoms, conventional risk factors, or physical activity, and incident stroke.

**Results:** During the 5-year of follow-up, 50 non-fatal and fatal strokes occurred. The score of GDS-15 was 4.6±3.0 at baseline. The prevalence of those who had GDS-15 ≥8 was 12.7%. The incidence of stroke in the patients who had the GDS-15 ≥8 was significantly higher than those who had the GDS-15 <8 (P<0.001, log-rank test). Depressive symptoms (GDS-15 ≥8) predicted incident stroke after adjusting for age, sex, HbA1c, systolic blood pressures, non-HDL-C, and HDL-C (HR=3.2, 95% CI: 1.7–6.2). After adding physical activity to the model, the association between depressive symptoms and incident stroke remained significant (HR=3.2, 95% CI: 1.6–6.3, p<0.001).

**Conclusion:** Depressive mood is one of independent predictors for stroke in older patients with diabetes mellitus.

### 1210

#### Fasting triglyceride is an independent cardiovascular risk factor in HbA<sub>1c</sub> less than 6.5%

Y.-P. Lin<sup>1</sup>, C.-Y. Wang<sup>2</sup>;

<sup>1</sup>Department of Internal Medicine, Division of Endocrinology and Metabolism, Taipei Medical University Hospital,

<sup>2</sup>Department of Internal Medicine, Division of Endocrinology and Metabolism, National Taiwan University Hospital, Taipei, Taiwan.

**Background and aims:** Although LDL is the primary target for lipid-lowering therapy and non-HDL cholesterol is a secondary target in patients with elevated triglyceride (TG) levels, triglyceride rich lipoprotein (TGRLP) is still an early, reliable, and practical predictor for vascular inflammation. However, the independent relationship of triglycerides to the risk of future CVD events has long been controversial. More commonly identified are milder triglyceride level elevations (ie, 100 to 500 mg/dl) associated with environmental triggers such as poor diet, lack of exercise, obesity, DM, and metabolic syndrome (Mets). The goal of our study tried to find whether TG less or more than 100 mg/dl could be the predictive factor for cardiovascular inflammation.

**Materials and methods:** A total of 6883 subjects (TG < 100 mg/dl, N=3639, mean age 51.4±11.9; TG ≥100 mg/dl, N=3244, mean age 52.6±11.2; p<0.01), whose HbA1c was less than 6.5%, without history of type 2 DM or documented cardiovascular diseases were enrolled in this retrospective case control cohort study. Levels of various lipid fractions and C-reactive protein (CRP) were measured.

**Results:** Data revealed as: (1) Total CHOL 198.2±32.3 mg/dl versus 208.9±34.4 mg/dl, in TG < 100 mg/dl & TG ≥100 mg/dl (p<0.01). (2) HDL-C 54.9±12.6 mg/dl versus 46.6±10.1 mg/dl, in TG < 100 mg/dl & TG ≥100 mg/dl (p<0.01). (3) LDL-C 111.4±28.6 mg/dl versus 124.8±30.7 mg/dl, in TG < 100 mg/dl & TG ≥100 mg/dl (p<0.01). (4) CRP 0.154±0.425 mg/dl versus 0.185±0.442 mg/dl, in TG < 100 mg/dl & TG ≥100 mg/dl (p<0.01). Linear regression for TG < 50 mg/dl, strong correlation with LDL-C, HDL-C, total CHOL (p<0.01), but not for CRP (p=0.5637). On the other hand, strong correlation in linear regression was noted between TG ≥100 mg/dl and HDL-C (p<0.01), total CHOL (p<0.01), CRP (p=0.0237), but not for LDL-C (p=0.0542). On the basis of CRP comparison, CRP is statistically correlated with subjects with TG ≥100 mg/dl, but not for subjects TG < 100 mg/dl.

**Conclusion:** Our results may suggest that healthy persons with HbA1c less than 6.5% but fasting TG ≥100 mg/dl could be the predictor for cardiovascular inflammation, independent from the level of LDL-C. An optimal triglyceride cut point is intended to define one physiological parameter of cardio-metabolic health in the future.

## 1211

### Lipoprotein(a), type 2 diabetes and vascular risk in angiographed coronary patients

K.-M. Ebner<sup>1,2</sup>, A. Vonbank<sup>3</sup>, C.H. Saely<sup>3,2</sup>, D. Zanolin<sup>1,2</sup>, P. Rein<sup>3</sup>, H. Drexel<sup>3,4</sup>;

<sup>1</sup>VIVIT Institute, Feldkirch, Austria, <sup>2</sup>Private University of the Principality of Liechtenstein, Triesen, Liechtenstein,

<sup>3</sup>Academic Teaching Hospital Feldkirch, Austria,

<sup>4</sup>Drexel University College of Medicine, Philadelphia, USA.

**Background and aims:** Lipoprotein (a) [Lp(a)] especially in young individuals is an important cardiovascular risk factor. However, data on the long-term vascular risk conferred by Lp(a) in patients with type 2 diabetes (T2DM) are scarce.

**Materials and methods:** Lp(a) was measured in a cohort of 909 consecutive patients undergoing coronary angiography for the evaluation of established or suspected stable coronary artery disease; vascular events were recorded over 10 years.

**Results:** Median Lp(a) at baseline was significantly lower in patients with T2DM (n=260) than in subjects without T2DM (10 [interquartile range 1-34] vs. 16 [1-54] mg/dl; p=0.017). Prospectively, 27.8% of our patients suffered vascular events. Lp(a) proved to be a strong and independent predictor of vascular events in total population with a standardized adjusted hazard ratio (HR) of 1.15 [1.03-1.27]; p=0.006) as well as in subjects without T2DM (HR 1.22 [1.10-1.36]; p<0.001) but not in patients with T2DM (HR 0.990 [0.79-1.22]; p=0.888). An interaction term T2DM x Lp(a) was significant (p<0.001), indicating that Lp(a) was a significantly stronger predictor of vascular events in subjects without T2DM than in patients with T2DM.

**Conclusion:** Lp(a) in patients with T2DM is low and is not associated with the incidence of vascular events. The power of Lp(a) as a predictor of cardiovascular events is significantly modulated by the presence T2DM.

## 1212

### Impact of age on the cardiovascular event risk conferred by HbA<sub>1c</sub> in patients with established coronary artery disease

A. Vonbank<sup>1</sup>, C.H. Saely<sup>1,2</sup>, P. Rein<sup>1</sup>, D. Zanolin<sup>3,2</sup>, H. Drexel<sup>1,4</sup>;

<sup>1</sup>Academic Teaching Hospital Feldkirch, Austria, <sup>2</sup>Private University of the Principality of Liechtenstein, Triesen, Liechtenstein, <sup>3</sup>VIVIT Institute, Feldkirch, Austria, <sup>4</sup>Drexel University College of Medicine, Philadelphia, USA.

**Background and aims:** In the present study we tested the hypothesis that age modulates the impact of HbA<sub>1c</sub> on cardiovascular event risk in patients with established coronary artery disease (CAD).

**Materials and methods:** We prospectively recorded cardiovascular events over a mean follow-up period of 4.4±1.2 years in a large consecutive series of 816 patients with angiographically proven CAD, including 376 subjects <65 years and 440 subjects ≥65 years.

**Results:** During follow-up, the incidence of cardiovascular events was 9.3% among subjects <65 years and 24.8% among subjects ≥65 years (p<0.001). Among the younger patients, HbA<sub>1c</sub> strongly and significantly predicted cardiovascular events (HR 1.54 [1.06-2.23]; p=0.022), but not among the older patients (HR 1.22 [0.94-1.59]; p=0.125). An interaction term age x HbA<sub>1c</sub> was statistically significant (p=0.007), indicating that HbA<sub>1c</sub> was a significantly stronger predictor of cardiovascular events among younger than among older CAD patients.

**Conclusion:** We conclude that HbA<sub>1c</sub> is a significantly stronger predictor of cardiovascular events in younger patients than in older patients with established CAD.

## 1213

### All-cause mortality in type 2 diabetes in New Zealand: development and validation of a risk model

P.L. Drury<sup>1</sup>, T.E. Robinson<sup>2</sup>, C.R. Elley<sup>2</sup>, T. Kenealy<sup>2</sup>;

<sup>1</sup>Auckland Diabetes Centre, <sup>2</sup>Department of General Practice & Primary Health Care, University of Auckland, New Zealand.

**Background and aims:** Type 2 diabetes is associated with a substantial increase in the risk of death. This study aimed to derive an up-to-date predictive risk model for all-cause mortality in type 2 diabetes in our multi-ethnic population.

**Materials and methods:** We used primary care data from a large national multi-ethnic cohort of patients with type 2 diabetes in New Zealand (the NZ Diabetes Cohort Study) and linked these with national death records to develop several predictive risk models for 5-year risk of mortality. We then validated these models using information from a separate cohort of patients with type 2 diabetes.

**Results:** 26,864 people, mean age 62 years, were included in the development cohort with a median follow up time of 9.1 years and 6333 deaths (24%). We developed three models initially using demographic information and then adding progressively more readily available clinical detail. The final model, which also included markers of renal disease (albuminuria and estimated GFR), proved to give best prediction of all-cause mortality with a C-statistic of 0.80 in the development cohort and 0.79 in the validation cohort (7,610 people, follow-up 5 years, 759 deaths, 10%); it was well calibrated. In addition to the usual known risk factors including HbA<sub>1c</sub>, ethnicity was a major influence with hazard ratios of 1.37 for Maori, 0.79 for Pacific Peoples, 0.41 for East Asian and 0.55 for Indo-Asian compared with European (all p<0.001).

**Conclusion:** We have developed a model that provides an accurate assessment of patients' risk of death using information normally available in primary care. While our results are broadly similar to models previously published from smaller cohorts in other countries, they are superior to most and apply to a wide range of patients of multiple ethnicities and over recent years since 2000. Reasons for the major influence of ethnicity, both adverse and protective, are as yet unclear.

## 1214

### Years of life lost attributable to type 2 diabetes in Germany

R. Brinks, A. Hoyer, T. Tamayo, B. Kowall, W. Rathmann; Biometry and Epidemiology, German Diabetes Center, Duesseldorf, Germany.

**Background and aims:** In Europe a decline in the diabetes-related mortality has been observed in recent years. However, in comparison to the general population, people with type 2 diabetes still had a reduced life expectancy. Years of life lost (YLL) is an important epidemiological measure to quantify the burden of a chronic disease in a population. YLL attributable to type 2 diabetes has never been reported for Germany.

**Materials and methods:** We calculated the sex-specific YLL attributable to type 2 diabetes for a birth cohort in Germany (born 1955). The resulting YLL is a population average, independent from the individual life-time diabetes risk. The underlying incidence and mortality rates of known and unknown diabetes stem from the KORA S4/F4 survey, a cohort study with baseline examinations in 1999-2001 and follow-up period until 11/2009. Mortality rates of the general population (including a projection for future years) stem from the German Federal Statistical Office. Since KORA data have a restricted age range, we used data from the Danish diabetes register to expand the age range. Beside an analytical calculation of YLL based on a comparison of the areas under the survival curves, we additionally used a micro-simulation to assess statistical uncertainty. Calendar time trends in the incidence of diabetes and mortality rates of persons with diabetes are not known for Germany and are assessed by scenarios. The scenarios assume a change of +/-1 and +/-2% per year for the incidence and a change of -2 and -1% in case of the mortality in the diabetic population.

**Results:** The results are shown in Table 1. In the base case, i.e. no annual trends, the average YLL in the cohort is 5.7 and 2.4 years for men and women, respectively. Results from the simulation and the analytical calculation agree well within the confidence bounds. The uncertainty about trends in diabetes incidence and mortality in the diabetic population exceeds the statistical uncertainties in these estimates. In the male and female subgroup of the cohort, the range of YLL in the scenarios is 2.2-9.9 and 0.6-3.9 years, respectively. Independent from the scenario, it is striking how big the difference between men and women is. The reason lies in the different age courses of the prevalence in men and women. The prevalence in men is higher than in women until the age of about 80.

**Conclusion:** On population average, presence of type 2 diabetes was associated with a loss of 5.7 life years in men and of 2.4 years in women of the 1955 birth cohort, respectively. The uncertainty about the trends in incidence and mortality leads to uncertainty in the estimated YLL. Due to the high numbers of persons born in Germany in 1955, the total YLL attributable to type 2 diabetes sums up to more than 1.5 million years in the best case, 4.6 million years base case, and 7.5 million years in the worst case. These numbers refer

to the 1955 birth cohort alone. Therefore, despite improved diagnosis of diabetes and better medical treatment, type 2 diabetes is still associated with an enormous reduction of life-time.

| Incidence | Mortality | Method     | YLL males (years) | YLL females (years) |
|-----------|-----------|------------|-------------------|---------------------|
| KORA      | KORA      | Simulation | 5.9 (5.3 – 6.5)   | 2.5 (2.0 – 2.9)     |
| KORA      | KORA      | Analytical | 5.7               | 2.4                 |
| KORA – 2% | KORA      | Analytical | 3.8               | 1.7                 |
| KORA – 1% | KORA      | Analytical | 4.5               | 2.0                 |
| KORA      | KORA – 2% | Analytical | 2.2               | 0.6                 |

**Table 1:** Sex-specific years of life lost (YLL) in the different incidence and mortality scenarios. The YLL in the simulation (first row) is given with 95% confidence intervals (in brackets).

## 1215

### Predictors of ischaemic heart disease and cerebrovascular attack in late elderly diabetic individuals: lessons from 9.1 years study of 4014 diabetic patients

K. Ina<sup>1</sup>, T. Hayashi<sup>1</sup>, H. Nomura<sup>1</sup>, M. Takemoto<sup>2</sup>, K. Yokote<sup>2</sup>, A. Araki<sup>3</sup>, H. Sone<sup>4</sup>, H. Noto<sup>5</sup>, M. Noda<sup>5</sup>;

<sup>1</sup>Department of Geriatrics, Nagoya University Graduate School of Medicine,

<sup>2</sup>Division of Diabetes, Metabolism and Endocrinology, Department of Internal Medicine, Chiba University Graduate School of Medicine,

<sup>3</sup>Division of Diabetes, Metabolism and Endocrinology, Tokyo Metropolitan Geriatric Hospital, <sup>4</sup>Department of Internal Medicine, Endocrinology and Metabolism, Niigata University Graduate School of Medicine,

<sup>5</sup>Department of Diabetes and Metabolic Medicine, National Center for Global Health and Medicine, Tokyo, Japan.

**Background and aims:** High LDL-cholesterol (LDL-C) and glucose levels are risk factors for ischemic heart disease (IHD) in middle-aged diabetic individuals; however, the risk among the elderly, especially late elderly older than 75y.o., is not well known. The aim of this study was to identify factors that predict IHD and cerebrovascular attack (CVA) in the elderly and to investigate their differences by age, especially legend effect.

**Materials and methods:** We performed a prospective cohort study (Japan Cholesterol and Diabetes Mellitus Study) with 9.1 years of follow-up. A total of 4,014 patients with type 2 diabetes and without previous IHD or CVA (1,936 women; age 67.4±9.5 years, median 70 years; <65 years old, n=1,261; 65 to 74 years old, n=1,731; and ≥ 75 years old, n=1,016) were recruited on a consecutive outpatient basis from 40 hospitals throughout Japan. Lipids, glucose, and other factors related to IHD or CVA risk, such as blood pressure (BP), were investigated using the multivariate Cox hazard model.

**Results:** Two hundred eighteen cases of IHD and 138 CVAs (7.8 and 5.7/1,000 people per year, respectively) occurred over 8.8 years. Systolic blood pressure on registration was correlated with IHD in all patients (hazard ratio (HR):1.012, P<0.05). LDL-cholesterol (LDL-C) on registration was correlated with IHD in patients >75 years old (HR:1.014, P<0.01). In contrast, fasting plasma glucose, HDL-C and age were correlated with CVA in all subjects (P<0.05) and HDL-C was correlated with CVA in all three generations (75 years old). Fasting plasma glucose and glycated hemoglobin (HbA1C) was correlated with CVA in patients of 65 to 74 years old. Age was correlated in patients >75 years old. Kaplan-Meier estimator curves showed same tendency, however, laboratory data on registration (legend effect) and those just before events (IHD and CVA) affects differently.

**Conclusion:** IHD and CVA in late elderly diabetic patients were predicted by LDL-C or HDL-C. LDL-C, fasting blood glucose, HbA1C and SBP may have the effect for atherosclerotic events (IHD or CVA) as legend effect, age dependently. These age-dependent differences in risk are important for developing individualized strategies to prevent atherosclerotic disease.

## PS 108 Predicting complications II

### 1216

#### Silent, advanced coronary artery disease in type 1 diabetes of forty years duration is prevalent and associated with glycaemic control

K. Sveen<sup>1</sup>, K. Dahl-Jørgensen<sup>2</sup>, W. Magyar<sup>3</sup>, M. Tuzcu<sup>4</sup>, M. Brekke<sup>5</sup>, K.F. Hanssen<sup>1</sup>;

<sup>1</sup>Dept. endocrinology, Oslo University Hospital, <sup>2</sup>Dept. of pediatrics, Oslo University Hospital, Norway, <sup>3</sup>Imaging Core Laboratory, Cleveland Clinic,

<sup>4</sup>Cleveland Clinic, USA, <sup>5</sup>Oslo University Hospital, Norway.

**Background and aims:** The natural history and the pathophysiology of atherosclerotic disease in type 1 diabetes is not known in detail. We therefore studied in detail the progression of atherosclerosis in a uniquely characterized cohort of type 1 diabetes with a long duration of the disease and defined factors associated with the progression of atherosclerosis in this population.

**Materials and methods:** The Oslo study cohort originally started in 1982. Forty-five individuals with type 1 diabetes were randomized and included. In 1999 a subpopulation of 29 participants, not significantly different from the total group, without signs or symptoms of coronary heart disease were evaluated for coronary artery disease with exercise ECG, quantitative coronary angiography (QCA) and intravascular ultrasound (IVUS). Twenty-six of these participants were enrolled for the same examination in 2009 (mean age 53 (7)). Twenty-three of these had technical adequate IVUS pullbacks for analysis. By QCA a vessel stenosis >50% of lumen diameter were classified as significant. By IVUS, an intimal thickness above 0.3mm was considered significant. % vessel area stenosis was defined as plaque area divided by vessel area x100.

**Results:** The QCA and IVUS results from 1999 and 2009 are reported in table 1. A total of 3264 arterial segments in 63 vessels were evaluated with IVUS in this last follow-up. In 1999 ten of the patients had mild atherosclerotic disease (% vessel area stenosis <20) whereas all had progressed to moderate to severe atherosclerosis examined by IVUS (% vessel area stenosis >20%) in 2009. We observed that HbA1c and LDL cholesterol levels ten years before this last follow-up were associated with progression of % vessel area stenosis,  $\beta$  0.1 (0.01-0.2),  $p=0.030$  and  $\beta$  0.12 (0.3-0.33),  $p=0.0013$ , respectively.

**Conclusion:** Our data show no over-all progression of severe atherosclerosis evaluated by QCA. The plaque thickness was not significantly changed over ten years. However, the IVUS examinations revealed a progression of moderate to advanced atherosclerosis over ten years in type 1 diabetes patients of forty years disease duration. This despite that many of the participants used statins for many years. One of the reasons for the discrepancy in QCA and IVUS may be that remodelling in the coronary vessels underestimates the stenosis on QCA. Our data show the need to evaluate coronary atherosclerosis thoroughly in long term type 1 diabetes and reconfirm that LDL and blood glucose through many years may be main drivers of the process. Our findings are novel as there are no other studies with longitudinal data of the atherosclerotic process evaluated by QCA and IVUS in long term type 1 diabetes with silent macrovascular disease.

**Table 1:** Comparison of the QCA and IVUS data from 1999 and 2009 in type 1 diabetes patients.

|                                | 1999 n= 29  | 2009 n=26 (23) |
|--------------------------------|-------------|----------------|
| Pathological exercise ECG      | 15 %        | 17 %           |
| QCA, >50 % stenosis            | 34 %        | 26 %           |
| IVUS, intima thickness >0.3 mm | 72.2 %      | 85.2%          |
| IVUS (mean plaque thickness)   | 0.56 (0.33) | 0.66 (0.26)    |

The data are presented as % and mean (SD).

## 1217

**Impact of gender on the risk of coronary atherosclerosis and cardiovascular events conferred by HbA<sub>1c</sub> in subjects without known diabetes**A. Muendlein<sup>1</sup>, C.H. Saely<sup>2,3</sup>, A. Vonbank<sup>2</sup>, D. Zanolin<sup>1,3</sup>, P. Rein<sup>2</sup>, H. Drexel<sup>2,4</sup>;<sup>1</sup>VIVIT Institute, Feldkirch, Austria, <sup>2</sup>Academic Teaching Hospital Feldkirch, Austria, <sup>3</sup>Private University of the Principality of Liechtenstein, Triesen, Liechtenstein, <sup>4</sup>Drexel University College of Medicine, Philadelphia, USA.**Background and aims:** Diabetes confers a larger increase in the relative risk of cardiovascular events among women than among men. Whether gender also affects the association of HbA<sub>1c</sub> with coronary atherosclerosis and cardiovascular events among subjects without known diabetes is unknown.**Materials and methods:** We enrolled a large consecutive series of 1479 patients undergoing coronary angiography for the evaluation of established or suspected coronary artery disease (CAD), including 495 women and 984 men who did not have previously known diabetes. Significant CAD was diagnosed in the presence of significant coronary stenoses  $\geq 50\%$ . Prospectively, we recorded cardiovascular events over  $4.4 \pm 1.2$  years.**Results:** Among women, 36.4%, 56.2%, and 7.4% and among men 44.2%, 46.6%, and 9.1% had HbA<sub>1c</sub> values of  $< 5.7\%$  (normal according to ADA criteria), 5.7–6.4% (at risk of diabetes according to ADA criteria), and  $\geq 6.5\%$  (diabetes according to ADA criteria), respectively. The prevalence of angiographically diagnosed significant CAD in these HbA<sub>1c</sub> categories was 31.2%, 38.2%, and 47.2% among women (ptrend = 0.041) and 63.2%, 65.3% and 64.8% among men (ptrend = 0.589). An interaction term gender x HbA<sub>1c</sub> was statistically significant ( $p < 0.001$ ), indicating that the association of HbA<sub>1c</sub> with CAD was significantly stronger among women than among men. During follow-up, the incidence of cardiovascular events was 21.5% in women and 28.5% in men ( $p = 0.002$ ). Among women, HbA<sub>1c</sub> strongly and significantly predicted cardiovascular events (adjusted OR for a 1% increase in HbA<sub>1c</sub> (HR 2.08 [1.24–3.03];  $p < 0.001$ ), but not among men (HR 1.12 [0.94–1.53];  $p = 0.145$ ). An interaction term gender x HbA<sub>1c</sub> again was statistically significant ( $p = 0.011$ ), indicating that HbA<sub>1c</sub> was a significantly stronger predictor of cardiovascular events among women than among men.**Conclusion:** We conclude that gender significantly modulates the risk of coronary atherosclerosis and cardiovascular events conferred by HbA<sub>1c</sub> in subjects without known diabetes.

## 1218

**Diabetes is not a coronary artery disease risk equivalent among women**H. Drexel<sup>1,2</sup>, C.H. Saely<sup>1,3</sup>, A. Vonbank<sup>1</sup>, D. Zanolin<sup>4,5</sup>, P. Rein<sup>1</sup>;<sup>1</sup>Academic Teaching Hospital Feldkirch, Austria, <sup>2</sup>Drexel University College of Medicine, Philadelphia, USA, <sup>3</sup>Private University of the Principality of Liechtenstein, Triesen, Liechtenstein, <sup>4</sup>VIVIT Institute, Feldkirch, Austria.**Background and aims:** Diabetes *per se* is widely considered a coronary artery disease (CAD) risk equivalent, particularly among women. We aimed at investigating the contribution of baseline coronary atherosclerosis to the risk of diabetic women for future vascular events in a prospective cohort study on subjects who were characterized by coronary angiography at baseline.**Materials and methods:** Vascular events were recorded over 10 years in 598 consecutive women undergoing coronary angiography for the evaluation of established or suspected stable CAD.**Results:** From our women, 271 had neither type 2 diabetes (T2DM) nor significant CAD (i.e. coronary stenoses  $\geq 50\%$ ) at the baseline angiography, 79 had T2DM but not significant CAD, 152 did not have T2DM but had significant CAD, and 96 had both T2DM and significant CAD. Non-diabetic women without significant CAD had an event rate of 12.5%. The event rate was similar in T2DM women without significant CAD (15.2%;  $p = 0.749$ ), but higher in non-diabetic women with significant CAD (32.9%;  $p < 0.001$ ). Women with both T2DM and significant CAD had the highest event rate (43.8%;  $p < 0.001$ ). Importantly, T2DM women without significant CAD had a significantly lower event rate than non-diabetic women with significant CAD ( $p = 0.003$ ).**Conclusion:** We conclude that T2DM *per se* is not a CAD risk equivalent among women. Moderate-risk diabetic women without significant CAD and very high-risk diabetic women with significant CAD add up to a grand total of high-risk diabetic women. This is why diabetes seems to be a CAD risk equivalent in many epidemiological studies.

## 1219

**Comparison of renal function markers for risk prediction in subjects with type 2 diabetes (ZODIAC-47)**A.E. Timmer<sup>1,2</sup>, I.J. Riphagen<sup>1,2</sup>, I. Drion<sup>1</sup>, A. Alkhalaf<sup>1</sup>, G.W.D. Landman<sup>1</sup>, K.H. Groenier<sup>1,2</sup>, G. Navis<sup>3</sup>, H.J.G. Bilo<sup>1,3</sup>, N. Kleefstra<sup>1,4</sup>, S.J.L. Bakker<sup>3</sup>;<sup>1</sup>Diabetes Centre, Isala Clinics, Zwolle, <sup>2</sup>Departments of Internal Medicine and General Practice, UMCG, <sup>3</sup>Department of Internal Medicine, UMCG, <sup>4</sup>Department of Internal Medicine, UMCG, Groningen, Netherlands.**Background and aims:** Advanced chronic kidney disease, one of the complications in type 2 diabetes, is a well known predictor for cardiovascular (CV) disease and mortality. Since measurement of glomerular filtration rate (GFR) is complex, clinical laboratories currently report an estimated GFR based on serum creatinine (SCr) measurement. Cystatin C was suggested to more accurately reflect kidney function and to improve risk prediction for the risk of death. However, it is not known whether other renal markers such as urea, uric acid and potassium improve risk prediction of CV and all-cause mortality. Our aim was to compare the predictive performance of these markers in type 2 diabetes.**Materials and methods:** Patients with DM2 participating in the Zwolle Out-patient Project Integrating Available Care (ZODIAC) study were included. Cox regression analyses were used to investigate the associations of the renal markers with CV and all-cause mortality. Our multivariable model consisted of CV risk factors including age, sex, BMI, smoking, systolic blood pressure, total cholesterol-to-HDL ratio, duration of diabetes, HbA<sub>1c</sub>, use of RAAS-inhibitors, history of CV diseases and log albumin-to-creatinine ratio. Harrell's C statistics were used to compare the predictive performance of the markers.**Results:** We included 1,185 patients (46% male, age  $67 \pm 12$  years). Mean plasma concentrations of SCr, cystatin C, urea, uric acid and potassium were  $95 \pm 21 \mu\text{mol/L}$ ,  $1.0 \pm 0.3 \text{ mg/L}$ ,  $6.7 \pm 2.3 \text{ mmol/L}$ ,  $0.33 \pm 0.09 \text{ mmol/L}$  and  $4.4 \pm 0.4 \text{ mmol/L}$ , respectively. After median follow-up for 5.5 [IQR 3.1–10.1] years, 354 patients died (30%), with 149 deaths (13%) attributable to CV causes. Univariable associations of the markers (per SD increase) with CV and all-cause mortality are shown in Table 1. In univariable Cox regression analyses, all markers were significantly associated with CV and all-cause mortality, with the highest C statistics for cystatin C. If renal markers were added to multivariable models, all renal markers except potassium remained independent predictors for CV and all-cause mortality, but the added value in terms of increase in C-statistic was limited and insignificant for all markers.**Conclusion:** In type 2 diabetes, we found that cystatin C was a better predictor of CV and all-cause mortality than SCr, urea, uric acid and potassium. After adjustment for known CV risk factors, there was no added value in predictive performance for any of the studied markers.

**Impaired kidney function is a diabetes risk equivalent in patients with established coronary artery disease**H. Winkler<sup>1</sup>, C.H. Saely<sup>2,3</sup>, D. Zanolin<sup>1,3</sup>, A. Vonbank<sup>2</sup>, P. Rein<sup>2</sup>, H. Drexel<sup>1,2,4</sup>;<sup>1</sup>VIVIT Institute, Feldkirch, Austria, <sup>2</sup>Academic Teaching Hospital, Feldkirch, Austria, <sup>3</sup>Private University of the Principality of Liechtenstein, Triesen, Liechtenstein, <sup>4</sup>Drexel University College of Medicine, Philadelphia, USA.**Background and aims:** Type 2 diabetes (T2DM) is a paramount risk factor for cardiovascular disease, in particular among patients with established coronary artery disease (CAD). Similarly, chronic kidney disease (CKD) confers a high risk of cardiovascular events. We aimed at investigating the single and joint effects of T2DM and of CKD on cardiovascular risk in patients with angiographically proven CAD.**Materials and methods:** We prospectively recorded cardiovascular events over 10 years in a cohort of 1423 patients with angiographically proven CAD.

CKD was defined as an estimated glomerular filtration rate (eGFR) <60ml/min/1.73m<sup>2</sup>.

**Results:** The risk of cardiovascular events was significantly higher in T2DM patients (n=171) than in non-diabetic subjects (39.1% vs. 28.7%; p <0.001) and also was higher in patients with CKD (n=116) compared to those with an eGFR ≥60ml/min/1.73m<sup>2</sup> (47.2% vs. 28.7%; p <0.001). When both, T2DM and CKD were considered, 841 subjects had neither T2DM nor CKD, 336 had T2DM but not CKD, 145 did not have diabetes but had CKD, and 101 had both diabetes and CKD. When compared with the event rate among patients with neither T2DM nor CKD (26.3%), event rates were significantly higher in patients with T2DM who did not have CKD (34.8%; p=0.007) and in non-diabetic patients with CKD (42.8%; p=0.020) and were highest in patients with both, T2DM and CKD (53.5%; p <0.001). Further, patients with both, T2DM and CKD were at a significantly higher event risk than those with T2DM but no CKD (p=0.011) and those without T2DM but with CKD (p=0.048). Event rates were similar in patients with T2DM but not CKD and in non-diabetic patients with CKD (p=0.798).

**Conclusion:** We here report the novel findings that CKD and T2DM contribute synergistically to cardiovascular event risk and that CKD is a T2DM risk equivalent in patients with established coronary artery disease.

## 1221

### Associations between BMI, HbA<sub>1c</sub> and mortality among people with screen-detected type 2 diabetes. ADDITION-Denmark

L. Grønbaek<sup>1</sup>, A. Sandbaek<sup>1</sup>, M.V. Skriver<sup>2</sup>;

<sup>1</sup>Section for General Practice, <sup>2</sup>Section for Health Promotion and Health Services, Department of Public Health, Aarhus, Denmark.

**Background and aims:** The associations between HbA<sub>1c</sub>, BMI, cardiovascular morbidity and all-cause mortality have earlier been investigated among people with type 2 diabetes, but not in the same study and previous results have been divergent. The obesity paradox implies greater survival among people with chronic diseases who are overweight or slightly obese compared to normal weight individuals. Considering this, we aim to examine whether BMI among people with screen-detected type 2 diabetes modify the associations between 1) HbA<sub>1c</sub> and cardiovascular morbidity and 2) HbA<sub>1c</sub> and all-cause mortality.

**Materials and methods:** This is a cohort study including 1533 patients aged 40–69 years with type 2 diabetes identified through the Danish arm of the Anglo-Danish-Dutch Study of Intensive Treatment in People with Screen-detected Diabetes in Primary Care (ADDITION-DK). At baseline, HbA<sub>1c</sub>, BMI and cardiovascular risk factors were measured and information on medication, lifestyle and socioeconomic status were provided by means of a questionnaire. At follow-up, information on death or discharge from a Danish hospital were obtained from national registers. Information on BMI were available for 1489 patients. Five groups were formed according to BMI. Hazard ratios for the associations between baseline HbA<sub>1c</sub>, cardiovascular morbidity and all-cause mortality will be estimated in each group using Cox multivariate regression model. The results will be adjusted for sex, age, medication, lifestyle, socioeconomic status and comorbidity.

**Results:** Baseline characteristics are shown in table 1. Preliminary results indicate that among people with screen-detected type 2 diabetes those with BMI ≥35 tend to be younger than those with BMI <35. The percentage of current smokers and the consumption of alcohol seem to be higher among people with BMI <30 compared to people with BMI ≥30. Interestingly the proportions of people with HbA<sub>1c</sub> >7% appear to be equally distributed among the five BMI groups and likewise there are no immediate differences in systolic blood pressure and levels of cholesterol.

**Conclusion:** Full results and conclusions concerning the associations between HbA<sub>1c</sub>, cardiovascular morbidity and all-cause mortality will be presented at EASD Annual Meeting 2014. Our data indicate that a high BMI increases the risk of diabetes as individuals in the heaviest group tend to have developed diabetes at a younger age. Overall our full results will play a part in optimizing treatment strategies by clarifying the basis of rational treatment. Importantly our results will also contribute to an overview of influential factors regarding prognosis for people with type 2 diabetes. Such identi-

fication may help general practitioners to direct attention to those with the poorest prognosis and consequently act at an earlier stage. This per se could reduce or delay complications to diabetes.

### Development of a prediction model for fatal and non-fatal coronary heart disease and cardiovascular disease in patients with newly-diagnosed type 2 diabetes mellitus

J.A. Piniés<sup>1</sup>, F. Gonzalez-Carril<sup>2</sup>, I. Irigoien<sup>3</sup>, J.M. Arteagoitia<sup>2</sup>,

J.M. Altzibar<sup>2</sup>, J.L. Rodriguez-Murua<sup>2</sup>, L. Echevarriarteun<sup>2</sup>,

Basque Country Sentinel Practice Network;

<sup>1</sup>Endocrinology and Nutrition Department, Cruces University Hospital,

Barakaldo, <sup>2</sup>Department of Health, Basque Government, Epidemiology

Unit, Public Health Service, Vitoria-Gasteiz, <sup>3</sup>Department of Computation

Science and Artificial Intelligence, University of the Basque Country (UPV-EHU), Donostia, Spain.

**Background and aims:** To construct a model for predicting CHD, and cardiovascular disease (CVD) risk in newly-diagnosed type 2 diabetic patients in a southern European region. External validation of two other cardiovascular risk models and internal validation of our developed model were assessed.

**Materials and methods:** A 10-year prospective population-based cohort study was performed with 777 newly-diagnosed type 2 diabetic patients older than 24 years in a Sentinel Practice Network. Cardiovascular risk factors, CVD events, and mortality were registered. The patients without CVD at baseline (659/777) who had data available for all variables (605/659) were included. Coefficients for the significant predictors of fatal/non-fatal CHD, and CVD were estimated using Cox models. Discrimination and calibration of the United Kingdom Prospective Diabetes Study risk engine (UKPDS-RE), the Framingham Risk Score-Regicor Study (FRS-RS), and the cardiovascular risk model we developed were assessed

**Results:** Beta coefficients, and standard error (SE) and HRs of risk factors in the best-fitting multivariable 5-year risk model for fatal/non-fatal CHD and CVD are shown in the table. The variable selection procedure identified baseline risk factors for fatal/non-fatal CHD, and CVD. Significant risk factors were age, non-HDL:HDL, and HbA<sub>1c</sub> for 5-yr risk prediction of CHD and the factors mentioned above, plus SBP and smoking, for 5-yr CVD risk prediction. In the CHD risk prediction equation, high SBP (TA ≥ 140 mmHg) was an independent, significant stratified variable. All of the risk factors that were retained through the variable selection procedure were incorporated into the Basque Country risk engine (BASCORE). Therefore, the risk of fatal/non-fatal CHD increased 24% for each 1% increase in HbA<sub>1c</sub> or 74% if the non-HDL:HDL was >5. The risk of fatal/non-fatal CVD increased 19% for each 1% increase in HbA<sub>1c</sub>, 2% for each mmHg of SBP or 19% for each 1 unit of increase in non-HDL:HDL; the risk was reduced by 64% if the patient was not a smoker. The UKPDS-RE and FRS-RS showed inadequate discrimination and calibration for predicting CHD risk. The internal discrimination and calibration of the developed model were acceptable for predicting fatal/non-fatal 2-, and 5-, but not 10-year CHD and CVD risk

**Conclusion:** This study is the first southern European validated population-derived model for predicting 5-year fatal/non-fatal CHD and CVD risk in newly-diagnosed type 2 diabetic patients

### Single and joint effects of obesity and of the metabolic syndrome on cardiovascular event risk

C.H. Saelly<sup>1,2</sup>, D. Zanolini<sup>3,2</sup>, A. Vonbank<sup>1</sup>, P. Rein<sup>1</sup>, H. Drexel<sup>1,4</sup>;

<sup>1</sup>Academic Teaching Hospital Feldkirch, Austria, <sup>2</sup>Private University of the Principality of Liechtenstein, Triesen, Liechtenstein,

<sup>3</sup>VIVIT Institute, Feldkirch, Austria, <sup>4</sup>Drexel University College of Medicine, Philadelphia, USA.

**Background and aims:** Obesity is a major risk factor for the metabolic syndrome (MetS), but some obese individuals do not have the MetS while others have the MetS but are non-obese. We prospectively investigated the single and joint effects of obesity and of the MetS on cardiovascular event risk.

**Materials and methods:** Cardiovascular events were prospectively recorded over 10 years in a large cohort of 1705 patients undergoing coronary angiography for the evaluation of established or suspected stable coronary artery disease. Obesity was defined as a BMI ≥30kg/m<sup>2</sup>; presence of the MetS was defined according to the current harmonized consensus definition.

**Results:** From our patients, 827 were non-obese and did not have the MetS, 443 were non-obese but had the MetS, 113 were obese but did not have the MetS, and 322 were obese and had MetS. Cardiovascular event risk was 34.1% in non-obese patients with the MetS. It was significantly higher in this patient group when compared to non-obese subjects without the MetS (25.3%; p<0.001), when compared to obese subjects without the MetS (22.1%; p=0.036), and even when compared to obese subjects with the MetS (25.2%; p=0.006).

**Conclusion:** We conclude that non-obese patients with the MetS face a particularly unfavourable cardiovascular prognosis.

## PS 109 Predicting complications III

### 1224

#### Age, insulin requirements, waist circumference and triglycerides predict hypogonadism in type 1 diabetic patients

J.J. Chillarón<sup>1</sup>, M. Fernandez-Miró<sup>2</sup>, M. Albarada<sup>3</sup>, J.A. Flores-Le Roux<sup>1</sup>, C. Colom<sup>2</sup>, S. Fontserè<sup>1</sup>, J. Pedro-Botet<sup>1</sup>, L. Vila<sup>3</sup>, TEST-DM<sup>1</sup> study group;

<sup>1</sup>Hospital del Mar, <sup>2</sup>Centre d'Atenció Integral Dos de Maig,

<sup>3</sup>Hospital Sant Joan Despí-Moisès Broggi, Barcelona, Spain.

**Background and aims:** The prevalence of hypogonadotropic hypogonadism (HH) in patients with type 2 diabetes mellitus is higher than in the general population and leads to detrimental effects on metabolic control, lipid profile and body composition. Few studies have examined its role in type 1 diabetes mellitus (T1DM). Aims: To characterize patients with T1DM and HH and to evaluate risk factors for this condition.

**Materials and methods:** Cross-sectional study including T1DM men over 18 years of age with a T1DM duration greater than six months, attended in the outpatient clinic of two hospitals between march-december 2013. A sample of fasting venous blood was taken to measure HbA1c, lipid profile, total testosterone, LH, FSH, SHBG and albumin. History of micro and macrovascular complications, hypertension, dyslipidemia and diabetes duration was gathered. Clinical examination included weight, height, hip and waist circumferences and blood pressure. Metabolic syndrome was diagnosed according to the NCEP-ATP III criteria and the CUN-BAE equation was used to estimate the percentage of body fat. HH was defined as total testosterone less than 8 nmol/L or a calculated free testosterone less than 225 pmol/L, with normal/low levels of LH and FSH. Statistical analysis: Student's t-test was performed to assess differences between two means. For non-normally distributed variables, Mann-Whitney U test was used. Either  $\chi^2$  test or Fisher's exact test was used to examine the degree of association of categorical variables. An experimental model to calculate HH risk was created (HH-Score) using the value of incremental odds for variables predisposing to HH (age, insulin requirements, waist circumference and triglycerides). HH Score = (1.060 x Age) + (1.084 x Waist circumference) + (14.00 x Insulin requirements) + Triglycerides, where age is expressed in years, waist circumference in cm, insulin requirements in IU/kg/d and triglycerides in mg/dL.

**Results:** 157 patients with a mean age of 44.7 ± 13.1 years and a mean T1DM duration of 19.2 ± 12.7 years were included in the study. HbA1c levels were 7.9 ± 1.3%. Fifteen patients had HH, representing a prevalence of 9.55% (95% CI: 5.0-14.1%).

HH patients presented more frequently hypertension (80.0% vs 47.2%, P <0.001) and peripheral neuropathy (33.3% vs 12.9%, P <0.05). No differences in other T1DM complications were detected. An HH-Score > 242.4 showed a 100% sensitivity and a 51.4% specificity for HH diagnosis. The positive and negative predictive values were 17.8% and 100%, respectively.

**Conclusion:** One in 10 patients with T1DM has HH. A simple formula, including easy and available clinical parameters and triglyceride levels, can predict HH risk; an HH-Score < 242.4 excludes the diagnosis of HH in T1DM patients.

## 1225

**Association between obstructive sleep apneas and complications of type 2 diabetes**

C. Langrand<sup>1</sup>, J. Glerant<sup>2</sup>, F. Gormand<sup>3</sup>, J. Guerin<sup>4</sup>, P. Moulin<sup>1</sup>;  
<sup>1</sup>Endocrinology, Diabetology and Metabolic Diseases, Hôpital Cardiologique Louis Pradel, <sup>2</sup>Pneumology, Hôpital Cardiologique Louis Pradel, Bron, <sup>3</sup>Pneumology, Centre Hospitalier Lyon Sud, Pierre Benite, <sup>4</sup>Pneumology, Hôpital de la Croix Rousse, Lyon, France.

**Background and aims:** Obstructive sleep apneas are highly prevalent in diabetes subjects. Chronic intermittent hypoxia and sleep fragmentation induced by sleep apnea increase sympathetic nervous system activity, oxidative stress and inflammation. These alterations are also involved in the development of diabetes complications, more especially in microvascular complications. The aim of this study was to establish an association between obstructive sleep apnea severity and complications of type 2 diabetes.

**Materials and methods:** A retrospective observational study was set up in 68 type 2 diabetic patients with obstructive sleep apnea syndrome (OSAS). Respiratory parameters of obstructive sleep apnea and occurrence of diabetes complications were reported between diagnosis of sleep apnea and a mean follow-up of 4 years.

**Results:** Participants were diabetic subjects with high cardiovascular risk. Most of them presented a severe OSAS (73%). Mean nocturnal oxygen saturation and time spent with oxygen saturation < 90% were significantly impaired in presence of microvascular complications compared to absence of microvascular complications (90% vs. 93% and 29% vs. 7% respectively,  $p < 0.005$ ). Using logistic regression analysis, occurrence of long-term microvascular complications was independently associated with hypoxemia indexes (OR=0.691[0.530-0.902]  $p=0.007$ ), regardless of adherence to CPAP therapy, age, sex, BMI, HbA1C and diabetes duration. Diabetic nephropathy was predicted both by hypoxemia indexes and diabetes duration. No correlation was found between apnea hypopnea index (AHI) and any diabetes complications. Optimal adherence to CPAP therapy did not improve metabolic parameters or prevent microvascular complications. However, myocardial infarctions were more prevalent in subjects with weak adherence to CPAP therapy (+17% vs. +9%;  $p=0.03$ ).

**Conclusion:** The independent association between hypoxemia indexes and microvascular complications suggests that chronic intermittent hypoxia induced by sleep apneas could contribute to the progression of microvascular complications in type 2 diabetes. These findings support the need of a specific trial to test the hypothesis of an effect of CPAP therapy in order to prevent microvascular diabetic complications.

## 1226

**Ectopic fat in the pancreas can predict diabetes complications in non-obese subjects**

H.-S. Kwon, M.-K. Kim, S.-H. Lee, B.-Y. Cha;  
 Department of Internal Medicine, The Catholic University of Korea, Seoul, Republic of Korea.

**Background and aims:** Evidence that pancreatic steatosis has a role in obesity, metabolic syndrome and type 2 diabetes mellitus (DM) is emerging. However, data on the influence of pancreatic steatosis on DM complications are lacking.

**Materials and methods:** We examined 198 patients with type 2 DM. Pancreatic computed tomography (CT) attenuations were assessed using CT imaging. Obesity was defined as BMI  $\geq 25$  kg/m<sup>2</sup> according to the Asian-specific BMI cut-offs. We defined pancreatic steatosis as pancreatic attenuations below median levels.

**Results:** The pancreatic attenuations was significantly correlated with age ( $r = -0.302$ ,  $p < 0.001$ ), visceral fat area ( $r = -0.194$ ,  $p = 0.006$ ) and vascular stiffness ( $r = -0.242$ ,  $p = 0.001$ ). In the non-obese group (BMI < 25 kg/m<sup>2</sup>), pancreatic steatosis was associated with a higher prevalence of diabetic complications reflecting retinopathy, nephropathy, carotid artery plaque and vascular stiffness. In the non-obese group, patients with pancreatic steatosis, compared with those without, had an odds ratio (OR) of 5.6 (95% confidence intervals [CI] 1.4 - 22.7) for diabetic retinopathy, 3.5 (95% CI 1.3-9.4) for diabetic nephropathy and 3.1 (95% CI 1.2 - 8.1) for carotid artery plaque, after adjusting for age, gender and BMI. However, significant associations between pancreatic steatosis and diabetic complications were not found in the obese group.

**Conclusion:** Pancreatic steatosis is associated with increased diabetic complications in non-obese subjects with type 2 DM. This finding highlights the importance of pancreatic fat deposits associated with the presence of diabetic complications, especially in non-obese subjects.

## 1227

**Ketosis-prone diabetes is associated with less microvascular complications in sub-Saharan African patients**

B. Baz<sup>1</sup>, J.-L. Nguewa<sup>1</sup>, S.P. Choukem<sup>2</sup>, E. Sobngwi<sup>3</sup>, M. Ait Djoudi<sup>1</sup>, P. Boudou<sup>4</sup>, J.-P. Riveline<sup>1</sup>, J.-F. Gautier<sup>1</sup>;  
<sup>1</sup>University Center for Diabetes and its Complications, Endocrinology and Diabetology Department, Lariboisiere Hospital, Paris, France, <sup>2</sup>Department of Clinical Science, University of Buea, <sup>3</sup>National Obesity Center, Endocrinology and Diabetology Department, Central Hospital of Yaounde, Cameroon, <sup>4</sup>Hormonology Department, Saint Louis Hospital, Paris, France.

**Background and aims:** Ketosis-prone diabetes (KPD) is a heterogeneous syndrome characterized by ketoacidosis or unprovoked ketosis but do not necessarily have the typical phenotype of autoimmune type 1 diabetes. Data from longitudinally followed cohorts have shown that the clinical features of KPD are "intermediate" between type 1 and type 2 diabetes (T2D). Long-term complications in KPD are not well studied. Our aim was to evaluate the prevalence of long-term microvascular complications in KPD patients compared with T2D patients.

**Materials and methods:** Data from our KPD cohort register and medical files of T2D patients attending our department were retrospectively analysed and compared. Only patients of sub-Saharan African origin were included.

**Results:** A total of 80 patients (40 KPD vs 40 T2D) were evaluated. Both groups were matched on sex (female to male ratio 1:4) and diabetes duration (11.5 $\pm$ 4.6 (SD) years). They had similar mean age (55.3 $\pm$ 7.7 vs 56.5 $\pm$ 8.9 years) and mean BMI (28.6 $\pm$ 5 vs 29.4 $\pm$ 5 kg/m<sup>2</sup>). There was no significant difference between mean HbA1c (8.8 $\pm$ 2.2 vs 8.4 $\pm$ 1.2 %  $p=0.42$ ). The number of patients with diabetic retinopathy (18 vs 27 patients) and nephropathy (8 vs 19 patients) were higher in T2D ( $p < 0.05$ ). There was no significant difference between the two groups regarding the diabetic neuropathy prevalence.

**Conclusion:** Some long-term microvascular diabetes complications are less prevalent in KPD patients compared with T2D patients. The protecting factors and mechanisms remain to be revealed.

## 1228

**Risk association of triglycerides variability with microvascular complications even in well-controlled type 2 diabetes**

G. Bardini<sup>1</sup>, M. Innocenti<sup>1</sup>, C.M. Rotella<sup>1</sup>, E. Mannucci<sup>2</sup>, S. Giannini<sup>3</sup>;  
<sup>1</sup>Obesity Agency, <sup>2</sup>Diabetology Agency, <sup>3</sup>Endocrinology Unit, University of Florence, Italy.

**Background and aims:** The risk of microvascular complications increases as the mean of glycated haemoglobin (HbA1c) levels increases. Recently, HbA1c variability seems to be an independent risk factor for diabetic microangiopathy. Basic and clinical studies strongly showed that hyperlipidemia accelerates the progression of microangiopathy. In particular, hypertriglyceridemia has an important role in the progression of diabetic kidney disease, while retinopathy (DR) is less clearly associated. Since no data are available, aim of this study was to examine the association between HbA1c and TG variability on the development of DR and nephropathy in type 2 diabetes (T2DM).

**Materials and methods:** Clinical and anthropometric data, HbA1c and lipid profile were serially recorded in each visit in 450 T2DM clinic outpatients (mean age 68.7 years, with 48.6% females) examined from 2007 to 2014. Patients who had a history of microangiopathy previous the baseline visit were excluded. HbA1c and TG variability, measured as the intrapersonal standard deviation (SD) of serially collected data, were compared in patients who did and did not develop DR or nephropathy. Retinopathy was assessed by dilated funduscopy and diabetic nephropathy was defined based on micro-macroalbuminuria. The association between TG variability and the development of nephropathy was determined by Cox regression analysis adjusted for age, sex, BMI, smoking, duration of diabetes, blood pressure, therapies.

**Results:** All subjects showed a mean HbA1c 7.2% and a mean duration of disease 13.8 years. Among patients studied, 88.0% were treated only with oral hypoglycemic drugs, 12.0% with insulin, 71.5% with statins and 68.0% assumed renin-angiotensin system antagonists. Over a mean follow-up period of 6.8 years, 9.8% and 27.1% of patients developed retinopathy and nephropa-

thy, respectively. Patients who progressed to retinopathy had higher mean HbA1c ( $7.4 \pm 0.8\%$  vs  $6.8 \pm 0.7\%$ ,  $p < 0.001$ ) and SD ( $0.63 \pm 0.3\%$  vs  $0.50 \pm 0.4\%$ ,  $p < 0.05$ ) than nonprogressors. Similarly, patients who developed nephropathy had higher mean HbA1c ( $7.1 \pm 0.8\%$  vs  $6.8 \pm 0.7\%$ ,  $p < 0.05$ ) and SD ( $0.60 \pm 0.4\%$  vs  $0.50 \pm 0.4\%$ ,  $p < 0.05$ ). Considering TG variability, no significant differences were observed between progressors and nonprogressors for retinopathy. Instead, patients who developed nephropathy had higher mean TG ( $170.2 \pm 65.0$  mg/dl vs  $133.0 \pm 47.6$  mg/dl,  $p < 0.001$ ) and TG-SD ( $52.1 \pm 30.0$  mg/dl vs  $35.5 \pm 24.2$  mg/dl,  $p = 0.001$ ) than nonprogressors. Cox analysis, adjusted for potential risk factors, showed that TG-SD was associated with nephropathy with HR of 2.2 (95% CI 1.2–4.3,  $p = 0.014$ ). Analyzing data from subjects with HbA1c-mean upper or below 7%, in patients with HbA1c  $> 7\%$ , as expected, the presence of hypertriglyceridemia (TG  $> 150$  mg/dl) increased the prevalence of nephropathy (from 31.6% to 43.0%,  $p < 0.001$ ). Of particular interest, an increased prevalence of nephropathy was also observed in subjects at therapeutical target with HbA1c-mean  $< 7\%$  (from 17.4% to 31.0%,  $p < 0.001$ ). Instead, independently of HbA1c levels considered, the TG were not associated to significant differences in the prevalence of retinopathy (from 4.3% to 4.8%,  $p = 0.68$ ).

**Conclusion:** The TG levels and their variability affect the development of diabetic nephropathy. This effect seems to be additive over HbA1c mean and variability even in patients at target for HbA1c levels.

## 1229

### Low levels of serum insulin-like growth factor-I increase the risk of osteoporotic fracture and mortality in postmenopausal women with type 2 diabetes mellitus

H. Miyake, I. Kanazawa, T. Yamaguchi, T. Sugimoto;  
Internal Medicine <sup>1</sup>, Shimane University Faculty of Medicine, Izumo, Japan.

**Background and aims:** Osteoporosis became a social problem in industrialized countries because osteoporotic fractures are associated with low mobility and high mortality. Accumulating evidence has shown that the risk of osteoporotic fractures is increased in type 2 diabetes mellitus. Since the risk is independent of bone mineral density (BMD), the measurement of BMD, which is a gold standard to detect primary osteoporosis, is not useful for screening diabetes-related bone fragility. Therefore, it is an important issue to find evaluation tools to assess the risk of future osteoporotic fracture instead of BMD measurement in type 2 diabetes. Insulin-like growth factor-I (IGF-I) is well-known to have anabolic effects on bone. In addition, serum IGF-I levels were reported to be associated with the presence of vertebral fracture. We previously showed that serum IGF-I levels was inversely associated with the prevalence and severity of vertebral fractures independent of BMD. We thus hypothesized that serum IGF-I was involved in the etiology of diabetes-related bone fragility and its serum levels might be a clinically useful marker for assessing future fracture risk in type 2 diabetes mellitus. In this study, we examined the association between serum IGF-I levels and the incidence of fracture as well as mortality in postmenopausal women with type 2 diabetes mellitus.

**Materials and methods:** In this study, we recruited 197 postmenopausal women with type 2 diabetes mellitus whose serum IGF-I levels and BMD at lumbar spine (L-BMD) were previously measured from 1993 to 2009 at Shimane university hospital. Medical doctors interviewed the history of the subjects with special attention to osteoporotic fractures in 2013. Student's *t* tests and multiple regression analyses were performed to examine the association of the incidence of osteoporotic fracture and death after IGF-I measurement with serum IGF-I levels.

**Results:** Of 197 subjects, 27 patients died, and 24 patients suffered from new osteoporotic fracture. Serum IGF-I levels were marginally lower in patients with osteoporotic non-vertebral fractures than in those without them ( $118 \pm 38$  ng/mL vs  $140 \pm 53$  ng/mL,  $p = 0.054$ ). Moreover, serum IGF-I levels were significantly lower in dead patients than in survivors ( $94 \pm 50$  ng/mL vs  $137 \pm 52$  ng/mL,  $p < 0.001$ ). Multiple logistic regression analysis adjusted for age, duration of diabetes, body mass index, HbA1c, serum creatinine, L-BMD showed that serum IGF-I levels were significantly and inversely associated with the incidence of osteoporotic non-vertebral fractures [odds ratio (OR) = 0.49, 95%CI 0.24–0.99,  $p = 0.049$ ] as well as with all-cause death (OR = 0.45, 95%CI 0.21–0.95,  $p = 0.035$ ).

**Conclusion:** The present study showed for the first time that serum IGF-I levels were associated with the incidence of osteoporotic non-vertebral fractures and death in postmenopausal women with type 2 diabetes, suggesting

that serum IGF-I could be clinically useful for assessing the risk of future osteoporotic fractures as well as mortality in postmenopausal women with type 2 diabetes mellitus.

### Metabolic and vascular characteristics of insulin resistance in Korean patients with type 2 diabetes

E. Lee<sup>1</sup>, Y. Choi<sup>2</sup>, S.-K. Kim<sup>3</sup>, B. Huh<sup>2</sup>, B.-W. Lee<sup>1</sup>, E. Kang<sup>1</sup>, B. Cha<sup>1</sup>, E. Lee<sup>1</sup>, H. Lee<sup>1</sup>, S. Lee<sup>2</sup>, K. Huh<sup>2</sup>;  
<sup>1</sup>Internal Medicine, Yonsei University College of Medicine,  
<sup>2</sup>Huh's Diabetes Center and <sup>3</sup>1th Century Diabetes and Vascular Research Institute, Seoul, <sup>3</sup>Internal Medicine, CHA Bundang Medical Center, CHA University, Seongnam, Republic of Korea.

**Background and aims:** Insulin resistance (IR) is a paramount concern of type 2 diabetes and its associated disorders. To investigate the association of IR with metabolic and vascular disorders related to diabetes, we analyzed 7,109 Korean type 2 diabetic patients according to IR.

**Materials and methods:** A total 7,109 patients with type 2 diabetes were recruited through our Diabetes Center from January 2003 to June 2009. Insulin sensitivity was measured by a rate constant for plasma glucose disappearance (Kitt, %/min) using short insulin tolerance test. Subgroup analyses were performed according to the tertiles of Kitt. Carotid atherosclerosis was defined as presence of isolated focal plaque or mean intima-media thickness (IMT) more than 1.0 mm.

**Results:** Mean age was  $58.1 \pm 10.1$  years old, and 71.5% of diabetic patients had IR. Patients with the lowest tertile of Kitt (IR group) showed higher levels of metabolic parameters such as body mass index (BMI), visceral fat thickness, blood pressure, fasting blood glucose, HbA1c, total cholesterol, triglyceride and LDL cholesterol but lower HDL cholesterol compared to the patients with the highest tertile of Kitt (insulin-sensitive group). Mean and maximal IMT of carotid arteries was significantly higher in the patients with the lowest tertile of Kitt. As the value of Kitt was lower, the prevalence of metabolic and vascular disorders related to diabetes increased. In multiple regression analysis, IR was an independent risk factor for the metabolic and vascular disorders related to diabetes after adjusting for age, sex, duration of diabetes, BMI and HbA1c. Odds ratios for metabolic syndrome and carotid atherosclerosis in patients with the lowest tertile of Kitt were 3.108 (95% CI, 2.721–3.549) and 1.232 (95% CI, 1.069–1.418), respectively.

**Conclusion:** IR is not only prevalent but also an important predictor for metabolic and vascular disorders in Korean patients with type 2 diabetes. Beyond reducing the HbA1c, management focusing on IR such as life-style modification or using insulin-sensitizing agents should be evidently considered in patients with type 2 diabetes.

## 1231

### Multi-morbidity in type 2 diabetes: systems biology analysis based on 196,627 patients from a real-life multicentre analysis

J.M. Hermann<sup>1</sup>, D. Crowther<sup>2</sup>, C. Giegerich<sup>2</sup>, M. Hofer<sup>3</sup>, R. Beer<sup>4</sup>, R.W. Holl<sup>1</sup>, on behalf of the DPV initiative;  
<sup>1</sup>ZIBMT, University of Ulm, <sup>2</sup>Sanofi-Aventis, Frankfurt, Germany,  
<sup>3</sup>First Department of Internal Medicine, General Hospital St. Pölten, Austria,  
<sup>4</sup>Department of Internal Medicine, Klinikum Hildesheim, Germany.

**Background and aims:** Patients with type 2 diabetes (T2D) often have various chronic comorbid diseases. The aim was to investigate electronic medical record data to examine the incidence of multi-morbidity as well as the co-occurrence of T2D with the most prevalent diagnoses and to attempt to stratify metabolic syndrome.

**Materials and methods:** A cohort of 196,627 T2D patients from the German/Austrian Prospective Diabetes Follow-up Registry (DPV) was analyzed. Data included gender, age, duration of diabetes and the additional diagnosis of the 20 most prevalent diseases. Proportional Venn diagrams were used to visualize patterns in the data. Subgroup analyses were compared with results from classical logistic regression models (SAS 9.4).

**Results:** The maximum number of comorbidities was 13. 95% of the patients had less than 6 diseases, 1.4% of the patients had no comorbidity. As expected, the most prevalent diseases were dyslipidemia (93.5%), hypertension (69.4%) and obesity (42.2%), matching the traditional components of metabolic syndrome. The next most prevalent comorbidities were polyneuropathy

(12.9%) and retinopathy (10.1%). Female and male prevalence of all diseases except stroke, fatty liver and retinopathy differed significantly (all  $p < 0.01$ ). Prevalence of obesity and fatty liver decreased with increasing age, all other disease distributions increased or remained constant. Proportional Venn diagrams revealed that obesity and hypertension were mostly combined with dyslipidemia (94.4% and 94.7%, respectively). However, the proportions differed with age: young patients were more obese, older patients were more hypertensive. The proportion of both obesity and hypertension increased with longer duration of diabetes. In contrast, duration of diabetes appeared to have little effect on the proportion of dyslipidemia. It is remarkable that a considerable fraction of T2D patients was not obese, and that some patients seemed to be resistant to diabetes-induced hypertension. Based on Venn diagrams metabolic syndrome was stratified into four main groups. Prevalence of additional comorbidities and their risk factors was different in these groups. For retinopathy, logistic regression models revealed duration of diabetes as risk factor in all 4 groups, whereas age was not significant in the 'hypertension and dyslipidemia' group. Both visualization and regression approach indicated interactions between age and duration of diabetes.

**Conclusion:** We found a high prevalence of multi-morbidity in T2D patients, with dyslipidemia being almost omnipresent in all age groups. The concept of "metabolic syndrome" can be clearly visualized and stratified into 4 main types. The emergence of the additional comorbidities appears different in these groups.

#### Alanine aminotransferase and mortality in patients with type 2 diabetes mellitus (ZODIAC-43)

P.E. Deetman<sup>1</sup>, A. Alkhalaf<sup>2</sup>, G.W.D. Landman<sup>3,4</sup>, K.H. Groenier<sup>3,5</sup>, G. Navis<sup>1</sup>, H.J.G. Bilo<sup>3</sup>, N. Kleefstra<sup>3</sup>, S.J.L. Bakker<sup>1</sup>;

<sup>1</sup>Department of Medicine, University of Groningen, University Medical Center Groningen, <sup>2</sup>Department of Gastroenterology, Isala Clinics, <sup>3</sup>Diabetes Centre, Isala Clinics, Zwolle, <sup>4</sup>Department of Medicine, Gelre Hospital, Apeldoorn, <sup>5</sup>Department of General Practice, University of Groningen, University Medical Center Groningen, Netherlands.

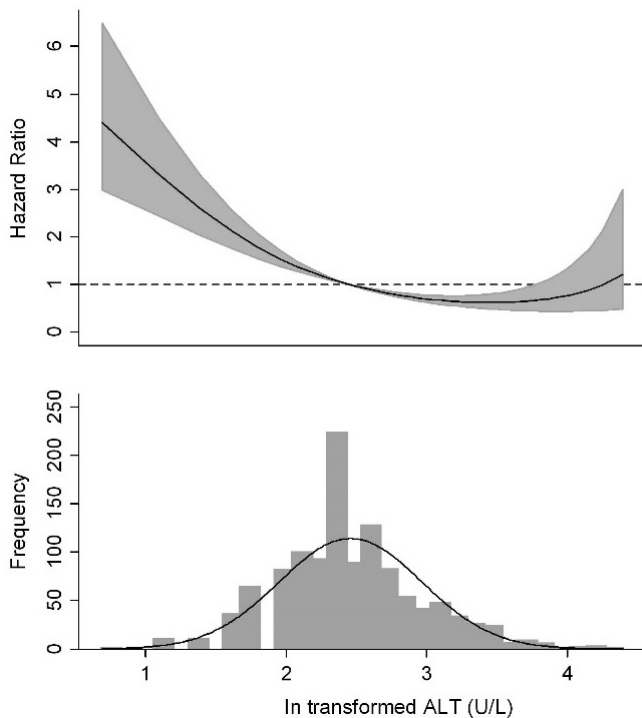

**Background and aims:** Combined data suggests the existence of a bimodal association of alanine aminotransferase (ALT) with mortality in the general population. Little is known about ALT as a predictor of mortality in patients with type 2 diabetes mellitus. We aimed to investigate the association of ALT with all-cause, cardiovascular, and non-cardiovascular mortality in patients with type 2 diabetes mellitus.

**Materials and methods:** A prospective cohort study was performed in patients with type 2 diabetes mellitus, treated in primary care, participating in the Zwolle Outpatient Diabetes project Integrating Available Care (ZODIAC) study. Cox regression analyses were performed to determine associations of log-transformed baseline ALT with all-cause, cardiovascular, and non-cardiovascular mortality.

**Results:** In 1,187 patients with type 2 diabetes mellitus, mean age was  $67 \pm 12$  years and 46% was male. Median (interquartile range) ALT levels were 11 (8-16) U/l. ALT levels were above the upper limit of normal (45 U/L) in sixteen (1.3%) patients. During median follow-up for 5.5 (3.1-10.1) years, 354 (30%) patients died, with 149 (42%) attributable to cardiovascular causes. ALT was inversely associated with all-cause mortality (HR 0.75; 95%CI 0.61-0.92;  $P=0.006$ ). Furthermore, ALT was not associated with cardiovascular mortality (HR 0.94; 95% CI 0.68-1.29;  $P=0.68$ ), but particularly with non-cardiovascular mortality (HR 0.65; 95%CI 0.50-0.86;  $P=0.002$ ). These associations were independent of potential confounders including age, sex, body mass index, cholesterol/HDL ratio, smoking, systolic blood pressure, diabetes duration, serum creatinine, HbA1c, cardiovascular history, treatment with ACE inhibitors, and albumin to creatinine ratio. In addition, there appeared to be a bimodal association of ALT and all-cause mortality ( $P=0.013$ , Figure 1), with a similar bimodal trend for non-cardiovascular mortality.

**Conclusion:** In conclusion, our findings suggest that low levels of ALT are associated with a high risk of all-cause mortality, in particular of non-cardiovascular mortality, in patients with type 2 diabetes mellitus with ALT levels largely within the normal range.

### Serum PEDF levels in type 2 diabetes: correlations, predictive power for vascular events and increases by fenofibrate in the FIELD Study

A. Jenkins, A. Januszewski, D. Calandro, D. Sullivan, J.-X. Ma, J. Best, R. O'Connell, S. Blankenburg, J. Simes, R. Scott, M. Whiting, P. Barter, M.-R. Taskinen, A. Keech, the FIELD Study; NHMRC Clinical Trials Centre, Sydney, Australia.

**Background and aims:** Pigment Epithelium Derived Factor (PEDF) is an endogenous glycoprotein with potent anti-angiogenic, anti-inflammatory and anti-oxidant effects and links with lipoprotein metabolism. In the Fenofibrate Intervention and Event Lowering in Diabetes (FIELD) Study of Type 2 diabetes subjects we aimed to determine if baseline serum PEDF levels (i) are correlated with traditional and novel vascular risk factors; (ii) are associated with on-trial occurrence of microvascular and cardiovascular complications over 5-year follow-up; and (c) are changed by allocation to (up to one year of) 200 mg daily comiconised fenofibrate.

**Materials and methods:** PEDF levels were quantified by ELISA (Merck Millipore, USA) with CVs <10% in sera from (n=8898) FIELD Study participants at baseline and after a 16 week run-in period, including 6 weeks of daily oral 200 mg fenofibrate and in 1832 FIELD subjects after one year of allocation to fenofibrate or placebo. Risk factors evaluated included: BMI, lipid levels, HbA1c, renal dysfunction, insulin and HOMA-IR, leptin, inflammation (including sVCAM-1, sICAM, se-Selectin, IL-6, CRP and fibrinogen) and oxidative stress (OxLDL and myeloperoxidase (MPO)). Tertiles of PEDF at baseline were related to composite CVD (CVD death, MI, stroke or coronary or carotid revascularization) and microvascular (retinal laser, albuminuria, neuropathy or microvascular amputation) end-points with and without adjustment for covariates. Covariates were age, sex, diabetes duration, HbA1c, systolic BP, fasting triglycerides, LDL-C and HDL-C, smoking, and baseline glucose control treatment and (for CVD only) urinary albumin creatinine ratio. Statistical significance was taken at  $p < 0.05$ .

**Results:** Baseline PEDF levels correlated (weakly) (Spearman correlation  $r$  values 0.05–0.30, all  $p < 0.0001$ ) with: baseline HbA1c, blood pressure, triglycerides, LDL-C and HDL-C (inverse), BMI and leptin, renal dysfunction (elevated plasma creatinine, cystatin C, lower calculated GFR and increased albuminuria), insulin levels and HOMA-IR, and with measures of inflamma-

tion (cell adhesion molecules, IL-6, CRP, fibrinogen) and MPO ( $p = 0.002$ ). On unadjusted analyses baseline PEDF tertiles were predictors of on-trial CVD (n=1199, HR up to 1.33,  $p < 0.001$ ) and microvascular events (n=3465, HR up to 1.47,  $p < 0.001$ ). With adjustment for all covariates (above) the relationship with subsequent CVD events was not statistically significant, whilst that with microvascular events was. In the active run-in period including 6 weeks fenofibrate, PEDF levels increased 18 (95% CI 17–19)% from baseline levels. Over one year PEDF levels increased by 16.6 (14.1–19.0)% in the group allocated fenofibrate (n=917;  $p < 0.0001$ ) vs. a 3.4 (1.6–5.9)% increase in the placebo allocated group (n=915;  $p < 0.006$ ).

**Conclusion:** In Type 2 diabetes patients in the FIELD Study serum PEDF levels correlated significantly, albeit weakly, with traditional and novel vascular risk factors, including renal dysfunction, adiposity, inflammation and oxidative stress. Baseline PEDF levels predict on-trial microvascular and CVD and events. PEDF levels are significantly increased by fenofibrate. We suggest that some of fenofibrate's clinical effects may be via effects on PEDF and PEDF may be a therapeutic target.

### Association of the alternative pathway of complement activation with incident cardiovascular diseases: the CODAM study

E. Hertle<sup>1,2</sup>, I.C.W. Arts<sup>1,3</sup>, C.J.H. van der Kallen<sup>1,2</sup>, E.J.M. Feskens<sup>4</sup>, C.G. Schalkwijk<sup>1,2</sup>, C.D.A. Stehouwer<sup>1,2</sup>, M.M.J. van Greevenbroek<sup>1,2</sup>; <sup>1</sup>CARIM School for Cardiovascular Diseases, Maastricht University Medical Centre, <sup>2</sup>Dept. of Internal Medicine, Maastricht University Medical Centre, <sup>3</sup>Dept. of Epidemiology and School for Public Health and Primary Care (CAPHRI), Maastricht University Medical Centre, <sup>4</sup>Division of Human Nutrition, Section Nutrition and Epidemiology, Wageningen University, Netherlands.

**Background and aims:** The complement system has been implicated in the development of both type 2 diabetes (DM2) and cardiovascular diseases. Complement can be activated spontaneously via the alternative complement pathway, which functions also as potent amplifier of other routes of complement activation. We measured plasma properdin and factor D - a positive regulator and a protease, respectively, of the alternative pathway, and factor Bb - an alternative pathway activation marker, and investigated their associations with incident cardiovascular diseases in a diabetes-prone population.

**Materials and methods:** We conducted prospective analyses in the CODAM study (Cohort on Diabetes and Atherosclerosis Maastricht, baseline examination 1999–2001; follow-up examination 2006–2009). Cardiovascular events (CVE) included myocardial infarction (self-reported or identified with ECG-examinations), self-reported stroke, self-reported cardiac angioplasty and/or cardiac bypass. Cardiovascular disease (CVD) additionally included signs of ischaemia on an ECG and/or ankle-brachial index <0.9. We included 371 individuals who were free of CVE at baseline (59% men, age  $58.2 \pm 6.9$  years, 21% DM2). Participants with CVD at baseline (n=53) were additionally excluded in analyses of incident CVD. Associations between properdin, factor D and Bb at baseline and incident CVE and CVD were studied with logistic regression analyses adjusted for baseline age, sex, impaired glucose metabolism, DM2, blood pressure, BMI, smoking, physical activity, renal function, and use of medication. We examined effect modification by prevalent DM2.

**Results:** After a mean follow-up time of  $7.1 \pm 0.1$  years, there were 48 incident CVE and 65 incident cases of CVD. Properdin was independently associated with CVE (per 1SD increase, OR=1.50, [95%CI: 1.10–2.06],  $P = 0.011$ ) but not CVD (OR=1.09, [0.81–1.46],  $P = 0.58$ ). Bb tended to be associated with CVD (per 1SD, OR=1.30, [0.98–1.71],  $P = 0.065$ ) but not with CVE (OR=1.06, [0.76–1.46],  $P = 0.75$ ). Factor D was in the whole population not associated with CVD (per 1SD, OR=1.32, [0.92–1.88],  $P = 0.14$ ) or CVE (OR=1.17, [0.80–1.72],  $P = 0.43$ ), but effect modification by DM2 was observed in the association with CVD ( $P_{\text{factor D} \times \text{DM2}} = 0.049$ ). In stratified analyses, factor D was associated with CVD (OR=4.42, [1.29–15.16],  $P = 0.018$ ) only in participants with baseline DM2 (N=61, 19 cases).

**Conclusion:** In CODAM, higher levels of properdin were independently associated with CVE and higher levels of Bb tended to be associated with CVD. In participants with DM2, factor D was independently associated with CVD. This suggests that the alternative complement pathway may play a role in the development of cardiovascular diseases both in individuals with and without DM2.

## Circulating resistin levels and mortality risk

A. Fontana<sup>1</sup>, S. Spadaro<sup>2</sup>, M. Copetti<sup>1</sup>, B. Spoto<sup>3</sup>, L. Salvemini<sup>4</sup>, P. Pizzini<sup>3</sup>, L. Frittitta<sup>2</sup>, F. Mallamaci<sup>3</sup>, S. Bacci<sup>5</sup>, F. Pellegrini<sup>1</sup>, V. Trischitta<sup>4</sup>, C. Menzaghi<sup>4</sup>;

<sup>1</sup>Unit of Biostatistics, IRCCS, San Giovanni Rotondo,

<sup>2</sup>Department of Clinical and Molecular Biomedicine, University of Catania,

<sup>3</sup>Nephrology, Dialysis and Transplantation Unit, CNR-IBIM, Reggio Calabria,

<sup>4</sup>Research Unit of Diabetes and Endocrine Diseases, IRCCS,

<sup>5</sup>Unit of Endocrinology, IRCCS, San Giovanni Rotondo, Italy.

**Background and aims:** Studies concerning the association between circulating resistin levels and mortality yielded mixed **Results:** some studies reported significant associations, while many others showed negative results. To address this question, we analyzed data from European subjects with type 2 diabetes and evidence of coronary artery disease (CAD), a prospective cohort followed over time for cardiovascular and all-cause mortality. To assess the consistency of the association between resistin and mortality risk, we also performed a meta-analysis of prospective studies.

**Materials and methods:** We investigated: i) the Gargano Heart Study (GHS) prospective design (n=359 diabetic patients; 81 and 58 incident cases of all-cause and cardiovascular (CV) mortality, respectively); ii) meta-analyzed in a dose-risk fashion our present data from GHS study and all studies from MEDLINE and EMBASE until February 2014 reporting adjusted hazard ratios (HR) of circulating resistin for all-cause or CV mortality.

**Results:** In GHS, the adjusted HRs per 10 ng/ml resistin increment were: 1.45 (95% CI: 1.10-1.91) and 1.52 (95% CI: 1.09-2.12) for all-cause and CV mortalities, respectively. The dose-risk meta-analyses included 7 studies (n=3,699, 997 events) for all-cause mortality and 6 studies (n=4,187, 412 events), for CV mortality. Pooled HRs per 10 ng/ml resistin increment were 1.33 (95% CI: 1.03- 1.72, p=0.028, Q-test p for heterogeneity<0.001) and 1.16 (95% CI: 0.95-1.43, p=0.147, Q-test p for heterogeneity=0.039) for all-cause and CV mortality, respectively. Due to the presence of between-studies heterogeneity, meta-regression analyses were performed. For all-cause mortality, study mean age (HR=1.08, 95%CI=1.01-1.14, p=0.017) explained 68.8% of heterogeneity resulting in a pooled HR per 10 ng/ml resistin increment equal to 1.33 (95% CI: 1.12-1.57, p=0.001). For CV mortality, study mean BMI (HR=1.07, 95%CI=1.02-1.11, p=0.004) explained the whole heterogeneity resulting in a pooled HR per 10 ng/ml resistin increment equal to 1.11 (95% CI: 1.02-1.22, p=0.016).

**Conclusion:** Our results provide strong evidence for an association between higher circulating resistin levels and increased mortality risk.

## 1236

## Prognostic value of plasma NT-proBNP levels in asymptomatic diabetic patients

I. Pham, E. Cosson, M. Nguyen, I. Banu, B. Chanu, P. Valensi; AP-HP, Jean Verdier hospital, Bondy, France.

**Background and aims:** Elevated plasma N-terminal (NT)-proBNP levels predict adverse cardiovascular events in the general population and in coronary patients. We previously showed that NT-proBNP is also a marker of silent coronary artery stenoses (CS) in diabetic patients without cardiac history or symptom. The aim of this study was to determine the prognostic value of plasma NT-proBNP levels independent from silent coronary disease and left ventricle hypertrophy (LVH).

**Materials and methods:** We included 323 diabetic patients (17 type 1, 306 type 2; 185 men, 138 women) without history or sign of cardiac disease but with at least one additional risk factor including nephropathy in 41% of the patients. Silent myocardial ischaemia (SMI) was assessed using stress myocardial scintigraphy and CS using coronary angiography in those with SMI. Left ventricular mass was evaluated reliably by echocardiography (ASE convention) in 282 of them. LVH was defined as LV mass  $\geq 106$  (women) or 110 g/m<sup>2</sup> (men). Plasma NT-proBNP was measured.

**Results:** SMI was detected in 108 patients, 39 of whom had CS, and LVH in 92 patients. The highest tertiles of NT-proBNP were associated with a higher prevalence of hypertension (p<0.0001), nephropathy (0.01), peripheral vascular disease (0.03), LVH (19.4, 35.1, 43.2%; p<0.001) and CS (5.6, 10.2, 20.4%; p<0.001). At follow-up (4.6 $\pm$ 2.6 years), 29 patients had a cardiovascular event (10 acute coronary syndrome, 4 cardiac death, 5 heart failure, 4 stroke, 1 amputation, 5 revascularisations). CS and the highest NT-proBNP

tertile ( $\geq 38$  pg/ml) were significant predictors of events (p=0.01 and 0.002, respectively). In multivariate analysis including SMI or CS the highest tertile of NT-proBNP predicted the events independently from SMI (OR 2.9 [1.4-6.0], p<0.005) and CS (OR 2.4 [1.1-5.2], p=0.02). In another model including also LVH the highest tertile of NT-proBNP was still an independent predictor (p<0.0001 and p=0.003, respectively).

**Conclusion:** This study suggests that in asymptomatic diabetic patients NT-proBNP is a risk marker for cardio-vascular events independent from coronary status and LVH.

## 1237

## Comparison of predictive capabilities of MR-proANP and NT-proBNP for mortality (ZODIAC-42)

K.J.J. van Hateren<sup>1</sup>, G.W.D. Ladman<sup>1</sup>, I.J. Riphagen<sup>2</sup>, K.H. Groenier<sup>1</sup>, S.J.L. Bakker<sup>2</sup>, N. Kleefstra<sup>1</sup>, H.J.G. Bilo<sup>1</sup>;

<sup>1</sup>Diabetes Centre, Zwolle, <sup>2</sup>Department of Internal Medicine,

University Medical Center Groningen, Netherlands.

**Background and aims:** The midregional fragment of pro-A-type natriuretic peptide (MR-proANP) has been suggested as an alternative for N-terminal pro-B-type natriuretic peptide (NT-proBNP), an established biomarker in heart failure. A previous head-to-head comparison in the general population between both peptides showed that MR-proANP was as efficient as NT-proBNP in predicting all-cause mortality and cardiovascular events. However, the association of MR-proANP with cardiovascular mortality was not independent from confounders. We aimed to compare the predictive capability of MR-proANP and NT-proBNP for all-cause and cardiovascular mortality in patients with type 2 diabetes mellitus (T2DM).

**Materials and methods:** Patients were selected from two cohorts (1998 and 2001) of the prospective observational ZODIAC study (n=1688). For this study, 541 patients were excluded because plasma MR-proANP and/or plasma NT-proBNP were not measured. A Cox proportional hazard model was used to investigate the relationship between the two natriuretic peptides and (cardiovascular) mortality. We used three models: a crude model, an age- and gender-adjusted model, and a model in which we additionally adjusted for smoking (yes or no), BMI, duration of diabetes, HbA1c, serum creatinine level, macrovascular complications (yes or no), albuminuria (yes or no) and total cholesterol-HDL ratio. Harrell's C statistic was used to compare between models with MR-proANP and those with NT-proBNP.

**Results:** After a median follow-up period of 11 years, 552 (48%) patients died of which 239 patients (43%) died from cardiovascular causes. The median (interquartile range) values for plasma concentrations of MR-proANP and NT-proBNP were 74 pmol/L (48-120 pmol/L) and 11 pmol/L (4-27 pmol/L), respectively. The results of the Cox regression analyses are presented in table 1. Increased plasma concentrations of both natriuretic peptides are independently associated with all-cause and cardiovascular mortality. The Harrell's C values of the models for all-cause mortality are similar for both peptides. For cardiovascular mortality, the Harrell's C values of the models with NT-proBNP are higher compared to the models with MR-proANP.

**Conclusion:** This study is the first study showing that MR-proANP is related to cardiovascular mortality after adjustment for cardiovascular risk factors. The predictive performance of both peptides is similar for all-cause mortality. Regarding cardiovascular mortality, NT-proBNP seems to perform slightly better.

**Table 1.** Results of the Cox regression analyses of the logarithmically transformed MR-proANP and NT-proBNP data, and the comparison of their capability for predicting all-cause and cardiovascular disease (CVD) mortality.

|                          | MR-proANP        |                   | NT-proBNP        |                   |

## 1238

**ProBNP strongly predicts future macrovascular events in angiographed coronary patients as well as in those without the metabolic syndrome**

**B. Patsch**<sup>1</sup>, P. Rein<sup>2</sup>, C.H. Saely<sup>2,3</sup>, A. Vonbank<sup>2</sup>, D. Zanolin<sup>1,3</sup>, H. Drexel<sup>2,4</sup>; <sup>1</sup>VIVIT Institute, Feldkirch, Austria, <sup>2</sup>Academic Teaching Hospital Feldkirch, Austria, <sup>3</sup>Private University of the Principality of Liechtenstein, Triesen, Liechtenstein, <sup>4</sup>Drexel University College of Medicine, Philadelphia, USA.

**Background and aims:** Pro-B-type natriuretic peptide (proBNP) is a prognostic biomarker for patients with congestive heart failure as well as in other patient populations. The power of proBNP to predict cardiovascular endpoints in patients with the metabolic syndrome (MetS) is unclear and is addressed in the present study.

**Materials and methods:** We measured serum proBNP in 722 patients undergoing coronary angiography for the evaluation of stable coronary artery disease (CAD). Significant CAD was diagnosed in the presence of coronary stenoses with lumen narrowing of  $\geq 50\%$ . Prospectively, we recorded vascular events over  $3.2 \pm 1.2$  years.

**Results:** ProBNP was significantly higher in patients with ( $n=386$ ) than in subjects without significant CAD at baseline ( $711 \pm 1287$  vs.  $663 \pm 1565$  pg/ml;  $p=0.001$ ). Prospectively, we recorded 121 cardiovascular events. The incidence of vascular events significantly increased over tertiles of proBNP in patients with the MetS (10.7%, 18.5%, and 28.8% respectively;  $p=0.004$ ) as well as in those without the MetS (10.4%, 11.5%, and 22.0%, respectively;  $p=0.011$ ). Similarly, serum proBNP significantly predicted the incidence of major cardiovascular events after adjustment for age, gender, BMI, smoking, systolic and diastolic blood pressure, LDL cholesterol, HDL cholesterol and the eGFR both in subjects with the MetS (standardized adjusted HR 1.48 [1.21–1.80];  $p < 0.001$ ) and in those without the MetS (HR 1.21 [1.04–1.40];  $p=0.011$ ). These results were not attenuated after further adjustment for the angiographically determined baseline CAD state (HRs 1.50 [1.23–1.83];  $p < 0.001$  and 1.26 [1.09–1.47];  $p=0.003$  in subjects with the MetS and in those without the MetS, respectively).

**Conclusion:** Serum proBNP predicts cardiovascular events independently of established cardiovascular risk factors and of the baseline coronary artery state both in patients with and in subjects without the MetS.

## 1239

**Type 2 diabetes mellitus in patients with terminal stage heart failure**

**G. Dóka**<sup>1</sup>, J. Mlynárová<sup>1</sup>, P. Křenek<sup>1</sup>, P. Musil<sup>1</sup>, J. Klimas<sup>1</sup>, E. Goncalvesová<sup>2</sup>, J. Kyselovič<sup>1</sup>;

<sup>1</sup>Department of pharmacology and toxicology, Faculty of Pharmacy, Comenius University,

<sup>2</sup>The National Institute of Cardiovascular Diseases, Bratislava, Slovakia.

**Background and aims:** Type 2 diabetes mellitus is a major independent risk factor for the development of heart failure. Prevalence of type 2 diabetes in patients with heart failure is higher than in general population. The cardiovascular disease mortality is higher in patient with diabetes and heart failure concurrently than in nondiabetics with failing heart. Based on these knowledge, our interest was to compare diabetic and nondiabetic patients in terminal stage heart failure and assess possible differences in routinely measured and recorded clinical parameters. On molecular level, we suspected deterioration of gene expression of cardiac myosin heavy chain isoforms and regulatory microRNAs originating from these isoforms. Possible shift in expression of these main components of cardiac contractile apparatus may be the underlying source of increased cardiovascular mortality in diabetic patients.

**Materials and methods:** Cohort consisted of 42 patients (38 male, 4 female) with terminal stage heart failure. Inclusion criteria were: heart failure classified NYHA III - IV, patients were indicated for orthotopic heart transplantation, the recorded underlying cause of heart failure was dilated cardiomyopathy or coronary artery disease (two most frequent causes). 16 of 42 patients was diagnosed type 2 diabetes previous to the heart transplantation. We tested the differences in clinical parameter: age, blood pressure, body mass index, data from right heart catheterization, echocardiography, electrocardiography, blood biochemistry, anamnesis of co-morbidities, interventional procedures and complete pharmacotherapy. Expression of cardiac myosin heavy chain isoforms (MYH6, MYH7, MYH7B) and microRNAs originating from their introns (miR-208a, miR-208b, miR-499 respectively) were analyzed in samples from left ventricular free wall of explanted hearts, using RT-qPCR.

**Results:** The most prominent difference between diabetic and nondiabetic patients was the expected difference in blood glucose (\*\*  $p = 0.002$ ;  $8.7 \pm 4.0$  vs.  $5.8 \pm 1.3$  mmol/l respectively; mean  $\pm$  SD). The only other detected differences were the values of uric acid (\*\*  $p = 0.006$ ;  $610.1 \pm 207.3$  vs.  $450.8 \pm 136.1$   $\mu\text{mol/l}$ ) and urea (\*\*\*)  $p < 0.001$ ;  $11.1 \pm 4.1$  vs.  $7.1 \pm 2.8$ ) contributing to altered metabolic state or perhaps resulting from modulated renal function. All other clinical parameter assessing heart function or blood biochemistry are indistinguishable between the two groups of patients. The same applies also for the indifference in gene expression of myosin heavy chain isoforms MYH6, MYH7, MYH7B and their innate microRNAs (miR-208a, -208b, -499).

**Conclusion:** In terminal stage of failing heart there is no clinical parameter, that would indicate even more deteriorate heart function in diabetic patients then it is all ready damaged in nondiabetic counterparts. The same is true also for gene expression of main motor proteins, cardiac myosin heavy chain isoforms and their innate regulatory microRNAs. Our results show that currently there is no indicator for deterioration of cardiac function in patient with diabetes in the terminal stage of heart failure.

**Head to head comparison of inflammatory and metabolic biomarkers for the long-term prediction of new onset left ventricular diastolic dysfunction in type 2 diabetes patients**

**E. Fousteris**<sup>1</sup>, A. Theodosis-Georgilas<sup>2</sup>, A. Destounis<sup>2</sup>, T. Mousiamas<sup>2</sup>, A. Aggelidi<sup>1</sup>, S. Matsaggos<sup>3</sup>, P. Spiropoulou<sup>3</sup>, S. Foussas<sup>2</sup>, E. Boutati<sup>4</sup>, G. Dimitriadis<sup>4</sup>, S. Iraklianos<sup>1</sup>, A. Melidonis<sup>1</sup>;

<sup>1</sup>Diabetes Center, Tzanio General Hospital of Piraeus,

<sup>2</sup>Cardiology Department, Tzanio General Hospital of Piraeus,

<sup>3</sup>Blood Bank Service, Tzanio General Hospital of Piraeus,

<sup>4</sup>2nd Department of Internal Medicine, Research Institute and Diabetes Center, Attikon University Hospital, Athens, Greece.

**Background and aims:** Left ventricular diastolic dysfunction in patients with diabetes is commonly used as an imaging finding of diabetic cardiomyopathy in the absence of other etiological factors. With this 48month prospective study we investigated the predictive value of the classic and novel biomarkers on the new onset left ventricular diastolic dysfunction in type 2 diabetes patients.

**Materials and methods:** We recruited 48 type 2 diabetes patients (45.83% males) of mean age  $55.45 \pm 10.13$  years with mean duration of diabetes  $2.81 \pm 2.50$  years with normal both systolic and diastolic cardiac function. Exclusion criteria were systolic or diastolic cardiac impairment, coronary heart disease, arrhythmias or valvular diseases and history of other chronic inflammatory states (e.g. COPD or autoimmune diseases). All recruits were examined annually for 4 years for: BMI, FPG, HbA1c, eGFR, lipidemic profile, aminotransferases, uric acid, BNP, hs-CRP, fibrinogen and the newer inflammatory biomarker soluble ST2. Complete echocardiograms at same time points revealed those that switched from normal to impaired diastolic function, according to the latest A.H.A./E.S.C. criteria.

**Results:** Left ventricular diastolic dysfunction (impaired relaxation pattern) was present at the 54.17% of our sample by the end of the study (switchers). The remaining 45.83% preserved their normal cardiac function (non switchers) throughout the 48month observation period. Statistical significant differences between switchers - non switchers were found only for: BMI ( $31.0 \pm 4.7$  vs  $27.5 \pm 5.0$ ,  $p=0.024$ ), FPG ( $148 \pm 35$  vs  $125 \pm 36$ ,  $p=0.011$ ), HDL-C ( $42 \pm 10$  vs  $52 \pm 19$ ,  $p=0.041$ ), triglycerides ( $139 \pm 35$  vs  $106 \pm 64$ ,  $p=0.034$ ), uric acid ( $6.3 \pm 1.4$  vs  $5.0 \pm 1.4$ ,  $p=0.008$ ) and hs-CRP ( $7.9 \pm 7.1$  vs  $2.8 \pm 3.2$ ,  $p=0.011$ ). No correlation was found with the rest of the study parameters. Mean serum soluble ST2 for switchers was  $11.5 \pm 3.4$  ng/mL while for non switchers  $11.0 \pm 2.4$  ng/mL ( $p=0.58$ ). Multivariate regression analysis revealed hs-CRP and triglycerides as the only study parameters that can predict the new onset of left ventricular diastolic dysfunction in our type 2 diabetes population.

**Conclusion:** High sensitivity CRP along with triglycerides act as independent predictive biomarkers for the instatement of new onset left ventricular diastolic dysfunction in type 2 diabetes patients, pattern not proven for the soluble ST2, fibrinogen, BNP and other metabolic parameters.

#### Protective effect of telomere length in patients with type 2 diabetes mellitus

E.N. Dudinskaya<sup>1</sup>, N.V. Brailova<sup>1</sup>, I.D. Strazhesko<sup>1</sup>, O.N. Tkacheva<sup>1</sup>, S.A. Boytsov<sup>1</sup>, M.V. Shestakova<sup>2</sup>;

<sup>1</sup>National Research Centre for Preventive Medicine,

<sup>2</sup>National Research Center for Endocrinology, Moscow, Russian Federation.

**Background and aims:** Type 2 diabetes mellitus (T2DM) is the primary risk marker influencing risk of cardiovascular disease. It is known that telomere length (TL) shortening is a marker of cell aging and associated with increased arterial stiffness (AS) in patients with T2DM, despite the patient's age, leading to the vascular aging. The aim of the study was to compare the vascular and cellular aging in patients with and without T2DM.

**Materials and methods:** TL was assessed by quantitative polymerase chain reaction (PCR) in 98 patients with T2DM (mean age 61±2,6 years) and in 101 healthy patients in mean age of 51±1,8 years. Intima media thickness (IMT) and plaque presence (PP) were determined by ultrasonography in both left and right carotid arteries. AS was appreciated by aortic pulse wave velocity (PWV) measuring by SphygmoCor (AtCor Medical).

**Results:** The median of telomere length (TLL) was 9,75. «Short» telomeres were considered if the telomere length was 9.75. All patients were divided into 4 groups by TL - "long" (T2DM+ (n=57) and T2DM- (n=49)) and "short" telomeres ((T2DM+ (n=41) and T2DM- (n=52)). Comparison of vascular aging parameters in patients with long telomeres showed that the state of vessels in T2DM were as similar as in healthy people - they had a lower arterial stiffness and other signs of vascular ageing : PWV 10,58±0,1 (T2DM+) vs 10,5±0,5 m/s (T2DM-), p=0,913; IMT 0,904±0,09 (T2DM+) vs 0,77±0,03 mm (T2DM-), p=0,1227; PP 0,886±0,4 (T2DM+) vs 0,782±0,2 (T2DM-), p=0,979. In contrast in patients with «short» TL and DM PWV was significantly higher than in non-diabetic people (15,08±1.3 vs 10,7±0.5 m/s, p=0,0151), there were greater number of plaques (1.125±0,29 vs 0,789±0,22, p=.04); IMT was 0,87±0,1 (T2DM+) vs 0,78±0,1 mm (T2DM-), p=0,1814.

**Conclusion:** In patients with short TL and T2DM the severity of vascular disorders is higher than in healthy people. In contrast, in patients with long TL with T2DM there are no significant differences in the vascular structure as compared with healthy individuals. Despite the presence of T2DM signs of vascular aging are minimal in patients with long TL. Short TL may be regarded as non-hemodynamic components of rapid vascular ageing in patients with T2DM.

### 1242

#### Sleep apnoea syndrome and type 1 diabetes: impact on macroangiopathies

J.-P. Courrèges<sup>1</sup>, E. Ghanassia<sup>2</sup>, A. Iosup<sup>1</sup>, J.-F. Thuan<sup>1</sup>, P. Fisher<sup>2</sup>, H. Bonnaure<sup>1</sup>, N. Vigier-Simmore<sup>1</sup>;

<sup>1</sup>Centre Hospitalier Général de Narbonne,

<sup>2</sup>Clinique Sainte Marguerite, Sète, France.

**Background and aims:** Sleep Apnoea Syndrome (SAS) is an independent cardiovascular morbi-mortality factor that is undoubtedly enhanced when associated with T1D. The aim of this study is to assess prevalence and profile of macroangiopathies in this situation (T1D + SAS), more precisely blood pressure and potential conduction defects (QT interval).

**Materials and methods:** SAS was found in 28 patients (20.7%) from a 135 T1D cohort consecutively enrolled with Apnoea Hypopnoea Index (AHI) ≥15/h confirmed with polysomnography. Among them, respectively 50% and 50% suffer from severe (AHI≥30/h) or moderate (AHI≥ 15 ≤29/h) SAS.

**Results:** Patients' characteristics at enrolment were: age 64 ± 12.9 years, diabetes duration 27.1 ± 13.7 years, 75% of males, HbA1c 8.0 ± 1.0% (39.3% with HbA1c≤7.5%), weight: 75.2 ± 18.8kg, BMI : 26.5 ± 5.8 kg/m<sup>2</sup> (50% lower than 25kg/m<sup>2</sup>, 21.4% between 25 and 26.9kg/m<sup>2</sup> et 28.6% higher than 27 kg/m<sup>2</sup>). Among them, 21 patients (75% of SAS T1D and 15.5% of all T1D) show at least one macroangiopathic damage (MA+): 8 coronaritis, 15 carotid damages, 13 lower limb arteriopathy). MA+ patients were compared to MA- patients on HbA1c (8.0 vs 8.0%), BMI (27.2 vs 24.7 kg/m<sup>2</sup>), creatinemia (10.4 vs 8.2mg/l), total cholesterol (1.8 vs 2.1g/l), triglyceride level (1.4 vs 0.6g/l), neuropathy

frequency (81 vs 57.1%), nicotine addiction frequency (14.3 vs 0%), Hypoxia (AHI : 30.4 vs 23.9/h ; 57.1 vs 28.6% of severe SAS and 42.9 vs 71.4% of moderate SAS). We have also studied blood pressure (SBP : 126.5 ± 15.3 vs 126.4 ± 15.5mmHg/DBP : 75.6 ± 7.7 vs 73.6 ± 10.3mmHg), Mean Arterial Pressure (MAP: 93.9 ± 9.2 vs 97.0 ± 3.0mmHg) and Pulse Pressure (PP: 50.9 ± 17.2 vs 55.0 ± 13.8mmHg). The electrocardiogram of MA+ patients shows mean QT and QTC intervals of 401.2 ± 42.5 et 414.9 ± 22.4 mm/s while the one of a 22 patients control group (C) with no SAS and no macroangiopathy shows mean QT and QTC intervals of 382.9 ± 22.5 et 398.8 ± 12.7 mm/s. There is a significant difference in QTC intervals (p = 0.012). No heart rhythm disorder is observed. SBP, DBP, MAP and PP have been compared too (SBP: 126.5 ± 15.3 vs 124.7 ± 11.4 mmHg - NS; DBP: 75.6 ± 7.7 vs 72.5 ± 9.4 mmHg - NS; MAP : 93.9 ± 9.2 vs 89.8 ± 9.4 mmHg - NS; PP : 50.9 ± 17.2 vs 52.2 ± 7.7mmHg - NS). The median QTC interval stands respectively (MA+ vs C) at 409 vs 396 mm/s; the proportion of patients with QTC interval longer than 430 mm/s is 14.3 vs 0%. **Conclusion:** The frequency of SAS in T1D patients is high and this population often suffers from macroangiopathies. The study of T1D with SAS and macroangiopathy underlines a high frequency of associated neuropathy. The comparison between this group and a control group with no SAS and no macroangiopathy shows no difference in usual blood pressure characteristics. On the contrary, the study of QT (and particularly QTC) interval shows a significant lengthening. Referring to its potential implication in rhythm damage, it has to be systematically assessed in this context.

### 1243

#### Presence of type 2 diabetes mellitus significantly modulates the power of thyroid stimulating hormone to predict cardiovascular mortality

E. Kinz<sup>1,2</sup>, A. Vonbank<sup>3</sup>, C.H. Saelly<sup>3,2</sup>, D. Zanolin<sup>1,2</sup>, P. Rein<sup>3</sup>, H. Drexler<sup>3,4</sup>;

<sup>1</sup>VIVIT Institute, Feldkirch, Austria,

<sup>2</sup>Private University of the Principality of Liechtenstein, Triesen,

Liechtenstein, <sup>3</sup>Academic Teaching Hospital Feldkirch, Austria,

<sup>4</sup>Drexel University College of Medicine, Philadelphia, USA.

**Background and aims:** Elevated thyroid stimulating hormone (TSH) is associated with an adverse cardiovascular risk profile, especially in patients with type 2 diabetes (T2DM). We investigated the association between TSH and cardiovascular mortality in patients with T2DM as well as in non-diabetic subjects.

**Materials and methods:** We measured TSH in a high-risk cohort of 1741 consecutive patients undergoing coronary angiography for the evaluation of established or suspected coronary artery disease (CAD). The incidence of vascular events was recorded over 10 years; T2DM was defined according to current ADA criteria.

**Results:** From our patients, 34% suffered vascular events. TSH proved to be a strong and independent predictor of cardiovascular mortality in subjects without T2DM (n=1220; standardized adjusted hazard ratio (HR) 1.11 [1.00-1.24]; p=0.036), but not in patients with T2DM (n=521; HR 0.99 [0.87-1.14]; p=0.934). An interaction term TSH x T2DM was significant (p=0.039), indicating that TSH was a significantly stronger predictor of vascular events in subjects without T2DM than in patients without T2DM.

**Conclusion:** From the data of this prospective cohort study we conclude that presence of T2DM significantly modulates the power of TSH to predict cardiovascular mortality.

#### Is it possible to improve the prediction of silent myocardial ischaemia in type 1 diabetes?

G. Llauradó<sup>1</sup>, A. Cano<sup>2</sup>, C. Hernández<sup>3</sup>, A. Rodríguez-Revuelto<sup>4</sup>, M. González-Sastre<sup>5</sup>, J. Puntí<sup>6</sup>, L. Albert<sup>2</sup>, R. Simó<sup>3</sup>, J. Vendrell<sup>1</sup>, J.M. González-Clemente<sup>2</sup>;

<sup>1</sup>Endocrinology and Diabetes Unit, CIBERDEM. Hospital Universitari Joan XXIII de Tarragona. IISPV. Universitat Rovira i Virgili, <sup>2</sup>Endocrinology

and Nutrition Department, Hospital de Sabadell. Corporació Sanitària i

Universitària Parc Taulí (UAB), <sup>3</sup>Diabetes and Metabolism Research Unit.

CIBERDEM. Institut de Recerca Hospital Universitari Vall d'Hebron.

Universitat Autònoma de Barcelona, <sup>4</sup>Nuclear Medicine Department, UDIAT

Centre Diagnòstic. Corporació Sanitària i Universitària Parc Taulí (UAB),

Sabadell, <sup>5</sup>Ophthalmology Department, <sup>6</sup>Cardiology Department, Hospital

de Sabadell. Corporació Sanitària i Universitària Parc Taulí (UAB), Spain.

**Background and aims:** Cardiovascular disease (CVD) is the major cause of mortality in type 1 diabetes (T1DM). Given the higher prevalence of silent

myocardial ischemia (SMI) in this population, the need to screen asymptomatic T1DM patients assumes increasing importance. The aims of this study were: 1) to assess the prevalence of SMI in asymptomatic patients with T1DM, 2) to evaluate the clinical predictors associated with its presence, including the evaluation of microvascular complications and the assessment of arterial stiffness (AS) (as a measurement of pre-clinic arteriosclerosis) and 3) to evaluate the diagnostic value of the previous established criteria for its diagnosis (ADA 1998) and how to improve them.

**Materials and methods:** 80 patients with T1DM (without previous history of CVD) were screened for SMI by stress myocardial perfusion gated-SPECT (Single Photon Emission Computed Tomography). Data on traditional cardiovascular risk factors and microvascular complications were also recorded. AS was assessed by aortic pulse wave velocity (aPWV - Sphygmocor®).

**Results:** The baseline characteristics of the patients included in the study are shown in Table 1. The prevalence of SMI was 12.5%. SMI was associated with the presence of hypertension (OR 4.5 (95%CI 1.1–18.9);  $p=0.041$ ) and HbA1c value (OR 2.4 (95%CI 1.1–5.0);  $p=0.023$ ). The ADA criteria for the screening of SMI showed a good predictive value (OR 8.3 (95%CI 1.7–40.6);  $p=0.009$ , AUC 0.73 (0.54–0.91)). However, the addition of HbA1c value (AUC 0.87 (0.75–0.99) vs. 0.73 (0.54–0.93);  $p=0.034$ ) and the presence of diabetic retinopathy (AUC 0.86 (0.74–0.98) vs. 0.73 (0.54–0.92);  $p=0.057$ ) improved the predictive value, thus resulting in the best model of SMI prediction (AUC 0.91 (0.83–0.99) vs. 0.73 (0.54–0.92);  $p=0.026$ ). aPWV did not add any significant improvement for SMI identification ( $p=0.583$ ).

**Conclusion:** The prevalence of SMI in patients with T1DM without previous CVD is 12.5%. Although The ADA criteria for the screening of SMI predicted its presence adequately, adding HbA1c and taking into account the presence of diabetic retinopathy significantly improve the prediction rate.

**Table 1. Clinical characteristics of patients with type 1 diabetes.**

| Clinical characteristics                                  | Total (n=80)     | No SMI (n=70)     | SMI (n=10)       | p     |

### Integrative analysis of biomarkers for cardiovascular complications through networks of metabolites and proteins

R.A. Momo<sup>1</sup>, F. Vitali<sup>2</sup>, F. Mulas<sup>3</sup>, V. Schnecke<sup>1</sup>, R. Bellazzi<sup>2</sup>;

<sup>1</sup>Translational Science, AstraZeneca, Mölndal, Sweden, <sup>2</sup>Dipartimento di Ingegneria Industriale e dell'Informazione, <sup>3</sup>Centro Interdipartimentale di Ingegneria Tissutale, Università degli Studi di Pavia, Italy.

**Background and aims:** The SUMMIT project (SUrrogate markers for Micro- and Macro-vascular hard endpoints for Innovative diabetes Tools), seeks to identify genetic and non-genetic biomarkers for prediction of disease progression and risk of vascular complications. A collection of samples from different cohorts have been provided by combining a variety of high-throughput techniques encompassing proteomics and metabolomics. Integrative bioinformatics methods that combine different data sources may provide deeper

insights into the molecular interactions underlying complex diseases. Within this context, we constructed a network with proteins and metabolites as nodes whose analysis suggests the most relevant entities involved in the disease pathways.

**Materials and methods:** Starting from a list of SUMMIT-discovered biomarkers, i.e., proteins and metabolites that have been shown to be associated with cardiovascular complications we obtained a disease-related network by combining evidences from different repositories. In detail, STRING, STITCH and MetaCore were used to initially build individual networks that were subsequently merged into a combined network associating the discovered markers to other molecules known to interact with them. Topological analysis of this network has been used to identify enriched biological pathways and mechanisms, and to suggest a set of relevant nodes as candidates for pharmacological therapies.

**Results:** The network representation could elucidate molecules and interactions involved in the disease and better define its global picture. While the different repositories can be used separately to build disease networks, merging these networks provided a better model of the whole disease context. The list of pathways identified as significantly enriched ( $p$ -value < 0.001) contained those related to insulin resistance as well as others that have not previously been identified as potential targets for standard diabetes therapies. For example, the signaling by Insulin-like Growth Factor 1 Receptor (IGF1R) was amongst those identified. This receptor is a negative regulator of insulin signaling and currently has not been taken into account for diabetes therapies. However, it has been shown that cardiac overexpression of IGF-1R in mice prevents diabetes-induced cardiac fibrosis and diastolic dysfunction.

**Conclusion:** We believe that higher integration across different systems biology platforms eases interpretation of discoveries, supports validation of hypothesis and ultimately speeds up the drug discovery process.

### Correlation of inflammatory markers and insulin resistance indexes with the short- and long-term outcome after an acute coronary syndrome in different glycaemic categories

A. Koutsovasilis<sup>1</sup>, A. Papazafiropoulou<sup>1</sup>, A. Sotiropoulos<sup>1</sup>, A. Melidonis<sup>2</sup>, S. Foussas<sup>3</sup>, T. Peppas<sup>1</sup>, E. Tamvakos<sup>1</sup>, S. Bousboulas<sup>1</sup>;

<sup>1</sup>3rd Internal Medicine Department & Diabetes Center, General Hospital of Nikaia-Piraeus, Athens, <sup>2</sup>1st Internal Medicine Department & Diabetes Center, <sup>3</sup>Cardiology Department, Tzanio General Hospital of Piraeus, Greece.

**Background and aims:** The glucose metabolism disorder is frequent in patients who are admitted after an Acute Coronary Syndrome (ACS). The aim of this study is to examine the correlation of ACS outcome with insulin resistance indexes and inflammatory markers in known diabetes patients, newly diagnosed diabetes patients, patients with impaired glucose tolerance (IGT) and normoglycaemic patients.

**Materials and methods:** 536 patients who were admitted at the Cardiology Department within a two-year period were included in the study. All patients underwent a clinical laboratory testing including insulin level in order to measure insulin-resistance indexes (HOMA- Homeostasis Model Assessment and QUICKI- Quantative Insulin Sensitivity Check Index) and inflammatory markers (high-sensitivity C-reactive protein (hs-CRP), white blood cells count (WBC), fibrinogen and erythrocyte sedimentation rate (ESR)). All non diabetic patients went under an oral glucose tolerance test (OGTT) one month after discharge. Study's end-points were death, a new ACS, arrhythmias and acute pulmonary oedema of cardiological origin during hospitalization and 12 months after the ACS.

**Results:** 199 (37.12%) patients were normoglycemic while 168 (31.34%) were known diabetics, 59 (11%) newly diagnosed diabetic patients and 110 (20.52%) were IGT patients. There was a statistically significant correlation of the hs-CRP with the outcome during hospitalization (HR=1.712, 95%CI:1.193–2.458,  $p=0.004$ ) for all patients. hs-CRP (HR=2.612, 95%CI:1.474–4.628,  $p=0.001$ ) and HOMA index (HR=1.967, 95%CI:1.184–3.267,  $p=0.009$ ) were significantly correlated with the appearance of a major cardiovascular event (MACE) during hospitalization for all patients but only hs-CRP was correlated with MACE for each group separately. Complications during the first 12 months after an ACS were significantly correlated only with the hs-CRP for all patient categories. hs-CRP, HOMA and QUICKI indexes were correlated with MACE in a multivariate analysis for known diabetes patients (HR=1.542,  $p=0.023$ , HR=1.482,  $p=0.039$  and HR=0.810,

$p=0.031$  respectively), newly diagnosed diabetes patients (HR=2.401,  $p=0.035$ , HR=1.364,  $p=0.046$ , HR=0.832,  $p=0.041$ ) and IGTs (HR=1.354,  $p=0.023$ , HR=1.269,  $p=0.047$ , HR=0.782,  $p=0.036$ ) 12 months after the ACS. Association of hs-CRP (HR=2.012,  $p=0.008$ ), HOMA (HR=2.438,  $p=0.002$ ) and QUICKI (HR=0.503,  $p=0.010$ ) with MACE was significant in an univariate analysis while only hs-CRP (HR=1.477,  $p=0.032$ ) remained significant in a multivariate analysis for normoglycaemic patients

**Conclusion:** hs-CRP is the inflammation marker which is correlated with the appearance of complications during hospitalization and 12 months after an ACS, while HOMA and QUICKI indexes are correlated with the appearance of major cardiovascular events during hospitalization as well as the 12-month follow-up period regardless of patient glycaemic profile. The combination of these indexes with hs-CR significantly improves the latter's prognostic model in particular regarding major cardiovascular events.

## 1247

### Both DHA/AA ratio and absolute DHA levels, but not EPA levels, constitute an independent risk factor for the severity of coronary atherosclerosis in type 2 diabetic patients

T. Nakamura, K. Murata, R. Kaneko, K. Ikeda;

Omihachiman Medical Community Center, Omihachiman, Shiga, Japan.

**Background and aims:** The concentrations of dietary n-3 polyunsaturated fatty acids (PFAs), such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) modify the incidence of coronary heart disease (CHD). Especially, the effects of EPA on cardiovascular events have been clarified through recent large-scale intervention clinical studies. However, it is still unknown whether DHA may make a contribution to clinical efficacy associated with the risk of CHD. Thus, we investigate which n-3 PFA is more effective on the association of the severity of CHD in type 2 diabetic patients.

**Materials and methods:** 184 type 2 diabetic subjects were nominated as poor blood glucose control from April 2008 to September 2010 and aged 40 to 72 years on this trial. We firstly calculated fasting plasma PFAs, LDL-cholesterol, HDL cholesterol and triglyceride (TG) levels. The subjects were asked about daily intake of different type of fish and n-3 PUFAs intake was calculated using computer food composition software. We excluded the subjects who reported the history of CHD or ECG abnormality consistent with ischemia at baseline survey. Then they had been followed for five years, focusing on the occurrence of major cardiovascular events or ECG abnormality for an observation period, which compromised nonfatal and fatal CHD diagnosed using percutaneous coronary intervention. CHD severity was assessed using the Gensini scoring system. Next, we divided them into 2 groups, who were in the presence of CHD (DM-PCI, N=56) and no episodes of CHD (DM, N=70) and 71 healthy volunteers were nominated (NGT). These values were analyzed using an ANOVA model, Pearson's test and multivariate logistic regression models analyses.

**Results:** The ratios of smokers and subjects with antihypertensive and/or lipid modifying treatment were not significant between DM-PCI and DM. The average of systolic blood pressure, age, BMI, the concentrations of HbA1c, LDL, HDL and TG were no different between two groups. On the contrary, the concentrations of FPG, HbA1c, LDL, TG and remnant like particle (RLP) were significantly lower in NGT than in DM-PCI and DM. Firstly, we investigated the relation between the basal plasma concentrations of both EPA and DHA and daily fish intake was the positive correlation in the diabetic subjects ( $r=0.77$   $p<0.001$ ,  $r=0.61$   $p<0.001$ , respectively). These data indicated the plasma concentrations of PFAs were considered to originate from fish intake. Both EPA/AA and DHA/AA levels in DM-PCI were significantly lower than those in NGT (EPA/AA; 0.31, 0.47  $p<0.001$ , DHA/AA; 0.69, 0.85  $p<0.001$ , respectively) but not significant compared to DM. Although the concentrations of both EPA/AA and DHA/AA in DM-PCI were significantly negative correlation to Gensini score ( $r=0.44$   $p<0.001$ ,  $r=0.50$   $p<0.001$ , respectively), there were no correlation between this score and non-HDL, LDL/HDL, RLP, HbA1c. In multivariate logistic regression model, only DHA/AA ratio increased up to 3.08 (95% CI 1.76-5.89) with statistical value of  $p=0.01$ .

**Conclusion:** A negative correlation was noted between the severity of CHD and DHA/AA ratio in DM-PCI, as same as the absolute values for DHA. In addition, the lower levels of DHA/AA in DM-PCI may show us the evidence that PFAs, especially DHA intake, was inversely and independently associated the severity of CHD.

## 1248

### Association of NLRP3 inflammasome activation and cardiovascular disease risk using Framingham score in patients with newly diagnosed type 2 diabetes mellitus

K. Joung, J. Lee, H. Kim, B. Ku;

Internal Medicine, Endocrinology, Chungnam National University, Daejeon, Republic of Korea.

**Background and aims:** Chronic low-grade inflammation caused by activation of the innate immune system plays an essential role in the pathogenesis of type 2 diabetes and its major complications. Emerging evidence suggests that activation of the nucleotide binding and oligomerization domain-like receptor family pyrin domain-containing 3 (NLRP3) inflammasome leads to the maturation and secretion of interleukin (IL)-1 $\beta$  and is involved in the pathogenic mechanisms of obesity-induced inflammation, insulin resistance, and type 2 diabetes development. In our previous study, NLRP3 inflammasome activation is elevated in myeloid cells from drug-naïve, newly diagnosed type 2 diabetic patients and antidiabetic treatment with metformin contributes to modulation of inflammasome activation. These previous reports prompted us to explore the association of cardiovascular risk and the inflammasome activation in type 2 Diabetes.

**Materials and methods:** We performed a sub-analysis to evaluate the association of cardiovascular risk using the Framingham cardiovascular risk score with the NLRP3 inflammasome activation in 47 diabetic patients.

**Results:** Patients had a male-to-female ratio of 31:16, mean age of  $51.9 \pm 11.8$  years, a mean body mass index of  $25.4 \pm 3.0$  kg/m<sup>2</sup>, a mean HbA1c of  $8.5 \pm 2.3$  %, a mean low density lipoprotein-cholesterol of  $140 \pm 37$  mg/dl, and a mean baseline Framingham risk score of  $7.3 \pm 6.7$  %. Framingham risk score was associated neither relative mRNA expression of NLRP3, apoptosis-associated speck-like protein containing a CARD (ASC) nor production of proinflammatory cytokines regardless of stimulation with lipopolysaccharide (LPS) in monocyte-derived macrophages (MDMs) from the type 2 diabetic patients (Table 1). Also, Framingham score was not correlated with IL-1 $\beta$  secretion in MDMs after stimulation with various danger molecules such as adenosine triphosphate, monosodium uric acid crystals, islet amyloid polypeptides, and free fatty acids. The type 2 diabetic patients with intermediate to high cardiovascular risk (Framingham risk score >10%) did not show the increase of either IL-1 $\beta$  or IL-18 in serum compared to the patients with low risk (Framingham risk score < 5%,  $23.3 \pm 11.5$  vs  $21.3 \pm 16.7$  pg/ml;  $P=0.651$ ,  $34.6 \pm 14.3$  vs  $31.2 \pm 16.5$  pg/ml;  $P=0.530$ ).

**Conclusion:** In conclusion, the NLRP3 inflammasome activation was not associated the cardiovascular risk in the newly diagnosed type 2 diabetes.

Table 1. Association inflammasome activity with Framingham cardiovascular risk score.

**Soluble urokinase plasminogen activator receptor is elevated in diabetes and associated with diabetic complications in patients with type 1 diabetes**S. Theilade<sup>1</sup>, S. Lyngbaek<sup>2</sup>, T.W. Hansen<sup>1</sup>, J. Eugen-Olsen<sup>3</sup>, M. Fenger<sup>4</sup>, P. Rossing<sup>1,5</sup>, J. Jeppesen<sup>2,5</sup>;<sup>1</sup>Steno Diabetes Center, Gentofte, <sup>2</sup>Department of Medicine, Glostrup Hospital, Glostrup, <sup>3</sup>Clinical Research Centre, Hvidovre Hospital,<sup>4</sup>Department of Biochemistry, Hvidovre Hospital,<sup>5</sup>Aarhus University, Denmark.

**Background and aims:** Soluble urokinase plasminogen activator receptor (suPAR) is a marker of inflammation and endothelial dysfunction. We investigate associations between suPAR and diabetic complications in type 1 diabetes.

**Materials and methods:** From 2009–2011, 667 type 1 diabetes patients and 51 non-diabetic control subjects were included in a cross-sectional study at our center. suPAR was measured with ELISA (ViroGates, Denmark). Diabetic complications were cardiovascular disease (CVD) (previous myocardial infarction, revascularisation, peripheral arterial disease and stroke), autonomic dysfunction (heart rate variability during deep breathing < 11 beats per minute), albuminuria (urinary albumin excretion rate (UAER)  $\geq$  30 mg/24-hours) or high arterial stiffness (pulse wave velocity  $\geq$  10 m/s). Adjusted analyses included gender, age, systolic blood pressure, estimated glomerular filtration rate, UAER, HbA<sub>1c</sub>, total-cholesterol, body mass index, C-reactive protein, antihypertensive treatment and smoking.

**Results:** suPAR was lower in controls vs. patients, controls vs. normoalbuminuric patients (< 30 mg/24-hours), normoalbuminuric patients with short vs. long diabetes duration (> 10 years), and increased with degree of albuminuria (adjusted  $p < 0.001$  for all). Furthermore, suPAR levels were higher in patients with vs. without CVD ( $n = 144$  (21.3%)), autonomic dysfunction ( $n = 349$  (59.2%)), albuminuria ( $n = 357$  (53.1%)) and high arterial stiffness ( $n = 297$  (47.2%)) (adjusted  $p \leq 0.024$ ). Per 1 unit increase in ln-suPAR adjusted odds ratios were for CVD: 2.5 (1.1–5.7), autonomic dysfunction: 2.7 (1.2–6.2), albuminuria: 3.8 (1.3–10.9) and high arterial stiffness: (2.5 (1.1–6.1) ( $p \leq 0.039$ )).

**Conclusion:** suPAR is associated with type 1 diabetes, diabetes duration and complications independently of other risk factors. suPAR may be a novel risk marker in the management of diabetes.

**The role of glucagon in post-prandial hyperglycaemia for children 5 years after onset of type 1 diabetes**S. Fredheim<sup>1,2</sup>, M.L.M. Andersen<sup>1</sup>, S. Pørksen<sup>1</sup>, L.B. Nielsen<sup>1</sup>, C. Pipper<sup>3</sup>, L. Hansen<sup>1</sup>, J. Johannesen<sup>1,2</sup>, H.B. Mortensen<sup>1,2</sup>, J. Svensson<sup>1,2</sup>;<sup>1</sup>Pediatric Department, Herlev Hospital, <sup>2</sup>Copenhagen University,<sup>3</sup>Department of Biostatistics, Copenhagen University, Denmark.

**Background and aims:** The role of glucagon on glycemic control in type 1 diabetes is debated, and high glucose concentrations have previously been shown to increase glucagon release. We investigated stimulated glucagon and glucagon-like peptide-1 (GLP-1) levels in children during 12 to 60 months after onset of type 1 diabetes.

**Materials and methods:** The study cohort comprised 129 children (66 boys) mean (SD) age at onset; 10.04 (3.9) range 0.6–16.6 years with newly diagnosed type 1 diabetes. Liquid mixed-meal (Boost) stimulated levels of C-peptide, glucagon, glucagon-like peptide-1 (GLP-1), gastric inhibitory polypeptide (GIP), blood glucose (measured 90 min post-ingestion of Boost drink), and HbA<sub>1c</sub> (DCCT), were analysed centrally 1, 3, 6, 12 and ( $N=40$ ) 60 months (m) after diagnosis. Robust multivariate regression methods were used for statistical analyses. Results are listed as RR [95% CI] corresponding to a doubling of the explanatory variable. Analyses were adjusted for age, sex, diabetes duration and stimulated C-peptide.

**Results:** During the 60 months, post-prandial glucagon levels were highly associated to the rise in stimulated GLP-1 (RR 1.33 [1.19; 1.48],  $p < 0.0001$ ) and stimulated blood glucose levels (1.36 [1.19; 1.56],  $p < 0.0001$ ). Post-prandial glucagon was negatively associated to stimulated C-peptide at 3 (RR 0.94, [0.89; 0.99],  $p = 0.019$ ), 6 (RR 0.91 [0.87; 0.95],  $p < 0.0001$ ) and 12 months ((RR 0.94, [0.90; 0.99],  $p = 0.021$ ), when residual beta-cell function is present), but no association existed 60 months post-diagnosis. HbA<sub>1c</sub> associated significantly to post-prandial glucagon levels (RR 1.03, [1.01; 1.05],  $p = 0.003$ ). A doubling of post-prandial glucagon levels corresponded to a 3% relative increase in HbA<sub>1c</sub> levels. Furthermore, HbA<sub>1c</sub> levels were negatively associated to stimulated C-peptide at 3 ( $p < 0.0001$ ), 6 ( $p < 0.0001$ ) and 12 months ( $p < 0.0001$ ), but not 60 months post-diagnosis.

**Conclusion:** Post-prandial glucagon levels were highly associated with worsening of glycaemic control and blood glucose levels during the first 60 months after diagnosis. This suggests that elevated glucagon augmented hyperglycaemia (HbA<sub>1c</sub>) observed in the time period. The positive association with GLP-1 suggests that physiologic levels of GLP-1 levels are insufficient to constrain glucagon.

## 1251

**Disease management and outcomes in European children, adolescents, and young adults with type 1 diabetes (T1D): the global TEENs study**M. Phillip<sup>1</sup>, L. Laffel<sup>2</sup>, C. Domenger<sup>3</sup>, V. Pilorget<sup>4</sup>, C. Candelas<sup>4</sup>, T. Danne<sup>5</sup>, C. Mazza<sup>6</sup>, B. Anderson<sup>7</sup>, R. Hanas<sup>8</sup>, S. Waldron<sup>9</sup>, R. Beck<sup>10</sup>, C. Mathieu<sup>11</sup>;<sup>1</sup>Schneider Children's Medical Center of Israel, Petah Tikva, Israel,<sup>2</sup>Joslin Diabetes Center, Boston, USA, <sup>3</sup>Sanofi, Paris, <sup>4</sup>Sanofi, ChillyMazarin, France, <sup>5</sup>Kinder und Jugendkrankenhaus "Auf der Bult",Hannover, Germany, <sup>6</sup>Hospital de Pediatría J P Garrahan, Buenos Aires,Argentina, <sup>7</sup>Baylor College of Medicine, Houston, USA, <sup>8</sup>GothenburgUniversity, Sweden, <sup>9</sup>Hosted by West Midlands Strategic Clinical Network,Birmingham, UK, <sup>10</sup>Jaeb Center for Health Research, Tampa, USA,<sup>11</sup>University Hospitals (UZ), Leuven, Belgium.

**Background and aims:** TEENs is the largest contemporary, international, cross-sectional study of young T1D patients ( $N=5,960$ ), aiming to identify approaches to optimise glycaemic control and outcomes. Data from the European cohort ( $n=2,943$ ; 49.4% of the global population) are reported.

**Materials and methods:** Of the 219 TEENs centres from 20 countries, 111 centres from 11 European countries (Denmark, France, Germany, Hungary, Italy, Portugal, Romania, Russia, Slovenia, Spain and Sweden) participated. Data were collected by patient interview, medical record review, and patient/parent survey from three age groups: children (8–12 years old [y/o]), adolescents (13–18 y/o), and young adults (19–25 y/o). A1c was measured uniformly (reference range 4–6%) using A1cNow™ (Bayer). Target A1c levels were cat-

egorised as <7.5% (58 mmol/mol) for patients ≤18 years of age (ISPAD) and <7% (53 mmol/mol) for patients 19–25 years of age (ADA). Patients aged 13–18 and 19–25 y/o completed the Problem Areas In Diabetes (PAID) questionnaire; parents of youth aged 8–12 and 13–18 y/o completed the PAID parent-revised (PAID-PR) version. Scores on each survey range from 0 to 100; higher scores indicate greater disease burden.

**Results:** Median (interquartile range) time since T1D diagnosis was 6.5 years (3.7–9.9). Overall mean (±SD) A1c was 8.1±1.6% (65±18 mmol/mol), with 35% of patients attaining A1c targets. Treatment characteristics and diabetes management methods by age group and A1c target attainment as well as treatment burden by age group are shown (Table).

**Conclusion:** In a sample of 8–25-year-olds with T1D from 11 European countries, A1c was suboptimal and approximately one third of patients achieved targets. In the TEENs study, European patients at target tended to receive more intensive management than those not at target, especially patients aged 8–18. Parents/guardians reported a significantly higher perceived burden of care compared with adolescents. Thus, opportunities exist to improve A1c outcomes and reduce burden of disease for youth with T1D.

### High and increasing prevalence of diabetic ketoacidosis at diagnosis of type 1 diabetes in children, Colorado, 1998–2012

A. Rewers, F. Dong, R. Slover, G. Klingensmith, M. Rewers; Pediatrics, University of Colorado, Aurora, USA.

**Background and aims:** Diabetic ketoacidosis (DKA) at the time of diagnosis of childhood diabetes is life-threatening and has a detrimental effect on the future course of the disease. Frequency of DKA reflects access to care and indicates the level of children's health in a country. The aim of this study was to analyze time trends in DKA at diagnosis of childhood diabetes in Colorado during 1998–2012 and to explore modifiable risk factors.

**Materials and methods:** A prospective registry of children diagnosed with diabetes before 18 y of age during 1998–2012 and treated at the Barbara Davis Center for Childhood Diabetes in Denver, CO. A total of 4989 children were registered, including 3544 diagnosed with type 1 diabetes and residing in Colorado at the time of diagnosis. The main outcome measure was prevalence of DKA at the time of diagnosis of diabetes.

**Results:** The prevalence of DKA increased significantly from 29.9% in 1998 to 46.2% in 2012 ( $p < .001$  for trend); the most rapid increase occurred between 2007 and 2012. DKA was most likely to occur at diagnosis among the youngest children and those of African-American ancestry. Family history of diabetes, especially type 1 diabetes among 1st degree relatives, was protective as was participation in research studies following children at high genetic risk. Coverage by a private health insurance (OR=0.37; 0.29–0.49) or a government-provided one (OR=0.63; 0.51–0.81), was associated with a lower likelihood of DKA, compared to no insurance. The number of children covered by government-provided health insurance has doubled and their DKA rates continue to be high. In addition, DKA is rapidly increasing among children with private health insurance.

**Conclusion:** The rapid and unabated increase in the prevalence of DKA at diagnosis of childhood type 1 diabetes suggests a major worsening in early recognition of diabetic symptoms and also in access to appropriate health care among Colorado children over the past 15 years. The frequency of DKA has increased to the levels rarely seen in developed countries.

Pediatrics, Brotzu H., Cagliari, <sup>9</sup>Dept of Pediatrics, 2nd University of Naples,

<sup>10</sup>Endocrinology and Diabetology Unit, Bambino Gesù Children's H., Rome,

<sup>11</sup>Dept of Pediatrics, Sacco H., Milan, <sup>12</sup>Pediatric Diabetology Unit, Meyer

Children's H., Florence, <sup>13</sup>Dept of Pediatrics, University of Chieti, <sup>14</sup>

<sup>14</sup>Dept of Pediatrics, University of Turin, Italy.

**Background and aims:** Italian children with T1DM are usually followed by pediatric diabetologists. Since recent data on epidemiology and management of primary diabetic ketoacidosis in children with T1DM are lacking a questionnaire was sent to the 77 centres belonging to the study group of diabetology of the Italian Society for Pediatric Diabetology and Endocrinology (ISPED) enquiring on epidemiology (2012–2013) and present management of DKA.

**Materials and methods:** From 1/1/2012 to 31/12/2013 a survey on DKA was conducted in all pediatric Centres belonging to the ISPED. Presence DKA was defined according to the IDF/ISPAD criteria. The following data were collected: treatment according IDF/ISPAD protocol yes or not, type of rehydrating solution used, bicarbonates use yes or not and amount of insulin infused.

**Results:** Data were returned from 68/77 Centres (87%) for a total of 14,493 patients with T1D. We recorded 2453 children with T1DM onset, with DKA in 945 (38.5%) (severe in 10.3%). Considering only preschool children DKA was observed in 72% (severe in 16.6%). Cerebral oedema following DKA treatment was observed in 5 cases (0.5%). DKA treatment according ISPAD guidelines was adopted in 67% of the Centres, while 11% did not follow any specific guidelines. In the first 1–2 hours, rehydration was started with normal saline, at different rates: 5–10 ml/kg/h in 71%, 10–20 ml/kg/h in 16%, <5 ml/kg/h in 4%. After the first hours, differences among Centres were observed regarding the type of solutions used: saline 0.9–0.45% in 75%, 5–10% glucose solution in 19%, irrespective of glycemic values. Potassium supplementation was performed at the rate of 20–40 mEq/l in 63% of Centres. Bicarbonates were never used in 17% of Centres, while in 68% were exceptionally used according to pH and clinical conditions. Insulin was infused starting from 2<sup>nd</sup>–3<sup>rd</sup> hour at the rate of 0.05–0.1 U/kg/h in 63% of Centres, while others used infusion rate lowest as 0.025 U/kg/h.

**Conclusion:** Notwithstanding prevention campaign, DKA is still observed at clinical diabetes onset in Italian children. Despite international guidelines significant variability in DKA treatment still exists, underlying the need to share them among Centres. In Italy cerebral edema is a rare complication of DKA.

## 1254

### Investigation of cerebrovascular changes in type 1 diabetic children and adolescents with transcranial Doppler ultrasound

A. Török<sup>1</sup>, R. Lovász<sup>2</sup>, A. Valikovics<sup>2</sup>, L. Barkai<sup>1</sup>;

<sup>1</sup>Postgraduate Institute of Pediatrics, University of Debrecen, <sup>2</sup>Department of Neurology, Borsod County Teaching Hospital, Miskolc, Hungary.

**Background and aims:** It is a well-known fact that diabetes (both type 1 and type 2) play a significant role in developing ischemic stroke in adults. Despite the fact that the prevalence of type 1 diabetes is rising among children and adolescents very few attention is paid to the cerebrovascular complication caused by this disease. Our aim was to measure the possible effect of dia-

betes on the cerebrovascular system with a simple, non-invasive method the transcranial Doppler sonography.

**Materials and methods:** We performed transcranial Doppler sonography in 62 type 1 diabetic patients (older than 10 years of age, mean  $14.59 \pm 2.46$  years) treated in our hospital and 46 (mean age  $13.66 \pm 2.06$ ) healthy children served as controls. We examined the middle cerebral arteries in both sides in lying position during rest by registering the velocities (peak systolic and end diastolic). Then we asked the children to stop their breathing as long as they can (but at least for 30 seconds) to increase the PCO<sub>2</sub> which led to vasodilatation. After a short period of resting period came the decreasing of PCO<sub>2</sub> (causing vasoconstriction) by asking the children to take deep breaths for 30 seconds. After collecting these data we calculated the pulsatility index ((systolic velocity-diastolic velocity)/mean velocity) and resistive index ((systolic velocity-diastolic velocity)/systolic velocity) in all the 3 cases.

**Results:** The Kolmogorov-Smirnov test showed that all of the investigated variables showed normal distribution thus two-tailed t tests could be performed to find statistical differences between diabetic patients and control group. After processing the data we can conclude that the diabetic group showed lower values in all investigated variables. The strongest difference ( $p=0.0214$ ) could be found in the peak systolic velocities after hyperventilation (82.8 cm/s vs. 91.8 cm/s). An other significant ( $p=0.0401$ ) difference was detected in the peak systolic velocities after hypoventilation (136.6 cm/s vs. 146.5 cm/s), while all other findings proved to be non-significant.

**Conclusion:** The fact that all measured velocities were lower among diabetic children and adolescents suggests that some kind of pathophysiological changes must have been started among these patients and this harmful influence would proceed and would be responsible for the further well-known effects among adults. We assume that the first phase of this process affects the response for the „CO<sub>2</sub> challenge“, that's why the peak systolic velocities are influenced after both hypo- and hyperventilation. Besides raising the number of performing transcranial Doppler sonography we are working on identification of factors which can play a role forming the changes among our patients.

## 1255

### 40 year follow up of childhood onset diabetes reveals little long-term decline in the cumulative incidence of complications by diagnosis cohort except for renal failure

T. Orchard, T. Costacou, R.G. Miller;

Department of Epidemiology, University of Pittsburgh, USA.

**Background and aims:** Despite dramatic improvements in life expectancy, morbidity rates in type 1 diabetes (T1D) still greatly exceed those of the general population. To evaluate trends, by year of diagnosis, in the cumulative incidence of micro- and macro-vascular complications over 22 years of follow-up, the prospective, observational, Pittsburgh Epidemiology of Diabetes Complications (EDC) study of childhood-onset T1D study was examined.

**Materials and methods:** Participants were categorized into five calendar year onset cohorts: 1950-59, 1960-64, 1965-69, 1970-74, and 1975-80. Renal failure (RF, self-report), hard coronary artery disease (CAD; MI, fatal CAD and revascularization), blindness (self-report) and amputations (self-report) were determined at 20, 25, 30, 35 and 40 years duration on the complete cohort (n=912). Proliferative retinopathy (PR; fundus photography), confirmed distal symmetric polyneuropathy (CDSP; clinical exam plus vibratron threshold), symptomatic autonomic neuropathy (SAN; 2+ symptoms and expiration/inspiration ratio <0.1), Lower Extremity Arterial Disease (LEAD; Ankle Brachial Index <0.9/amputation/intermittent claudication) and overt nephropathy (ON; albumin excretion rate >200 µg/min), were assessed at 20, 25, 30, and 35 years' duration on the subset of participants with a clinical examination (n=658).

**Results:** There was a marked decline in the cumulative incidence of RF across diagnosis cohorts at all durations ( $p<0.01$ - $<0.001$ ). An early decline in blindness in those more recently diagnosed at 20 years duration ( $p<0.001$ ) was no longer apparent at 30 or 40 years duration ( $p>0.6$ ). CAD showed a small decline at 30 years across cohorts ( $p<0.03$ ) which was less marked at 40 years ( $p=0.07$ ). Amputations, PR, LEAD, ON, CDSP and SAN showed no diagnosis cohort declines except for CDSP at 20 years alone ( $p=0.04$ ).

**Conclusion:** These data suggest that the cumulative incidences of T1D complications are not declining universally although a strong decline in RF is apparent which may represent better management of renal disease rather than prevention.

### Type 2 diabetes and associated complications in Western Australian children: a population based study (1990 - 2012)

A. Haynes<sup>1,2</sup>, R. Kalic<sup>1</sup>, J. Curran<sup>1</sup>, N. Paramalingam<sup>1,2</sup>, M.K. Bulsara<sup>3</sup>, M. Shah<sup>1</sup>, T.W. Jones<sup>1,2</sup>, E.A. Davis<sup>1,2</sup>;

<sup>1</sup>Department of Endocrinology & Diabetes, Princess Margaret Hospital, Perth, <sup>2</sup>Telethon Kids Institute, Perth, <sup>3</sup>Institute of Health and Rehabilitation Research, Fremantle, Australia.

**Background and aims:** Data on childhood diabetes are available from the Western Australian Children's Diabetes Database (WACDD), maintained by the only tertiary paediatric hospital in Western Australia servicing all children diagnosed with diabetes throughout the State. This study aimed to describe the incidence of type 2 diabetes in Western Australian children and examine the prevalence of complications of diabetes.

**Materials and methods:** The study included children aged 0-16 years diagnosed with type 2 diabetes at our hospital, between 1990 to 2012, in a population-based sample. Incidence rates per 100,000 person-years at risk were calculated by Indigenous status and year of diagnosis. Mean ( $\pm$ SD) were estimated for age, BMI Z-score and HbA<sub>1c</sub> at diagnosis. Prevalence of microalbuminuria and hypertension were evaluated for patients at different time points for all available complications screening data.

**Results:** From 1990 to 2012, there were 135 (82 F:53 M) incident cases of type 2 diabetes in children aged <17 years. Although Indigenous children make up ~6% of the general population, they were grossly over-represented, accounting for 56% of cases. The mean incidence of type 2 diabetes was 0.6 per 100,000 (95%CI: 0.5-0.8) in non-Indigenous children compared to 12.6 per 100,000 (95%CI: 10.0-15.8) in Indigenous children. The mean age at diagnosis was  $13.3(\pm 2.0)$  years. At diagnosis, the mean BMI Z-score was  $2.0(\pm 0.6)$ , with 12% of cases classified as being overweight and 61% obese. Mean HbA<sub>1c</sub> at diagnosis was  $9.0(\pm 2.8\%)$  compared to  $7.7(\pm 2.5\%)$  3-12 months post-diagnosis. Hypertension was observed in 15/75 (20%) of cases at the time of diagnosis and in 19% of cases 2 years post-diagnosis. Similarly, microalbuminuria was detected in 11/61 (18%) of cases at the time of diagnosis and 23% of cases 2 years post-diagnosis.

**Conclusion:** In keeping with other populations, the incidence of childhood type 2 diabetes is increasing in Western Australia, the highest incidence being observed in Indigenous children. Despite their youth, complications of diabetes were already present in this cohort at diagnosis and their prevalence increased markedly even with short duration of disease. There is presently no screening program for children at increased risk of developing type 2 diabetes in Western Australia, and older adolescents with type 2 diabetes may not be ascertained by the paediatric service. Therefore, undiagnosed cases are likely to exist in the study population, and these data represent a likely underestimation.

## 1257

### Glycaemic control and acute complications in children, adolescents, and young adults with type 1 diabetes (T1D): the global TEENs study

L. Laffel<sup>1</sup>, C. Domenger<sup>2</sup>, V. Pilonnet<sup>3</sup>, C. Candelas<sup>3</sup>, T. Danne<sup>4</sup>, M. Phillip<sup>5</sup>, C. Mazza<sup>6</sup>, B. Anderson<sup>7</sup>, R. Hanas<sup>8</sup>, S. Waldron<sup>9</sup>, R. Beck<sup>10</sup>, C. Mathieu<sup>11</sup>;

<sup>1</sup>Joslin Diabetes Center, Boston, USA, <sup>2</sup>Sanofi, Paris, <sup>3</sup>Sanofi, Chilly Mazarin, France, <sup>4</sup>Kinder und Jugendkrankehaus "Auf der Bult", Hannover, Germany, <sup>5</sup>Schneider Children's Medical Center of Israel, Petah Tikva, Israel, <sup>6</sup>Hospital de Pediatria J P Garrahan, Buenos Aires, Argentina, <sup>7</sup>Baylor College of Medicine, Houston, USA, <sup>8</sup>Gothenburg University, Sweden, <sup>9</sup>Hosted by West Midlands Strategic Clinical Network, Birmingham, UK, <sup>10</sup>Jaeb Center for Health Research, Tampa, USA, <sup>11</sup>University Hospitals (UZ), Leuven, Belgium.

**Background and aims:** Optimal glycaemic control remains elusive for many young patients with T1D. The TEENs study is the largest contemporary, international, observational study of young T1D patients (N=5,960), aiming to identify approaches to optimise glycaemic control and outcomes.

**Materials and methods:** 219 centres from 20 countries collected data by patient interview, medical record review, and patient/parent survey from three age groups (8-12-year-olds [y/o], n=1,724), adolescents (13-18 y/o, n=2,854), and young adults (19-25 y/o, n=1,382). A1c was measured uniformly (reference range 4-6%) using A1cNow™ (Bayer). Target A1c levels were categorised as <7.5% (58 mmol/mol) for patients ≤18 years of age (ISPAD) and <7% (53 mmol/mol) for patients 19-25 years of age (ADA). Factors associated with attaining target A1c were identified by multivariate analysis.

**Results:** Median (interquartile range) duration of T1D was 6.1 (3.3–9.6) years; mean ( $\pm$ SD) A1c was  $8.5\pm 1.8\%$  ( $69\pm 20$  mmol/mol). A1c targets were achieved by 28% of patients (32% of 8–12 y/o, 29% of 13–18 y/o, and 19% of 19–25 y/o). Overall, 351 (5.9%) patients reported diabetic ketoacidosis (DKA) in the past 3 months, with the highest occurrence in 19–25 y/o (6.6% vs 5.6% in 8–12 y/o and 5.7% in 13–18 y/o). Severe hypoglycaemia leading to seizure or loss of consciousness was reported by 162 (2.7%) patients with the highest occurrence in 19–25 y/o (4.1% versus 2.5% in 8–12 y/o and 2.2% in 13–18 y/o). Incidence of acute T1D complications by A1c goal attainment and age are shown (Table). In all age groups, occurrence of DKA rates was higher in those not at A1c target. Rates of microalbuminuria, retinopathy treatment, and neuropathy were highest in 19–25 y/o and in patients not at target. In multivariate analyses, presence of DKA (OR 0.53 [95% CI 0.39, 0.73]) and diabetic neuropathy symptoms (OR 0.47 [95% CI 0.34, 0.66]) were significantly associated with not attaining A1c target ( $p<0.001$ ).

**Conclusion:** In the TEENS study, occurrence of acute complications tended to be higher in patients not at target. Diabetes outcomes in these young T1D patients was suboptimal, with mean A1c above target for approximately two thirds of participants and many youth experienced acute complications, supporting the need for further improvements.

#### Recent trends in type 1 diabetes incidence in children and adolescents in Germany

J. Rosenbauer<sup>1</sup>, A. Stahl-Pehe<sup>1</sup>, C. Baechle<sup>1</sup>, K. Castillo<sup>1</sup>, M. Grabert<sup>2</sup>, G. Giani<sup>1</sup>, R.W. Holl<sup>2</sup>, in cooperation with ESPED, DPV and the GCNDM; <sup>1</sup>Institute for Biometrics and Epidemiology, German Diabetes Centre, Duesseldorf, <sup>2</sup>Institute for Epidemiology and Medical Biometry, Ulm University, Germany.

**Background and aims:** Recent data from Nordic European countries suggest that the increase in the incidence of childhood type 1 diabetes (T1D) may have levelled off or the trend may have even reversed in recent years. Aim of the present study was to estimate the recent time trend in T1D among children and adolescents 0–19 years of age in the German federal state North Rhine-Westphalia (NRW) between 2002 and 2012.

**Materials and methods:** The average risk population consisted of 3.08 million children and adolescents. The NRW diabetes incidence register ascertains newly diagnosed cases of T1D by means of three data sources: the prospective hospital-based active surveillance system ESPED, annual inquiries among medical practices, and the DPV database, a computer-based documentation system for quality control and scientific research in diabetes care. Completeness of ascertainment was estimated by the capture-recapture-method. Point and interval estimates (95%CI) of incidence rates (per 100,000 person-years) were based on Poisson distribution. Age- and/or sex-standardized rates were estimated by the direct method using equal weights. Poisson regression analysis was applied to assess time trends adjusted for annual completeness of ascertainment.

**Results:** Between 2002 and 2012, a total of 8,274 children and adolescents (4,465 boys) aged 0–19 years with new-onset T1D were registered. Ascertainment was estimated to be 98.7% (95%CI: 98.4%; 99.0%) complete. The overall incidence rate was 20.8 (20.3; 21.2). The incidence among boys (21.8 (21.2; 22.5)) was higher than among girls (19.8 (19.1; 20.4), rel. risk 1.11 (1.07; 1.16),  $p<0.001$ ), mainly owing to the male preponderance among the age groups 10–14 (30.8 (29.4; 32.3) vs. 24.6 (23.3; 26.9)) and 15–19 years (11.4 (10.6; 12.3) vs. 8.3 (7.6; 9.1)). Age-specific estimates for age groups 0–4, 5–9, 10–14, and 15–19 years were 17.7 (16.8; 18.5), 28.0 (26.9; 29.0), 27.7 (26.7; 28.7), and 9.9 (9.3; 10.5), respectively ( $p<0.001$ ). The annual incidence rates ranged between 17.6 in 2002 and 23.3 in 2012. The average relative annual increase was estimated as 2.1% (1.4%; 2.8%). Overall, there were no significant differences in trends among boys and girls (annual increase: 2.3% (1.3%; 3.2%) vs. 1.9% (0.9%; 2.9%),  $p=0.592$ ). Among boys, significant increasing trends were observed in the 0–4, 5–9 and 10–14 years age groups (2.3% (0.1%; 4.5%) vs. 2.9% (1.2%; 4.7%) vs. 2.3% (0.8%; 3.9%),  $p<0.05$  each), but no change in adolescents (0.6% (-2.2%; 3.4%),  $p=0.529$ ). Among girls, significant increasing trends were observed in the 5–9 and 10–14 years age groups (3.7% (2.0%; 5.4%) vs. 2.9% (1.1%; 4.7%),  $p<0.05$  each), there was no change among 0–4 year-olds (0.1% (-2.1%; 2.4%),  $p=0.909$ ). The incidence among 15–19 year old girls tended to decrease (-2.6% (-5.3%; 0.1%),  $p=0.062$ ).

**Conclusion:** The data suggest that T1D incidence in childhood and adolescents is still increasing in Germany, unlike in Nordic European countries. However, age-specific trends are not uniform in both sexes. Based on the current data, there are annually about 3,200–3,700 children and adolescents newly diagnosed with T1D in Germany underlining the public health importance of the disease. Causes of the continuous rise and, in particular, the differential age-specific trends of T1D incidence between sexes have still to be identified. #### Insulin pumps or injections in children with type 1 diabetes

R. Schiel, D. Burgard;  
Department of Diabetes and Metabolic Diseases, MEDIGREIF Inselklinik Heringsdorf GmbH, Ostseebad Heringsdorf, Germany.

**Background and aims:** During the last decades the percentage of children/adolescents with type 1 diabetes and insulin pump treatment (continuous subcutaneous insulin infusion [CSII]) increased substantially. In Germany about 40% of the children younger than 6 years are currently treated with

CSII. It was the aim of the trial to analyse the quality of diabetes control and patients' ability for a sufficient diabetes self-management using CSII versus injection therapy.

**Materials and methods:** All children/adolescents ( $n=901$ , age  $11.5\pm 4.0$ , diabetes duration  $4.0\pm 3.6$  years) with type 1 diabetes were enrolled in the trial, admitted to an in-patient rehabilitation during the period 04/2004–10/2010.

**Results:** At the time of hospital admission  $n=707$  patients (78%) had an injection therapy (IT),  $n=194$  (22%) had a CSII. Quality of diabetes control (IT vs CSII: HbA1c  $8.72\pm 2.26$  vs  $8.35\pm 1.71\%$ ,  $p=0.09$ ), mean amplitude of daily blood glucose excursions ( $9.4\pm 3.4$  vs  $9.8\pm 3.2$  mmol/l,  $p=0.22$ ), incidences of acute complications (hypo-/hyperglycaemia) were comparable. Children/Adolescents with CSII had a longer diabetes duration ( $5.3\pm 3.7$  vs  $3.6\pm 3.5$  years,  $p<0.01$ ), better postprandial blood glucose levels ( $10.0\pm 3.0$  vs  $12.2\pm 3.3$  mmol/l,  $p=0.03$ ) and a higher frequency of blood-glucose self-tests ( $45.4\pm 13.3$  vs  $38.2\pm 11.5$  self-tests/week,  $p<0.01$ ). Neither there were substantial differences in the group of children younger than 6 years: CSII ( $n=34$ ) vs IT ( $n=58$ ) (HbA1c  $7.44\pm 0.82$  vs  $7.45\pm 1.21\%$ ,  $p=0.99$ , mean amplitude of daily blood glucose excursions  $10.5\pm 3.4$  vs  $10.4\pm 3.1$  mmol/l,  $p=0.87$ , number of hypoglycaemia during the preceding 4 weeks  $15.4\pm 11.1$  vs  $14.1\pm 11.7$ ,  $p=0.61$ ). However, CSII offers children and adolescents more flexibility, more effective diabetes self-management and in adolescents a higher quality of life ( $p<0.01$ ).

**Conclusion:** In children/adolescents CSII is an highly effective therapy. It offers children and adolescents a good and to the injection therapy comparable quality of diabetes control (with even lower postprandial blood glucose levels), but a significant better flexibility, more effective diabetes self-management and additionally for adolescents a higher quality of life.

## 1260

### The timing of transition from paediatric to adult care for childhood-onset type 1 diabetes in Japan: DERI mortality study

Y. Onda<sup>1</sup>, R. Nishimura<sup>1</sup>, A. Morimoto<sup>2</sup>, H. Sano<sup>1</sup>, K. Utsunomiya<sup>1</sup>, N. Tajima<sup>3</sup>,

<sup>1</sup>Department of Internal Medicine Division of Diabetes and Endocrinology, The Jikei University School of Medicine, <sup>2</sup>Department of Internal Medicine, Morimoto Hospital, <sup>3</sup>The Jikei University School of medicine, Tokyo, Japan.

**Background and aims:** The timing for transition of patients with childhood-onset type 1 diabetes (T1DM) from pediatric care (PC) to adult care (AC) has become a subject of much debate in recent years, which led to a position statement being released by the ADA transition working group, and this topic is also being hotly debated in Japan, where not a few patients appear to continue to seek PC even after attaining adulthood. The aim of this study is to follow up patients with childhood-onset T1DM for a maximum duration of 40 years to see how they transitioned from PC to AC and to examine the factors that contributed to their transition.

**Materials and methods:** The study participants consisted of 1,299 patients (525 males/774 females) from two nationwide T1DM surveys in Japan who had been diagnosed as having T1DM at less than 15 years of age between 1965 and 1979. Their attending physicians and affiliations were determined by questionnaire surveys conducted every 5 years. Patients were classified as having received either PC or AC when they were 15 years old. In addition, for those who sought PC at that time, the timing for transition from PC to AC as well as factors such as their age at diagnosis, sex, their physicians' board certification status, and calendar year of diagnosis that contributed to their transition were assessed by Kaplan-Meier and Cox proportional hazard analyses as of 1 January 2010. All statistical analyses were performed by using SAS version 9.3.

**Results:** At the age of 15, 44.0% of the participants ( $n=571$ ) and 55.4% ( $n=720$ ) consulted PC (PC group) and AC (AC group), respectively. Their mean age at diagnosis according to their attending physicians was  $7.9\pm 3.7$  vs  $8.6\pm 3.7$  years, respectively (PC group vs. AC group;  $P<0.0001$ ). There were no significant sex differences between the PC and AC groups (PC, 46.7% vs. 42.4%; AC, 53.1% vs. 57.6%;  $P=0.11$ ). Of the 571 patients in the PC group, 74.8% ( $n=569$ ), 58.1% ( $n=562$ ), 45.1% ( $n=483$ ), and 15.1% ( $n=394$ ) sought PC at 20, 30, 40, and 50 years of age, respectively. Cox proportional hazard analyses for patients with childhood-onset T1DM indicated that the more recent the calendar year of their diagnosis, the younger their age at diagnosis, and the more likely they were to continue to consult diabetes specialists, the significantly higher the risk of continuing to seek PC after attaining adulthood (hazard ratios, 1.03, 0.93, 1.80;  $P=0.0046$ ,  $<0.0001$ ,  $<0.0001$ ), while this risk was not significantly different between the sexes.

**Conclusion:** A majority of patients with childhood-onset T1DM sought AC at the age of 15 years in Japan. However, more than half of those who sought PC at the age of 15 continued to seek PC even after the age of 30 years, suggesting that their transition from PC to AC was far from smooth. Further study is needed to identify the obstacles to their smooth transition to AC.

### Predictor factors associated with higher risk of developing disordered eating behaviour in a group of female adolescents with type 1 diabetes mellitus

M. Marigliano, S. Zaffani, F. Tomasselli, M. Tommasi, A. Morandi, A. Sabbion, G. Contreas, C. Maffei;

Regional Center for Pediatric Diabetes, Clinical Nutrition & Obesity, Verona, Italy.

**Background and aims:** Patients with type 1 Diabetes Mellitus (T1DM) are at high risk for disordered eating behavior (DEB), due to an emphasis on nutrition management in diabetes care. In particular females with T1DM may be principally vulnerable to develop DEBs due to factors related to the onset and management of the disease. Moreover DEBs can have negative effects on the management of T1DM. Because DEBs could be dangerous for people with T1DM, it is important to identify not only clinical and sub-clinical factors but also predictors of DEBs in adolescent females with T1DM. The aims of this study were: 1) to examine disordered eating attitudes and behaviors and body dissatisfaction in a sample of Italian adolescent and young adults with T1D; 2) to analyze what factors before and at the onset of T1DM could be associated with an increased risk of developing DEB.

**Materials and methods:** We enrolled 44 patients, adolescent females, aged 12–20 years old, in therapy with multiple daily insulin injections (MDI), recruited from our center. Inclusion criteria were: T1DM, duration of diabetes for at least 12 months, daily insulin dose of at least 0.5 U/Kg; age at the onset of T1DM 9–16 years, Caucasian race; no history of diabetes complications or autoimmune disorders. Patients with previously diagnosed eating disorders were excluded. Anthropometrical characteristics (weight, height, BMI, BMI z-score) were collected before and at the onset. The bio-clinical data at the T1DM onset (age, HbA1c, blood pH, weight loss) and the family data (including mother's and father's BMI, socio-economic status) were also collected. All patients completed the Eating Disorder Examination Questionnaire (EDE-Q); it assess the frequency of key behavior such as binge eating, objective or subjective episodes of overeating, self-induced vomiting, laxative and diuretics misuse, and the other feature of eating disorder. A patient with an EDE-Q score  $>1SD$  from the mean was considered pathological and with a high risk of developing eating disorder.

**Results:** 44 patients completed the EDE-Q test, 6 of them reported a score  $>1SD$  (6/44, 13.2%) and were considered at risk of developing eating disorders. The logistic regression showed that, among all the anthropometric and metabolic variables, the only one that could be considered a predictor of a high score at the EDE-Q test ( $>1SD$  from the mean) was the BMI z-score before the onset of diabetes. The BMI z-score (index of overweight/obesity) before the onset of T1DM was then identified as an independent predictor of a positive EDE-Q test ( $p<0.05$ , OR=2.029, 95% CI 1.059–3.889).

**Conclusion:** The presence of overweight/obesity, represented by BMI z-score, before the onset of T1DM could be considered an independent predictor of an increased risk of developing eating disorders in the medium/long term. Therefore, the overweight/obese girls with T1DM and their families should be included in adequate prevention programs for the management of DEBs since the onset of diabetes and should be followed by a multidisciplinary diabetes team with a peculiar attention to nutrition and psychological management.

## 1262

**International comparison of quality of life in children and adolescents with type 1 diabetes**A. Lukács<sup>1</sup>, E. Kalyva<sup>2</sup>, M. Abdul-Rasoul<sup>3</sup>, L. Barkai<sup>1,4</sup>;<sup>1</sup>Faculty of Health Care, Department of Theoretical Health Sciences, University of Miskolc, Hungary, <sup>2</sup>The International Faculty of the University of Sheffield, City College, Thessaloniki, Greece, <sup>3</sup>Faculty of Medicine, Kuwait University, Kuwait, <sup>4</sup>Postgraduate Institute of Pediatrics, Medical and Health Science Center, University of Debrecen, Miskolc, Hungary.

**Background and aims:** The ultimate goal of chronic patient care is to maintain or improve the quality of life. The patients' quality of life may be affected the successful disease management in short- and long term. There is a lack of researches examining the quality of life in pediatric diabetic population across countries, because of the lack of appropriate validated age- and disease-specific quality of life instruments. Our research aimed to assess the diabetes-specific quality of life in children and adolescents with type 1 diabetes from different geographically located countries using the child self- and parent proxy-reports. We looked for the relationship between the glycemic control and quality of life.

**Materials and methods:** A total of 416 youths with type 1 diabetes (212 boys and 204 girls) aged 8–18 years participated in the study (84 Greek, 135 Hungarian and 197 Kuwait participants). There were no significant differences among the study participants in gender, age and glycemic control. Diabetes-specific quality of life was measured using the Pediatric Quality of Life™ 3.0 Diabetes Module culturally adapted in every country. Glycemic control was expressed by HbA1c. Data were analysed with Chi-square test, paired t-test, one-way analysis of variance. The difference across countries was evaluated using Tukey post hoc test. SPSS 19.0 was used for statistical analysis.

**Results:** There were significant differences among countries both in self- ( $F(2, 413)=13.17$ ,  $p<0.001$ ) and proxy-report ( $F(2, 413)=30.02$ ,  $p<0.001$ ). Greek youths ( $M=62.18$ , 95% CI [59.07, 65.29]) had significantly lower quality of life scores than the Hungarian ( $M=71.32$ , 95% CI [69.25, 73.40],  $p<0.001$ ) and Kuwait youths ( $M=68.35$ , 95% CI [66.60, 70.10],  $p=0.001$ ). These results were confirmed by the proxy reports. Parents of Greek youths ( $M=55.77$ , 95% CI [52.91, 58.62]) reported significantly lower quality of life scores than parents of Hungarian ( $M=67.80$ , 95% CI [65.80, 69.79],  $p<0.001$ ) and Kuwait youths ( $M=59.75$ , 95% CI [58.09, 61.40],  $p=0.031$ ). Comparisons between quality of life of Hungarian and Kuwait youths we found statistically significant differences only in parents' report ( $p<0.001$ ). We found negative significant correlation between the glycemic control and quality of life for the overall sample ( $r(416)=-0.212$ ,  $p<0.001$ ) and for each country (Gr:  $r(84)=-0.384$ ,  $p<0.001$ , Hu:  $r(135)=-0.207$ ,  $p=0.016$ , Ku:  $r(197)=-0.207$ ,  $p=0.004$ ). It was the case in the parent proxy-report (Gr:  $r(84)=-0.387$ ,  $p<0.001$ ; Hu:  $r(135)=-0.170$ ,  $p=0.049$ ) except Kuwait ( $r(197)=-0.067$ ,  $p=0.349$ ).

**Conclusion:** Regardless the cultural and geographical differences, relationship is found between glycemic control and diabetes-specific quality of life. Parents perceived their children's quality of life worse than children themselves. Despite the similar clinical status of the study participants, the perceived quality of life of diabetic youths differed across cultures. There is a challenge to find ways of improving the quality of life of youths and maintain throughout childhood and adolescence in every culture.

**Effect of aerobic exercise on HDL function in women with polycystic ovary syndrome: a randomised controlled trial**

K. Distelmaier, A. Asante, A. Konopka, M. Shankarappa, M. Amols, K. Nair;

Division of Endocrinology, Mayo Clinic, Rochester, USA.

**Background and aims:** Polycystic ovary syndrome (PCOS) is associated with increased cardiovascular risk. Insulin resistance and low levels of high-density lipoprotein (HDL) cholesterol are considered as potential mechanism for the increased cardiovascular risk. Here we determined whether HDL function in PCOS women is different from healthy women who are more insulin sensitive. Since aerobic exercise (AE) enhances insulin sensitivity and is an effective treatment option in PCOS women we determined whether PCOS women improve their HDL concentrations and HDL function in response to 12 weeks of AE.

**Materials and methods:** HDL function, assessed by cholesterol efflux capacity, paraoxonase-1 (PON1) activity and total anti-oxidative capacity was compared between sedentary women with PCOS ( $n=25$ ) and age- and sex-matched non-PCOS, women ( $n=12$ ). PCOS women were then randomized to a 12-week intervention of AE ( $n=12$ ), or no treatment ( $n=13$ ) to analyze the effect of AE on fasting serum insulin levels and glucose tolerance to a meal, and on HDL function. AE consisted of 5 supervised exercise sessions per week on a stationary bicycle to elicit heart rates corresponding to 65% of participants' pre-training VO2max. Participants in the control group maintained their regular sedentary behavior.

**Results:** The HDL of PCOS women exhibited impaired cholesterol efflux capacity compared to insulin-sensitive healthy women ( $15.9\% \pm 2.2$  versus  $17.8\% \pm 2.4$ ,  $p=0.034$ ), whereas PON1 activity and total antioxidative function showed no differences. Although AE resulted in a significant increase in VO2 max ( $+4.53$  ml/kgFFM/min  $\pm 2.52$ ,  $p=0.003$ ), and improved glucose tolerance, no effect on HDL concentration and function was observed.

**Conclusion:** PCOS women have an impaired cholesterol efflux capacity, which cannot be normalized by a 12 week AE despite improvement in glucose tolerance and endurance capacity.

**Association between bone metabolism and resting energy expenditure in postmenopausal women with type 2 diabetes**

M. Ogata, R. Ide, N. Iwasaki, M. Takizawa, Y. Uchigata;

Tokyo Women's Medical University, Diabetes Center, Tokyo, Japan.

**Background and aims:** Osteoporosis negatively affects quality of life in individuals with diabetes. While bone fractures occur more easily in patients with both type 1 diabetes (T1D) and T2D compared to non-diabetics, the pathology of osteoporosis is different between T1D and T2D. Although bone mineral density (BMD) is increased in patients with poorly controlled T2D, the bone quality is low. It is therefore important to determine criteria for osteoporosis other than BMD in patients with T2D. Recently, it has been reported that bone resorption suppression may prevent T2D, and BMD correlates more strongly with basal metabolic rate than body mass index (BMI) in African Americans. These studies imply a direct association between bone metabolism and basal metabolic rate. The aim of this study was to examine the relationship between bone metabolism and resting energy expenditure (REE) in postmenopausal women with T2D.

**Materials and methods:** Postmenopausal Japanese women with T2D were recruited from the outpatient clinic at the Diabetes Center of our University. 46 patients with over 1-year attendance, no other diseases except hypertension, dyslipidemia and overweight ( $BMI \leq 30$  kg/m<sup>2</sup>), no history of taking dietary supplements for previous 3 months, were included in this study. Fasting serum procollagen type 1 N-terminal propeptide (P1PN), Carboxy-terminal collagen crosslink's-1 (CTX-1), intact parathyroid hormone, 25-hydroxyvitamin D (25[OH]D), urine microalbumin, body composition and REE were evaluated. BMD was examined using dual-energy X-ray absorptiometry of the nondominant distal radius. Data are presented as mean  $\pm$  standard deviation.

**Results:** The mean REE of the patients ( $940 \pm 156$  kcal) was lower than the predicted value ( $1177 \pm 98.3$  kcal). The mean T-score was low with high variance ( $1.7 \pm 1.6$ ). 18 patients (39%) met the criterion for osteoporosis. Although 12 patients (26%) had a history of bone fractures, there was no difference in REE or BMD between the patients with or without the history of fractures. The respiratory quotient ( $0.87 \pm 0.01$ ) was positively correlated with serum 25(OH)D ( $21.5 \pm 7.4$  ng/mL). REE was positively correlated with BMI ( $24.5 \pm 3.6$  kg/m<sup>2</sup>), serum calcium ( $9.2 \pm 0.3$  mg/dL), HbA<sub>1c</sub> for the prior 6 months ( $7.6\% \pm 1.1\%$ ), and the ratio of serum P1PN to CTX-1 ( $37.5 \pm 11.7$   $\mu$ g/L :  $0.36 \pm 0.1$  ng/mL).

**Conclusion:** The present study shows that bone metabolism was significantly associated with REE ( $p<0.009$ ). The basal metabolic rate interrelated with bone turnover in postmenopausal women with T2D. Declining bone turnover related to low REE may result in decreased therapeutic efficacy of bone resorption suppression.

## 1265

**Comparison of the effect of minodronic acid hydrate and bazedoxifene on biochemical markers of bone turnover in postmenopausal type 2 diabetes women with low bone mass**

A. Miyoshi, H. Miyoshi, S. Nagai, T. Kondo, H. Nomoto, K. Yamamoto, T. Atsumi;

Division of Rheumatology, Endocrinology and Nephrology, Hokkaido University, Sapporo, Japan.

**Background and aims:** Although patients with type 2 diabetes (T2D) are at significant risk for well-recognized diabetic complications, including macrovascular disease, retinopathy, nephropathy, and neuropathy, it is also clear that T2D patients are at increased risk for fragility fractures. It is suggested abnormalities in not only bone material strength but also bone microarchitecture (bone quality) are risk factors of bone fractures in T2D. It is reported that urinary pentosidine levels predict the future fracture independent of bone turnover and bone mineral density (BMD) without treatment for osteoporosis. Pentosidine is a surrogate marker of whole advanced glycation end products, which is characterized as non-enzymatic collagen cross-linking. Non-enzymatic cross-links reduce the mechanical and biological integrity of bone and so pentosidine is one of bone quality markers. It has been reported that selective estrogen receptor modulator (SERM) decreases urinary pentosidine and ameliorates bone quality in postmenopausal women with osteoporosis. However, effects of osteoporosis medication to bone quality have not been proven in T2D with osteoporosis. Thus, we administered bisphosphonate or SERM to postmenopausal T2D women with low bone mass and evaluated the effects of bone turnover including bone quality markers.

**Materials and methods:** We measured femoral neck (FN) and lumbar spine (LS) BMD of postmenopausal women with T2D by dual-energy X-ray absorptiometry and 31 patients with a T score  $\leq -2.0$  at the FN or LS in this test were randomized 1:1 to receive minodronic acid hydrate (n=15) or bazedoxifene (n=16). Changes in bone turnover and quality markers, BMD at the FN and LS, and common clinical data involved in T2D were assessed at 6 month. This was a prospective observational study. Primary endpoint was set as the reduction of urinary pentosidine level. A total of 31 patients consented to participating in this study. On average, the patient group was aged  $69 \pm 7$  years and they had been living with T2D for the past  $15.5 \pm 10.7$  years. Their HbA1c was  $7.0 \pm 0.7\%$  and BMI was  $24.0 \pm 3.8$ .

**Results:** There was no difference in urinary pentosidine levels between the groups. No significant reduction was seen in both groups, which urinary pentosidine levels were very high and more than the level considered as a risk level of future fractures. In the other bone turnover and quality markers, minodronic acid hydrate significantly decreased serum P1NP levels, urinary DPD and serum ucOC compared with bazedoxifene (-58.6% versus -19.1%, -30.1% versus 1.6%, -55.3% versus -29.1%, respectively). Significantly greater increases in BMD were observed with minodronic acid hydrate treatment at the FN or LS (6-mo treatment difference: 2.3%, FN; 2.4%, LS;  $p < 0.05$ ) but no changes were observed with bazedoxifene therapy. Bazedoxifene significantly decreased serum non HDL-C levels compared with minodronic acid hydrate (-13.6 mg/dl versus 5.4 mg/dl;  $p < 0.05$ ). Both treatments didn't aggravate diabetes conditions.

**Conclusion:** Urinary pentosidine levels did not change in both treatments in this study. Minodronic acid hydrate showed significantly improvement in BMD and bone turnover markers compared with bazedoxifene therapy in also T2D patients. Bazedoxifene may ameliorate lipid metabolism in T2D women with osteoporosis.

Clinical Trial Registration Number: UMIN000008783

**Clinical features and management of new-onset diabetes mellitus presenting with diabetic ketoacidosis in China: a multicentre, clinic-based study**X. Wu<sup>1</sup>, Y. Xu<sup>1</sup>, J. Bai<sup>2</sup>, J. Shaw<sup>3</sup>, China Initiative for Diabetes Excellence (CIDE) Collaborative Group;<sup>1</sup>Department of Endocrinology, First Affiliated Hospital of Nanjing Medical University, <sup>2</sup>Department of Epidemiology & Biostatistics, Nanjing Medical University, China,<sup>3</sup>Baker IDI Heart and Diabetes Institute, Melbourne, Australia.

**Background and aims:** Diabetic ketoacidosis (DKA) is a serious acute complication of diabetes, resulting from severe insulin deficiency and an excess of counter-regulatory hormones. Under certain circumstance, new-onset diabetes patients may present with DKA, which is typical for type 1 diabetes mellitus (T1DM) or ketosis-prone diabetes in western countries. However, there is little information on hospitalization for this kind of diabetes patients in the Chinese population. The present study is to evaluate the clinical features and management of new-onset diabetes mellitus presenting with DKA in China.

**Materials and methods:** A retrospective cohort study of adult and adolescents new-onset diabetes patients hospitalized with DKA between 2010 and 2012 were carried out in fifteen tertiary hospitals around China. Clinical and laboratory data were collected. Patients were classified based on clinical features. Groups were compared for differences in vital statistics and biochemical profiles at presentation.

**Results:** The study cohort comprised 255 new-onset diabetes patients presenting with DKA: 115 patients (45.1%) with type 2 diabetes mellitus (T2DM), 98 patients (38.4%) with T1DM, 24 patients (9.4%) with atypical DM (ADM) and 18 patients (7.1%) with Fulminant T1DM. T1DM exceeded T2DM in the age group less than 40 years while T2DM predominated in the age group more than 40 years. Male patients were predominant in T1DM, T2DM and ADM group. The most common precipitating factors were unknown reason (36.9%) and infection (29.0%). The typical symptoms included polyuria/polydipsia (72.9%), nausea/vomiting (67.1%), dehydration (27.1%), variable degree of confusion (26.7%) and abdominal pain (22.4%). More gastrointestinal symptoms and dehydration were found in T1DM due to severe ketoacidosis. The levels of blood glucose and HbA1c were  $25.3 \pm 11.1$  mmol/L and  $12.1 \pm 3.1\%$  at admission. About 89.0%, 74.4% and 55.9% of patients were evaluated for HbA1c, beta-cell function and autoantibodies for classification. The complications included electrolyte disturbance (71.4%), arrhythmia (19.6%), hyperosmotic state (14.5%), renal failure (6.7%), shock (3.1%), heart failure (0.8%) and cerebral edema (0.8%). During the first day after admission, total fluid supplement were  $3550.4 \pm 1904.1$  ml. Low doses insulin infusion lasted for  $2.8 \pm 5.4$  days. The disappearance of urine ketone body took  $3.3 \pm 2.7$  days. Therapeutic regimen was markedly different within the four groups when they discharged from hospitals.

**Conclusion:** New-onset diabetes patients presenting with DKA occur in a spectrum of diabetes types in China, including T2DM, T1DM, ADM and Fulminant T1DM. Its clinical heterogeneity has significant implications for classification and management of diabetes.

## 1267

**Effects of cardiovascular risk factors in urban community in patients with type 2 diabetes mellitus: a 48-months prospective trial**X.-L. Zhang<sup>1</sup>, S.-Y. Yuan<sup>1</sup>, G. Wan<sup>2</sup>, L.-X. Zhu<sup>1</sup>, H.-J. Fu<sup>1</sup>, M.-X. Yuan<sup>1</sup>, G.-R. Yang<sup>1</sup>, S.-F. Pan<sup>1</sup>, R.-R. Xie<sup>1</sup>, Y.-J. Lv<sup>3</sup>, Beijing Community Diabetes Study Group;<sup>1</sup>Department of Endocrinology, Beijing Tongren Hospital, Capital Medical University, <sup>2</sup>Medical Records and Statistics Department, Beijing Ditan Hospital, Capital Medical University,<sup>3</sup>Cuigezhuang Community Health Service Center, Beijing, China.

**Background and aims:** To assess whether prospective interventions have long-term effects on the risk of diabetes-related macrovascular complications in patients with type 2 diabetes mellitus in urban communities of Beijing.

**Materials and methods:** A total of 3,264 type 2 diabetic subjects (aged 20–80 years) was recruited from 15 community health centers in Beijing in 2008.

The subjects were divided into three groups: DM group (n=930), HTN group (n=1397), and CVD group (n=937). By using Framingham risk score (FRS), the subjects in afore three groups are subdivided into risk categories of 20% (high Framingham risk strata). After 48 months, study participants were followed-up to assess the long-term effects of the interventions.

**Results:** Subjects with CVD in diabetes were more prone to be older, have a longer duration of diabetes, higher systolic blood pressure and diastolic blood pressure than that of DM group ( $P<0.01$ , respectively). The mean NC at the baseline was significantly higher in HTN and CVD group than that in DM group ( $P<0.05$ ). In the post-intervention, participants in CVD group or HTN group comparing the DM group, higher levels were detected on blood pressure, and lipid profiles ( $P<0.01$ , respectively). In 48-months of follow-up, no significant increase of FRS could be demonstrated in low framingham risk strata and median framingham risk strata when compared with baseline levels. In particular, a significant reduction of FRS was found in the high framingham risk strata at the end of follow-up. In COX multivariate analyses, participants in the HTN group and CVD group had a higher incidence of events than those in the DM group (HR 2.561; 95% CI 1.043–6.289; HR 4.678; 95% CI 1.937–11.298).

**Conclusion:** This study demonstrated for the first time the existing relationship between NC and CVD in diabetic patients. Multi-factorial intervention of CVD risk factors in community for 48-months results in favorable changes in cardiovascular risk factors, and lowered the estimated 10-year risk for CVD events. Multi-factorial intervention of CVD risk factors in community is important to prevent the incidence of events in hypertension or CVD in Chinese diabetic patients.

### Cardiovascular risk factors outcomes in patients with newly-diagnosed type 2 diabetes. The Basque country 10-yr prospective diabetes study

J.M. Arteagoitia<sup>1</sup>, J.A. Piniés<sup>2</sup>, J.M. Altzibar<sup>1</sup>, F. Gonzalez-Carril<sup>1</sup>,

L. Irigoien<sup>3</sup>, L. Echevarriarteun<sup>1</sup>, J.L. Rodriguez-Murua<sup>1</sup>,

Basque Country Sentinel Practice Network;

<sup>1</sup>Epidemiology Unit, Public Health Service, Department of Health, Basque Government, Vitoria-Gasteiz, <sup>2</sup>Endocrinology and Nutrition Department, Cruces University Hospital, Osakidetza-Basque Country Health Service, Barakaldo (Bizkaia), <sup>3</sup>Department of Computation Science and Artificial Intelligence, University of the Basque Country (UPV-EHU), Donostia, Spain.

**Background and aims:** To describe the cardiovascular risk factor outcomes in newly-diagnosed type 2 diabetes in the Basque Country Prospective Complications and Mortality Study.

**Materials and methods:** A 10-year prospective population-based cohort study was performed with 777 newly-diagnosed type 2 diabetic patients older than 24 years in a Sentinel Practice Network. We recorded cardiovascular risk factors at baseline and during the 10-year follow up study. High blood pressure (systolic blood pressure (SBP)  $\geq 140$  mmHg and/or diastolic blood pressure (DBP)  $\geq 80$  mmHg), elevated LDL  $\geq 2.58$  mmol/l, low HDL  $< 1.29$  mmol/l in women and  $< 1.03$  mmol/l in men, hypertriglyceridemia (triacylglycerol  $\geq 1.69$  mmol/l), HbA<sub>1c</sub>  $\geq 7\%$  ( $\geq 53$  mmol/mol), and albuminuria (albumin/creatinine ratio  $\geq 3$  mg/mmol) were recorded. Obesity (BMI  $\geq 30$  kg/m<sup>2</sup>), and adiposity (% body fat) were calculated. The air displacement plethysmography prediction equation was used to measure adiposity (obesity: above 25.1% and 35.1% in males and females, respectively). The patients were classified as sedentary if they rarely exercised and active if they performed three or more hours of exercise per week. With regard to smoking habits, the patients were classified as non-smokers, and smokers.

**Results:** Baseline characteristic of the patients are shown in table. At the end of the study, all cardiovascular risk factors outcomes were favorable, improving the percentage of patients at target for blood pressure from 87% to 78.3%, and LDL from 88.8% to 65%. However, the patients at HbA<sub>1c</sub>  $\geq 7\%$  increased from 29% to 35% in the cohort study. Sedentary life style and obesity did not change over time. Smoking habits decreased from 16.1% to 8.3%. Treatment with statins, blood pressure drugs and anti-hyperglycemic drugs increased in the follow-up study.

**Conclusion:** Cardiovascular risk factors prevalence and percentage of patients upper control target are very high. All risk factors except HbA<sub>1c</sub>, improved or maintained in newly-diagnosed type 2 diabetic patients during 10-yr. follow-up study.

### The relationship between coronary artery disease and peripheral artery disease in diabetes patients

S. Kawasaki<sup>1</sup>, H. Misawa<sup>1</sup>, Y. Tamura<sup>1</sup>, Y. Kondo<sup>2</sup>, S. Satoh<sup>2</sup>, O. Hasegawa<sup>3</sup>, Y. Terauchi<sup>4</sup>;

<sup>1</sup>Department of Endocrinology and Metabolism, Shonan Fujisawa Tokushukai Hospital, Fujisawa, <sup>2</sup>Department of Endocrinology and Metabolism, Chigasaki Municipal Hospital, <sup>3</sup>Department of General Medicine, Yokohama City University Medical Center,

<sup>4</sup>Department of Endocrinology and Metabolism, Yokohama City University Graduate School of Medicine, Japan.

**Background and aims:** In step with the aging of the population and the increasing number of diabetes patients, patients with peripheral artery disease (PAD) are increasing in number along with those with coronary artery disease (CAD). It is important for PAD to be detected early and managed because it has a poor prognosis and higher mortality rate than malignant disease. This study examined the associations of CAD and PAD in patients with type 2 diabetes mellitus (DM).

**Materials and methods:** Subjects were 1368 ambulatory patients with type 2 diabetes (795 males, 573 females). They were classified into CAD+ and CAD- groups, or into PAD+ and PAD- groups. Those with ischemic findings such as abnormal Q, ST depression and negative T on resting electrocardiogram or a past history of angina pectoris or myocardial infarction were categorized as CAD+, otherwise as CAD-; those with ankle-brachial index (ABI)  $\leq 0.99$  or with a history of PAD were categorized as PAD+, otherwise as PAD-. They were further divided into two groups: one with diabetic retinopathy and the other without it. Diabetic nephropathy was treated as positive if urinary albumin excretion was 30 mg/gCr or larger and as negative if it was less than 30 mg/gCr. We compared risk factors between CAD which is representative of diabetic macrovascular disease and PAD.

**Results:** The characteristics of the 1368 patients with type 2 DM were as follows: age, 64.1 $\pm$ 12.0 (SD) years; duration of DM, 11.4 $\pm$ 10.0 years; BMI, 24.5 $\pm$ 8.0 kg/m<sup>2</sup>; blood pressure (BP), 135 $\pm$ 19/76 $\pm$ 13 mmHg; and hemoglobin A1c, 7.9 $\pm$ 2.0 %. Three hundred thirty-two patients had retinopathy, while 795 did not. Nephropathy afflicted 572 patients but did not afflict 720 patients. The CAD+ group comprised 498 subjects (36.4%). After data correction, independent risk factors for CAD were age (OR1.03, 95%CI 1.01-1.04,  $p<0.0005$ ), nephropathy (OR1.53, 95%CI 1.12-2.09,  $p<0.01$ ), retinopathy (OR1.52, 95%CI 1.07-2.15,  $p<0.05$ ) and smoking habit (OR1.58, 95%CI 1.09-2.29,  $p<0.05$ ). The PAD+ group comprised 227 subjects (16.6%). After data correction, age (OR1.05, 95%CI 1.03-1.07,  $p<0.0001$ ), waist diameter (OR1.03, 95%CI 1.01-1.05,  $p<0.005$ ), nephropathy (OR1.60, 95%CI 1.06-2.42,  $p<0.05$ ), retinopathy (OR2.61, 95%CI 1.67-4.08,  $p<0.0001$ ), male gender (OR2.73, 95%CI 1.62-4.64,  $p<0.0005$ ) and smoking habit (OR3.37, 95%CI 1.98-5.85,  $p<0.0001$ ) were independent risk factors for PAD. The cut-off value of the ROC curve for age was 75 years (sensitivity:0.39, specificity:0.82). PAD was found in 27% of the CAD+ group ( $p<0.0001$ ), while CAD was found in 59% of the PAD+ group ( $p<0.0001$ ).

**Conclusion:** About 30% of CAD patients had PAD while about 60% of PAD patients had CAD. Factors common to CAD and PAD were age, smoking habit, nephropathy and retinopathy. Especially PAD is considered clinically worthy of note in people over 75 years old. In our increasingly aging country, we consider it essential to educate the public as well as diabetes patients about the importance of early diagnosis of PAD which carries a poor prognosis.

### Outcome reduction with an initial glargine intervention and legacy effects (ORIGINALE)

Z. Punthakee<sup>1</sup>, J. Tyrwhitt<sup>1</sup>, J. Bosch<sup>1</sup>, G.R. Dagenais<sup>2</sup>, R. Díaz<sup>3</sup>, H. Jung<sup>1</sup>, A.P. Maggioni<sup>4</sup>, J. Pogue<sup>1</sup>, J. Probstfield<sup>5</sup>, A. Ramachandran<sup>6</sup>, M.C. Riddle<sup>7</sup>, L.E. Rydén<sup>8</sup>, S. Yusuf<sup>1</sup>, H.C. Gerstein<sup>1</sup>, ORIGIN Trial Investigators; <sup>1</sup>Medicine, Population Health Research Institute and McMaster University, Hamilton, <sup>2</sup>Institut Universitaire de Cardiologie et de Pneumologie de Québec, Canada, <sup>3</sup>Estudios Clínicos Latino América, Rosario, Argentina, <sup>4</sup>Associazione Nazionale Medici Cardiologi Ospedalieri Research Center, Florence, Italy, <sup>5</sup>University of Washington, Seattle, USA, <sup>6</sup>India Diabetes Research Foundation, Chennai, India, <sup>7</sup>Oregon Health and Science University, Portland, USA, <sup>8</sup>Karolinska Institute, Stockholm, Sweden.

**Background and aims:** ORIGIN was a 2 x 2 factorial randomised trial assessing cardiovascular and other effects of insulin glargine vs standard care and omega-3-fatty acids vs placebo among people with IFG, IGT or early type 2 diabetes and other cardiovascular risk factors. After a median 6.2-year follow-up, insulin glargine had a neutral effect on cardiovascular outcomes and cancers, and reduced the incidence of diabetes in people with IFG or IGT. Omega-3-fatty acids also had a neutral effect on cardiovascular outcomes. ORIGIN participants who consented to the ORIGIN and Legacy Effects Study (ORIGINALE) were followed for more than 2 years after the trial finished to determine the longer term effect of therapy on cardiovascular outcomes and new diabetes.

**Materials and methods:** By the end of March 2014, consenting participants completed up to 2 study visits to ascertain anthropometrics, blood pressure, creatinine, A1C, medication use and outcomes. Cumulative incidence, hazard ratios and odds ratios from the time of randomisation to the end of follow-up will be calculated for the ORIGIN trial outcomes. Participants will be analysed in the groups to which they were randomised.

**Results:** At the end of ORIGIN, 10,544 of the original 12,537 participants were alive and followed at 553 sites. 283 sites (comprising 6,497 participants) agreed to participate in ORIGINALE and obtained ethics approval. To date, at least 5721 participants from 274 sites have contributed data comprising approximately 96 new MIs, 63 new strokes, 194 new cardiovascular deaths and 231 new cancer outcomes. Verification of events and data accuracy are ongoing. Analyses comparing insulin glargine vs standard care, and omega-3-fatty acids vs placebo will be completed by August 2014.

## 1271

### Effect of three insulin regimens on carotid intima-media thickness in patients with type 2 diabetes: the randomised Copenhagen Insulin and Metformin Therapy (CIMT) trial

L. Lundby-Christensen<sup>1,2</sup>, the CIMT trial group, Copenhagen university hospitals;

<sup>1</sup>Steno Diabetes Center, Gentofte, <sup>2</sup>Department of Paediatrics, Copenhagen University Hospital, Hvidovre, Denmark.

**Background and aims:** Post prandial hyperglycaemia may be associated with increased risk of cardiovascular disease in patients with type 2 diabetes. Insulin analogue regimens targeting post prandial and/or fasting plasma glucose may therefore influence the risk of cardiovascular disease differently. Carotid intima-media thickness (IMT) is a frequently used risk marker for cardiovascular disease. The aim of the Copenhagen Insulin and Metformin Therapy (CIMT) trial was to evaluate the effects of three insulin analogue regimens in combination with metformin or placebo. The metformin/placebo comparison has previously been reported. This abstract reports the insulin regimen comparisons.

**Materials and methods:** The CIMT trial is an investigator initiated, 3 x 2 factorial, treat-to-target (HbA<sub>1c</sub> ≤ 7.0% (53 mmol/mol)), multicenter randomised clinical trial. 412 participants with type 2 diabetes, HbA<sub>1c</sub> ≥ 7.5%

(58 mmol/mol), receiving oral antidiabetic agents for at least one year and/or insulin for at least three months, were randomised 1:1:1 to 18 months open label treatment with one of three insulin regimens: insulin aspart biphasic one to three times daily (n=137) versus insulin aspart three times daily in combination with insulin detemir once daily (basal-bolus, n=138) versus insulin detemir once daily (n=137). Primary outcome measure was change in mean carotid IMT. Other outcomes were change in HbA<sub>1c</sub>, weight, and insulin dose, and risk of hypoglycaemia and serious adverse events. After multiple imputations of missing data on the primary outcome, intention-to-treat analyses adjusting for baseline and stratification variables were performed.

**Results:** 90% (biphasic group), 80% (aspart+detemir group), and 72% (detemir group) of the participants completed the trial. Mean carotid IMT changed by -0.009 mm (95% confidence interval -0.022 to 0.004, P=0.17) in the biphasic group, 0.000 mm (-0.013 to 0.013, P=0.99) in the aspart+detemir group, and -0.012 mm (-0.025 to 0.000, P=0.06) in the detemir group. These changes were not significantly different between the groups. HbA<sub>1c</sub> was significantly more reduced (P<0.001) in the aspart biphasic group (-1.0% (-1.2 to -0.8) (-11 mmol/mol (-13 to -9)) compared with the aspart+detemir (-0.4% (-0.6 to -0.3) (-4 mmol/mol (-7 to -3)) and the detemir (-0.3% (-0.4 to -0.1) (-3 mmol/mol (-4 to -1)) groups. Weight gain was significantly higher (P<0.01) in the biphasic group (3.3kg (2.7 to 4.0)) and the aspart+detemir (3.2kg (2.6 to 3.9)) groups compared with the detemir group (1.9kg (1.3 to 2.6)). Total insulin dose at end-of-trial was significantly higher (P<0.001) in the detemir group (1.6 IU/kg/d (1.4 to 1.8)) compared with the biphasic (1.0 IU/kg/day (0.9 to 1.1) and aspart+detemir (1.1 IU/kg/day (1.0 to 1.3)) groups. The number of participants with severe hypoglycaemia and other serious adverse events did not differ between the groups.

**Conclusion:** Despite major differences in HbA<sub>1c</sub>, weight gain and insulin dose, no significant differences on the progression of carotid IMT were found during 18 months treatment with three frequently used insulin analogue regimens targeting post prandial and/or fasting plasma glucose in patients with type 2 diabetes. Further long-term trials are needed examining whether different insulin regimens affect cardiovascular risk differently.

### Glycaemic variability and glucose control in post-transplant diabetes mellitus after renal transplantation

J. Werzowa<sup>1</sup>, G. Pacini<sup>2</sup>, H. Brath<sup>3</sup>, M.D. Säemann<sup>1</sup>, A. Tura<sup>2</sup>;

<sup>1</sup>Division of Nephrology and Dialysis, Medical University of Vienna, Austria, <sup>2</sup>Metabolic Unit, ISIB-CNR, Padova, Italy,

<sup>3</sup>Health Center South, WGKK, Vienna, Austria.

**Background and aims:** Post-transplant diabetes mellitus (PTDM) is a common and serious complication after renal transplantation leading to increased cardiovascular morbidity and mortality. In patients with type 2 DM increased glycaemic variability and poor glucose control have been associated with cardiovascular complications. We therefore aimed at determining glycaemic variability and glucose control in patients with PTDM in comparison to type 2 DM.

**Materials and methods:** We studied 10 non-diabetic transplanted subjects (TR\_ND), 10 transplanted subjects with PTDM (TR\_D), and 9 non-transplanted type 2 diabetic subjects (T2\_D) using Continuous Glucose Monitoring (CGM). Subjects had similar age (60.4±2.9, 57.6±2.2, 56.2±2.5 years, P>0.26) and BMI (26.9±1.3, 28.9±1.3, 29.6±2.1 kg/m<sup>2</sup>, P>0.24). Subjects underwent CGM for 2 to 8 days. The following indices were computed: (i) Basic indices: glucose mean and standard deviation (SD); (ii) Indices of glycaemic variability: CONGA<sub>n</sub> equal to the SD of the difference between values obtained 5 minutes apart; J-INDEX, equal to 0.001x(mean + SD)<sup>2</sup>; MAGE equal to the arithmetic mean of the glycaemic excursions greater than one SD; Lability Index equal to the mean of (G<sub>n+1</sub>-G<sub>n</sub>)<sup>2</sup>/(h<sub>n+1</sub>-h<sub>n</sub>), where G<sub>n</sub> is the n-th glucose value and h<sub>n</sub> is the time when that value was collected; (iii) Indices of glucose control quality: GRADE equal to 425x[log [log(G<sub>n</sub>)]+0.16]<sup>2</sup>; Hyperglycaemia index, equal to the weighted average of hyperglycaemic values, for glucose values higher than 140 mg/dl; Hypoglycaemia index, for glucose values below 80 mg/dl; IGC equal to the sum of Hyperglycaemia and Hypoglycaemia indices.

**Results:** Mean glucose in TR\_D and T2\_D was higher than in TR\_ND (P<0.021), whereas SD was different only between TR\_ND and T2\_D (P<0.011). No difference in Mean and SD was found between TR\_D and T2\_D (P>0.3). Among the variability indices, main differences among groups

were shown by J-INDEX (lower in TR\_ND than in TR\_D and in T2\_D,  $P < 0.019$ ) and by Lability Index (lower in TR\_ND and in TR\_D than in T2\_D,  $P < 0.029$ ). Among the control quality indices, GRADE was found significantly lower in TR\_ND than in TR\_D and in T2\_D ( $P < 0.034$ ).

**Conclusion:** TR\_D patients display worse glucose control than TR\_ND, however, the degree of impairment parallels that of T2\_D. Glycemic variability expressed by Lability Index is significantly higher in T2\_D compared to TR\_ND but also to TR\_D. These data underscore potential important pathophysiological differences between type 2 DM and PTDM indicating that although development of PTDM leads to increased glycemic variability, the degree of variability is significantly higher in type 2 DM and may thus play a less important role in PTDM.

Table 1 – Values of the CGM indices in the three groups of subjects. Data are mean±SE

### The association between metformin use and change of serum creatinine after administration of contrast medium

S. Kim, J. Hahm, J. Jung, J. Jung;

Gyeongsang National University School of Medicine, Jinju, Republic of Korea.

**Background and aims:** Metformin is widely used in the treatment of type 2 diabetes mellitus. Because of a association between iodinated contrast medium and the development of lactic acidosis in patients taking metformin, it usually restricted the use of metformin in situations considered to be high risk for the development of lactic acidosis. Several guidelines recommend stopping metformin before injection of contrast medium. Nevertheless, this has been controversial, because cases of lactic acidosis in patient taking metformin occurred in patient who had high risk factors for lactic acidosis. Thus, we evaluated the change of serum creatinine and total CO<sub>2</sub> concentration in patients receiving metformin after administration of contrast medium.

**Materials and methods:** From January 2012 to August 2012, the patient's records after administration of contrast medium for patients receiving metformin were retrospectively reviewed. Patients were excluded if 1)cancer with chemotherapy or radiation therapy, 2)death after admission, 3)serum creatinine  $\geq 3.0$  mg/dL, or hemodialysis, 4) shock. Ninety patients were included in the final analysis. Serum creatinine is measured 1-3 days after administration of contrast medium. We measure serum total CO<sub>2</sub> content instead of measuring serum bicarbonate. The total CO<sub>2</sub> content includes the serum bicarbonate as well as available forms of carbon dioxide (such as dissolved CO<sub>2</sub> and carbonic acid). Generally, the serum bicarbonate comprises about 95% of the total CO<sub>2</sub> content, thus we can use this measurement as an excellent estimator of serum bicarbonate. We defined metabolic acidosis when total CO<sub>2</sub> level is below 23 mEq/L. The Wilcoxon's signed rank test was used to analyze the effects of contrast medium use on change in serum creatinine and total CO<sub>2</sub> content level from baseline to 1-3 days after contrast medium.

**Results:** The mean subject age was  $67.4 \pm 10.5$  years, and the mean A1C and metformin dosage of subjects were  $7.3 \pm 1.6$  kg/m<sup>2</sup> and 500(500-1000), respectively. Serum BUN level before and after administration of contrast medium were  $17.2 \pm 9.2$  and  $15.0 \pm 7.9$  mg/dL, respectively. Serum creatinine level before and after administration of contrast medium were  $0.91 \pm 0.38$  and  $0.89 \pm 0.36$  mg/dL, respectively. There was no significant change of BUN or Cr level after administration of contrast medium ( $p > 0.05$ ). The total CO<sub>2</sub> level before and after administration of contrast medium were  $24.3 \pm 3.5$  mEq/L and  $27.7 \pm 3.8$  mEq/L, respectively. There was also no significant change of CO<sub>2</sub> level ( $p = 0.435$ ). There was no significant relationship between increased creatinine and presence of metabolic acidosis (Table 1).

**Conclusion:** There is no significant increase or change of serum creatinine in patients with low risk of lactic acidosis after contrast media exposure. There-

fore, it imply that there is no evidence to stop metformin before administration of contrast medium in patients with normal renal function with low risk of lactic acidosis.

| Increased serum creatinine | Presence of metabolic acidosis |           | P value |
|----------------------------|--------------------------------|-----------|---------|
|                            | Absent                         | Present   |         |
| Absent                     | 42 (46.7%)                     | 12(13.3%) | 0.76    |
| Present                    | 27 (30.0%)                     | 9 (10.0%) |         |

#### Non-invasive predictor of non-alcoholic fatty liver disease in Japanese patients with type 2 diabetes mellitus

M. Miyasato<sup>1</sup>, Y. Murase-Mishiba<sup>1</sup>, M. Bessho<sup>1</sup>, M. Miyawaki<sup>1</sup>, H. Imbe<sup>1</sup>, C. Tsutsumi<sup>1</sup>, K. Tanimoto<sup>1</sup>, A. Imagawa<sup>2</sup>, J. Terasaki<sup>1</sup>, T. Hanafusa<sup>1</sup>;

<sup>1</sup>First department of Internal Medicine, Osaka Medical College, <sup>2</sup>Metabolic of Medicine, Graduate School of Medicine, Osaka University, Japan.

**Background and aims:** Individuals with type 2 diabetes mellitus (T2DM) have a higher risk of developing nonalcoholic fatty liver disease (NAFLD) than those without. The serum cytokeratin-18 fragment (CK-18) level has been suggested to be a biomarker of NAFLD, although its usefulness in patients with T2DM is unknown. The objective of the present study was to assess the usefulness of the serum CK-18 level as a biomarker for NAFLD in T2DM patients.

**Materials and methods:** The study was divided into two parts. In the first cross-sectional study, a total of 200 patients with T2DM and 58 healthy control subjects were recruited. NAFLD was diagnosed using ultrasonography, and the T2DM patients and nondiabetic control subjects were subdivided into groups with or without NAFLD (DM/NAFLD, DM/nonNAFLD, nonDM/NAFLD and nonDM/nonNAFLD, respectively). We used the scoring system, based on the criteria of hepatorenal echo contrast, vascular blurring and liver brightness and deep attenuation, to evaluate the presence of NAFLD. The ultrasonography scores ranged from 0 to 6 points, and a diagnosis of NAFLD was made for scores of  $\geq 2$ . In the subsequent longitudinal study, we evaluated the three-month change ( $\Delta$ ) in the CK-18 level and other parameters in 40 T2DM patients with NAFLD. Serum CK-18 levels were measured using ELISA.

**Results:** The median [IQR] level of serum CK18 was 158.4U/L [107.1–291.9] in the DM/NAFLD group, 96.1 U/L [74.1–142.6] in the DM/nonNAFLD group, 172.4 U/L [130.4–278.8] in the nonDM/NAFLD group and 120.4 U/L [97.5–158.1] in the nonDM/nonNAFLD group. The serum CK18 values were significantly higher in the NAFLD group than in the nonNAFLD group among both diabetic ( $p < 0.0001$ ) and nondiabetic subjects ( $p = 0.004$ ). The median [IQR] level of CK18 was not significantly different between the patients with diabetes and the controls (139.9 U/L [84.0–223.6] vs 147.4 U/L [104.0–198.7],  $p = 0.63$ ). The CK-18 level was found to be an independent determinant of NAFLD (Odds ratio 1.01, 95%CI 1.00–1.02,  $p = 0.004$ ) and was positively correlated with the ultrasonography score and AST and ALT levels in the T2DM patients. Positive correlations were also identified between the CK-18 and transaminase levels in the T2DM and NAFLD cohorts. Among the T2DM patients, the area under the ROC curve (AUROC) analysis indicated that the CK-18 level was the best serum predictor of NAFLD (0.75, 95%CI 0.67–0.81 compared with 0.73, 95%CI 0.65–0.79 for ALT, and 0.62, 95%CI 0.54–0.70 for AST). The best cutoff point predicting NAFLD was 180.93U/L, with a sensitivity of 44% and a specificity of 97%.  $\Delta$ CK-18 was found to be significantly associated with  $\Delta$ BMI in the T2DM patients with NAFLD.

**Conclusion:** The CK-18 level and the severity of NAFLD was positively correlated in the T2DM patients; thus, the CK-18 level is a potentially useful biomarker for assessing not only the severity but also the efficacy of treatment and the improvement in NAFLD in patients with T2DM.

### 1275

#### Unexpected prevalence of NAFLD among metabolically healthy patients with massive obesity

S. Chiheb<sup>1</sup>, N. Helmy<sup>2</sup>, B. Merioud<sup>1</sup>, C. Barrat<sup>2</sup>, M. Ziou<sup>3</sup>, C. Vons<sup>2</sup>, P. Valensi<sup>1</sup>;

<sup>1</sup>Endocrinology Diabetology Nutrition, Jean Verdier Hospital,

<sup>2</sup>Digestive and Metabolic Surgery, Jean Verdier Hospital,

<sup>3</sup>Pathology, Jean Verdier Hospital, Bondy, France.

**Background and aims:** Metabolically healthy obese (MHO) is a phenotype referring to obese patients who are relatively insulin sensitive, normotensive and have favourable glucose and lipid profiles. However, clinical and biological parameters defining this group remain imprecise. In addition, data concerning the hepatic status of these patients and the presence or absence of non alcoholic liver disease (NAFLD) are scarce. It is widely agreed that NAFLD contributes to insulin resistance and poor metabolic prognosis. To

evaluate the prevalence and the extent of NAFLD in MHO patients eligible for bariatric surgery

**Materials and methods:** In a prospective cohort of morbid obese patients undergoing bariatric surgery. Surgical liver biopsies were obtained from the left hepatic lobe at the beginning of different laparoscopic procedures, allowing sufficient histological analysis. The study was approved by the ethical committee, and all included patients signed informed consent. Currently, 66 patients were included (54 women), aged 36.4 $\pm$ 9.6 years, body mass index 44.8 $\pm$ 5.3 kg/m<sup>2</sup>. All patients were free of other liver disease (alcohol, viral...). Liver changes were classified by histological analysis into 2 Groups (according to Bedossa and al 2012): normal liver, and NAFLD including simple steatosis and steatohepatitis (NASH). All clinical and biological data were collected: comorbidities, liver, lipid and glycemic profile, and HOMA-IR and fatty liver index (FLI) were calculated. MHO phenotype was defined as no or only one feature of the metabolic syndrome (IDF criteria)

**Results:** Of the 66 patients 22 had definite MHO status. Ten of them had histologically normal liver and 12 had NAFLD (9 steatosis and 3 NASH). In the metabolically unhealthy obese patients (44 MUO), 6 had histologically normal liver and 38 had NAFLD (25 steatosis, 13 NASH). Among MHO patients, those with NAFLD had higher BMI than patients with histologically normal liver (47.4 $\pm$ 6.4 vs 41.6 $\pm$ 3.8 kg/m<sup>2</sup>,  $p = 0.03$ ) while ALAT, ASAT, GGT, fasting plasma glucose and insulin, FLI index, HOMA-IR were mostly normal and similar

**Conclusion:** The prevalence of liver lesions is high in massive obesity, even in metabolically healthy patients, with no simple predictive marker except a higher BMI

### 1276

#### Combination of empagliflozin and linagliptin shows promise in a rodent model of non-alcoholic fatty liver disease

T. Klein<sup>1</sup>, M. Kern<sup>2</sup>, N. Klötting<sup>3</sup>, R. Grempler<sup>1</sup>, E. Mayoux<sup>1</sup>, M. Mark<sup>1</sup>, M. Blüher<sup>2</sup>;

<sup>1</sup>Boehringer Ingelheim, Biberach, <sup>2</sup>Department of Medicine, <sup>3</sup>IFB Obesity Diseases, Junior Research Group Animal Models, University of Leipzig, Germany.

**Background and aims:** Non-alcoholic fatty liver disease (NAFLD) and non-alcoholic steatohepatitis (NASH) are gaining increasing importance as the hepatic manifestations of metabolic syndrome and as primary causes for developing severe liver disease. Dipeptidyl peptidase (DPP)-4 and sodium-dependent glucose cotransporter (SGLT)-2 inhibitors are established treatments for type 2 diabetes (T2D). The DPP-4 inhibitor linagliptin (LINA) has been shown to improve hepatic steatosis and insulin sensitivity and reduce inflammation in preclinical models. The SGLT-2 inhibitor empagliflozin (EMPA) has been shown to improve insulin sensitivity of the liver, and improve several inflammatory markers in tissue of diabetic animal models. Here we investigated the effects of the combination of EMPA and LINA (EMPA+LINA) on hepatic parameters in db/db mice.

**Materials and methods:** We determined the effects of 8 weeks' treatment with EMPA (10 mg/kg/day) and LINA (3 mg/kg/day), alone or in combination, and vehicle on whole body insulin sensitivity in female db/db mice ( $n = 15$ /group) using euglycaemic-hyperinsulinaemic clamps. Due to the mechanism of action of SGLT-2 inhibitors, euglycaemic-hyperinsulinaemic clamps were performed 4 days after the end of drug treatment. Liver triglyceride content was determined and inflammatory markers (F4/80 and suppressor of cytokine signaling [SOCS]-3) were detected using RT-PCR.

**Results:** Insulin-mediated suppression of hepatic glucose production (HGP) was significantly greater in the EMPA (13.1 mg/kg/min;  $p < 0.05$ ) and EMPA+LINA groups (11.8 mg/kg/min;  $p < 0.05$ ) compared with vehicle (26.3 mg/kg/min). LINA monotherapy decreased HGP (21.8 mg/kg/min), although statistical significance was not achieved. Tissue-specific labelled glucose uptake in liver was higher with EMPA (822 dpm/g/ml;  $p < 0.05$ ), LINA (935 dpm/g/ml;  $p < 0.05$ ), and EMPA+LINA (1040 dpm/g/ml;  $p < 0.01$ ) compared with vehicle (610 dpm/g/ml). The glucose disposal rate was improved in the EMPA (5.9 mg/kg/min;  $p < 0.001$ ), LINA (3.4 mg/kg/min;  $p < 0.01$ ), and EMPA+LINA groups (7.8 mg/kg/min;  $p < 0.001$ ) compared with vehicle (1.9 mg/kg/min). Glucose uptake into muscle and adipose tissue was not affected by any treatment. Compared with vehicle (14.6%), triglyceride content was significantly lower with EMPA (9.1%;  $p < 0.05$ ), LINA (12.1%;  $p < 0.01$ ), and EMPA+LINA (5.7%;  $p < 0.01$ ) compared with vehicle. Levels of F4/80 and SOCS-3 mRNAs in the liver were reduced in the combination treatment compared with control.

**Conclusion:** The combination of EMPA+LINA was superior to the respective monotherapies in improving insulin sensitivity of the liver and in reducing liver lipid content. These results suggest that the combination of both drugs may be a potential therapy for the most common liver diseases associated with T2D.

### Mosapride citrate improves non-alcoholic steatohepatitis with increased faecal lactic acid bacteria and plasma glucagon-like peptide-1 level in a rodent model

H. Okubo<sup>1</sup>, M. Yoneda<sup>2</sup>, H. Sakoda<sup>3</sup>, A. Kushiyama<sup>4</sup>, M. Fujishiro<sup>3</sup>, Y. Nakatsu<sup>1</sup>, T. Fukushima<sup>1</sup>, Y. Matsunaga<sup>1</sup>, H. Kamata<sup>1</sup>, M. Iwashita<sup>5</sup>, F. Nishimura<sup>5</sup>, A. Tomoichiro<sup>1</sup>;

<sup>1</sup>Department of Medical Science, Graduate School of Medicine,

<sup>2</sup>Department of Molecular and Internal Medicine, Graduate School of Biomedical and Health Sciences, University of Hiroshima, <sup>3</sup>Department of Internal Medicine, Graduate School of Medicine, University of Tokyo,

<sup>4</sup>Institute for Adult Disease, Asahi Life Foundation, Tokyo, <sup>5</sup>Department of Dental Science for Health Promotion, University of Hiroshima, Japan.

**Background and aims:** Several lines of evidence have suggested a role of gut microbiota in the etiology of non-alcoholic steatohepatitis (NASH). Gastrointestinal motility may influence gut microbiota and NASH subjects reportedly had a prolonged orocecal transit time coexistent with small intestinal bacterial overgrowth. Thus, we investigated effects of the gastroprokinetic agent mosapride citrate (MC) on gut microbiota and the development of NASH using methionine–choline deficient diet (MCDD)-induced NASH rodent model.

**Materials and methods:** 6-week-old C57BL/6 mice were divided into three groups, given the normal chow diet (NCD), the MCDD or the MCDD containing 10 mg/kg/day MC (MCDD plus MC) for 6 weeks.

**Results:** Gut microbiota analyses revealed that total numbers of bacteria were lower in the MCDD than in the NCD group, but similar to those in the MCDD plus MC group. Calculation of the relative abundance of each strain indicated lactic acid bacteria such as *Bifidobacterium* and *Lactobacillus* in feces to be specifically decreased in the MCDD group. Interestingly, the reduction in lactic acid bacteria in the MCDD group was reversed in the MCDD plus MC group. Subsequently, HE staining of livers from the MCDD group revealed remarkable NASH development as evidenced by deformity of hepatocytes, large fat droplets and inflammatory cell infiltration, all of which were suppressed in the MCDD plus MC group. Serum ALT levels were also elevated in the MCDD group, but were normal in the MCDD plus MC group. Azan staining revealed marked collagen deposition and mRNA levels of fibrosis markers such as  $\alpha$ -smooth muscle actin, tissue inhibitor of metalloproteinase 1 and transforming growth factor  $\beta$  were elevated in the MCDD group, while these abnormalities were significantly reversed in the MCDD plus MC group. Finally, the molecular mechanism underlying the resistance to NASH development conferred by MC treatment was investigated. The mRNA level of tumor necrosis factor  $\alpha$  and the serum concentration of lipopolysaccharide, a possible inducer of hepatic inflammation, were increased in the MCDD group, while these increases were suppressed in the MCDD plus MC group. Glucagon-like peptide-1 (GLP-1) reportedly attenuated the development of NASH. Plasma GLP-1 levels were lower in the MCDD than in the NCD group. Interestingly, plasma GLP-1 levels were increased in the MCDD plus MC group. To evaluate intestinal inflammation, immunostaining employing the anti-NF $\kappa$ Bp65 antibody was performed. Nuclear NF $\kappa$ Bp65 positive cells in the colon were increased in the MCDD group, while the numbers of these cells were reduced in the MCDD plus MC group.

**Conclusion:** MC showed a protective effect against the NASH development induced by MCDD, in which increased fecal lactic acid bacteria and plasma GLP-1 may be involved. Thus, MC may be effective for treating NASH.

## 1278

### PDK2 deficiency reduces hepatic steatosis and insulin resistance in mice fed a high fat diet

S.-W. Kim<sup>1</sup>, K.-U. Lee<sup>2</sup>, M.-G. Choi<sup>3</sup>, K.-H. Bae<sup>1</sup>, Y.-H. Go<sup>1</sup>, I.-K. Lee<sup>1</sup>;

<sup>1</sup>Department of Endocrine and Metabolism of Internal medicine,

Kyungpook National University School of Medicine, Daegu, <sup>2</sup>Department

of Endocrine and Metabolism of Internal medicine, Asan Medical Center,

Seoul, <sup>3</sup>Department of Endocrine and Metabolism of Internal medicine,

Hallym University Medical Center, Chuncheon, Republic of Korea.

**Background and aims:** Hepatic steatosis is rapidly evolving as a major medical problem in the world. It involves a variety of lipid abnormalities including enhanced fatty acid influx from the adipose tissue, increased *de novo* lipogenesis, reduced fatty acid oxidation and ketogenesis. The pyruvate dehydrogenase kinases (PDKs) regulate pyruvate oxidation by controlling the activity of the pyruvate dehydrogenase complex (PDC). We examined whether PDKs were increased in the liver of HFD-fed mice and how they regulate hepatic steatosis and insulin resistance.

**Materials and methods:** The physiological importance of regulation of PDC activity by PDK isoenzyme 2 was assessed by comparing PDK2 knockout (PDK2 KO) mice with wild type mice fed a high fat diet (HFD) and an isocaloric low fat diet (LFD).

**Results:** Body weight gain and hepatic steatosis were attenuated by PDK2 deficiency in the HFD fed mice. Fasting blood glucose, serum insulin, and liver pyruvate, lactate, oxaloacetate, citrate, diacylglycerols, and triacylglycerols were also reduced. Hepatic glucose production was also reduced and insulin sensitivity was increased in the HFD fed PDK2 KO mice. The hepatic enzyme capacity for fatty acid oxidation and ketogenesis was increased while the capacity for lipogenesis was decreased. In spite of this but consistent with greater PDC activity, the respiratory exchange ratio was higher in the PDK2 knockout mice. Energy expenditure was increased without changes in physical activity. Increased hepatic insulin sensitivity and improved glucose tolerance correlated with reduced PKC $\epsilon$  phosphorylation.

**Conclusion:** The findings support the case for PDK2 as a promising target for hepatic steatosis and insulin resistance.

## 1279

### Pro- and antioxidant status in dependence on vitamin D<sub>3</sub> availability in the development of diabetes-induced liver injury

D. Labudzynski, I. Shymanskyi, A. Mazanova, O. Lisakovskaya, M. Veliky; Laboratory of Medicine Biochemistry, Palladin Institute of Biochemistry of the National Academy of Sciences of Ukraine, Kyiv, Ukraine.

**Background and aims:** Diabetes is known to be associated with overproduction of ROS and/or impaired antioxidant defence contributing to the onset and progression of diabetic complications on vessels, retina, kidneys, nerves and liver. Nevertheless, precise mechanism by which oxidative stress could facilitate and accelerate the development of hepatic lesions in diabetes is not fully clarified. Recent studies have shown that vitamin D<sub>3</sub> is currently recognized as a potent immunomodulator and antioxidant affecting various inflammatory and autoimmune diseases. The present study was performed to determine the relationship between 25-hydroxyvitamin D<sub>3</sub> (25(OH)D<sub>3</sub>) availability and pro-/antioxidant profile in liver of diabetic mice.

**Materials and methods:** Type 1 diabetes was induced in male C57BL/6 mice (weighing 25.0  $\pm$  1.5g) by i.p. injection of multiple low dose streptozotocin (40 mg/kg b.w.). Control and STZ-diabetic mice were treated with or without vitamin D<sub>3</sub> (15 IU/mouse per os, for 8 weeks). Serum 25OHD<sub>3</sub> was assessed by ELISA. The levels of phospho-NF- $\kappa$ B/p65, poly(ADP-ribose)polymerase 1 (PARP-1), poly-ADP-ribosylated and nitrosylated proteins were measured by Western-blot analysis. Intracellular reactive oxygen and nitrogen species (ROS and RNS) production were detected by 2',7'-dichlorofluorescein (DCF) and 4,5-diamino-fluorescein diacetate (DAF-DA) fluorescence respectively using flow cytometry. Hepatic pro-/antioxidant factors and enzymes activity in liver were measured spectrophotometrically.

**Results:** Serum level of 25OHD<sub>3</sub>, the main circulating metabolite of D<sub>3</sub>, was shown to be reduced to 23.8 $\pm$ 1.9 in diabetes vs. 39.7 $\pm$ 2.9 nmol/l in control, that reflects reliably vitamin D<sub>3</sub> deficiency (p<0.05). As a strong evidence of diabetes-induced oxidative stress that may lead to liver lesions, increased hepatocytes ability to oxidize the fluorogenic substrate DCF and DAF was found. These changes were accompanied by a significant rise in the levels of protein nitrotyrosine, carbonyl groups and PAR by 42, 38, and 61% respec-

tively vs. control,  $p < 0.05$ . Diabetes also caused more than 1.67-fold increase in the level of 89 kDa apoptotic cleavage fragment of PARP. It was established diabetes-associated increase in the activities of key pro- and antioxidant enzymes in the liver: catalase (20%), SOD (7%), GPX (41%), xanthine oxidase (27%) DT-diaforase (54%) and NADPH-oxidase (39%). Alterations in pro-/antioxidant status in diabetes were paralleled by 1.51- and 2.04-fold over-expression of cytosolic and nuclear NF- $\kappa$ B/p65 respectively as compared to control ( $p < 0.05$ ), indicative of NF- $\kappa$ B-mediated signaling pathways contribution to hepatic oxidative stress and inflammation. Vitamin D3 treatment completely restored blood serum 25OHD3 level, partially decreased PARP-1 and NF- $\kappa$ B/p65 expression and counteracted diabetes-induced abnormalities of pro-/antioxidant profile in liver tissue. Normalized 25OHD3 availability strongly correlated with a significant decrease in ROS and RNS generation in hepatocytes as compared with diabetic mice.

**Conclusion:** The findings indicate that diabetes-associated vitamin D3 insufficiency can be related, at least in part, to increased prooxidant status of liver cells. Our data suggest a potential role of vitamin D3 treatment in the regulation of impaired oxidative metabolism in diabetes.

## 1280

### Liver-specific deletion of mitochondrial prohibitin-2 alters glucose homeostasis associated with liver damage

J. Martin-Levilain<sup>1</sup>, S. Supale<sup>1</sup>, C. Merkwirth<sup>2</sup>, D. Metzger<sup>3</sup>, P. Chambon<sup>3</sup>, T. Langer<sup>2</sup>, P. Maechler<sup>1</sup>;

<sup>1</sup>Department of Cell Physiology and Metabolism, University of Geneva, Switzerland, <sup>2</sup>Institute for Genetics, University of Cologne, Germany, <sup>3</sup>Institut de Génétique et de Biologie Moléculaire et Cellulaire,

University of Strasbourg, Illkirch, France.

**Background and aims:** Regulation of mitochondrial dynamics and functions depends on various proteins. Recent studies highlighted the role of prohibitins which are highly conserved and ubiquitously expressed as two interdependent isoforms (Phb1 and Phb2). Prohibitins are found in the inner mitochondrial membrane of mitochondria and form large ring complexes. Their dysfunctions are associated with aging, cancer, obesity and inflammation. Mice lacking liver Phb1 exhibit hepatic injury and hepatocellular carcinoma. Recently, it showed that Phb2 is essential to maintain beta-cell mitochondrial function and integrity, thereby controlling insulin secretion and beta-cell survival. The present study focused on the role of Phb2 in liver biology using transgenic mice with liver-specific and time-controlled deletion of Phb2 (Hep-Phb2<sup>-/-</sup>).

**Materials and methods:** Conditional liver-specific (Alb-Cre-ERT/lox) deletion of Phb2 was induced in 9-week old mice by sub-cutaneous implantation of one tamoxifen pellet per animal. After 3 weeks, mice were sacrificed, body and liver weights were measured and liver tissues analyzed by histology. The levels of hepatic transaminases (ALT and AST), bilirubin, cholesterol, triglycerides and glucose were determined in blood and glycogen content was measured in liver. Pyruvate tolerance test was also performed. Expression of Phb2, Phb1 and proteins involved in glycogenesis/glycogenolysis/gluconeogenesis were assessed by Western Blot.

**Results:** Three weeks after Tamoxifen implantation, hepatic levels of Phb2 protein were reduced by 90%. This deletion was associated with a 70–80% decrease of hepatic Phb1 protein. The body and liver weights of Hep-Phb2<sup>-/-</sup> were significantly lower compared to control (Phb2fl/fl) mice. Levels of AST (642±94 vs 90±19 IU/L,  $p < 0.001$ ), ALT (247±41 vs 33±3 IU/L,  $p < 0.001$ ) and bilirubin (45±13 vs 2±0.1  $\mu$ M,  $p < 0.05$ ) were increased in Hep-Phb2<sup>-/-</sup> animals versus controls. Plasmatic levels of triglycerides (0.07±0.1 vs 1.1±0.1 mM,  $p < 0.05$ ) and cholesterol (1.40±0.2 vs 1.9±0.07 mM,  $p < 0.01$ ) were lower in Hep-Phb2<sup>-/-</sup> mice compared to Phb2fl/fl mice. H&E staining showed pronounced histologic damages in Hep-Phb2<sup>-/-</sup> such as bile duct hyperplasia, fibrosis and accumulation of lipid droplets. In fed conditions, blood glucose levels were lower (4.5±0.6 vs 7.8±0.8 mM,  $p < 0.005$ ) in Hep-Phb2<sup>-/-</sup> mice compared to Phb2fl/fl mice. Pyruvate tolerance test revealed impaired hepatic glucose production in Hep-Phb2<sup>-/-</sup> mice. The hepatic glycogen content was reduced by 80% in Hep-Phb2<sup>-/-</sup> animals versus Phb2fl/fl mice. Accordingly, marked reduction of expression of glucose-6-phosphatase (-25%), glucokinase (-90%), glycogen phosphorylase (-75%) and glycogen synthetase (-50%) were observed in liver of Hep-Phb2<sup>-/-</sup> mice.

**Conclusion:** Hepatic deletion of Phb2 induced liver damage associated with impaired hepatic glycogen metabolism and hypoglycaemia. Liver Phb2 is required for the fine tuning of glycogenesis, glycogenolysis and gluconeogenesis, ultimately participating to glucose homeostasis.

### Increased inflammatory and procoagulant state are responsible for vascular complications in diabetic patients with albuminuria accompanied by fatty liver

S. Ljubic<sup>1</sup>, M. Tomić<sup>1</sup>, A. Piljac<sup>1</sup>, D. Majić Milotić<sup>1</sup>, L. Smircić Duvnjak<sup>1</sup>, T. Bulum<sup>1</sup>, A. Jazbec<sup>2</sup>;

<sup>1</sup>Merkur Clinical Hospital, Vuk Vrhovac University Clinic, Zagreb,

<sup>2</sup>University of Zagreb, Croatia.

**Background and aims:** Vascular complications in diabetes are characterised by inflammation and a procoagulant state due to hyperglycaemia. The aim of this study was to compare the behaviour of inflammatory and other markers responsible for endothelial dysfunction and atherosclerosis related to nephropathy and liver steatosis in type 2 diabetic patients.

**Materials and methods:** Markers of inflammation and metabolic syndrome, were tested in 594 patients according to the presence of non-alcoholic fatty liver disease (NAFLD) and the albumin excretion rate (AER) (normoalbuminuria <30 mg/24h; albuminuria: 30–300 mg/24h). NAFLD was diagnosed by ultrasonography. Fatty liver index (FLI) ( $\leq 60$ ;  $>60$ ) was used as a predictor of liver steatosis (FLI =  $[e^{(0.953 \times \log_e(\text{triglycerides [Tg]}) + 0.139 \times \text{body mass index [BMI]} + 0.718 \times \log_e(\text{gamma-glutamyl transpeptidase [GGT]} + 0.053 \times \text{waist-to-hip ratio [WHR]} - 15.745))} / 1 + e^{(0.953 \times \log_e[\text{Tg}] + 0.139 \times \text{BMI} + 0.718 \times \log_e[\text{GGT}] + 0.053 \times \text{WC} - 15.745)}] \times 100$ ). AER was measured from three urine samples. Peripheral insulin sensitivity was measured using estimated glucose disposal rate (eGDR =  $24.31 - [12.22 \times \text{WHR}] - [3.29 \times \text{hypertension}] - [0.57 \times \text{glycated haemoglobin (HbA1c)}]$ ). Patients were divided into quartiles according to FLI and AER (1<sup>st</sup>: FLI  $\leq 60$  and AER <30, 2<sup>nd</sup>: FLI >60 and AER <30, 3<sup>rd</sup>: FLI  $\leq 60$  and AER:30–300 and 4<sup>th</sup>: FLI >60 and AER:30–300).

**Results:** Significant differences ( $p < 0.05$ ) were determined using analysis of variance in waist circumference (WC), postprandial blood glucose (BGPP), HbA1c, adiponectin (ApN), fibrinogen (FIB), white blood cell (WBC) count, AER, high density lipoprotein (HDL), Tg, alanine transaminase (ALT), fasting C-peptide (FC) and eGDR among the groups according to the presence of NAFLD and albuminuria. Tested groups that differed were determined using Tukey post hoc test. Patients in the 4<sup>th</sup> quartile had significantly higher FIB, WBC, WC, BGPP, HbA1c, Tg, ALT, and fC-peptide, and lower ApN, HDL and eGDR values compared with the 1<sup>st</sup> quartile. Patients in the 2<sup>nd</sup> quartile had higher WC and lower eGDR compared with the 1<sup>st</sup> quartile. After stepwise regression procedure for FIB as a dependent variable, the best model included ( $R^2 = 0.479$ ) high-sensitivity C-reactive protein (hs-CRP), systolic blood pressure (SBP), WHR, WBC and ApN. The best model for WBC ( $R^2 = 0.310$ ) included FLI and interleukin-6 (IL-6). FIB and WBC correlated significantly ( $p < 0.05$ ) with hs-CRP, IL-6, BGPP, HbA1c, AER, HDL, uric acid, FLI and eGDR; FIB additionally correlated with fasting BG, and WBC with WC, ApN and Tg.

**Conclusion:** Increased FIB, WBC, Tg, ALT, BGPP and HbA1c, and decreased ApN, HDL and eGDR pointed to increased inflammatory and procoagulant state in the presence of albuminuria and NAFLD. Decreased eGDR reflected increased insulin resistance even in normoalbuminuric patients with NAFLD. Reported correlations among the tested variables unravelled the association between inflammation, procoagulant state and glycaemia as a culprit of vascular complications in the studied patients.

## 1282

### Hepatic heat shock proteins in long term diabetic complications

M. Brune<sup>1,2</sup>, N.B. Nillegoda<sup>3</sup>, B. Bukau<sup>3</sup>, P.P. Nawroth<sup>1</sup>, S. Herzig<sup>2</sup>;

<sup>1</sup>Department of Internal Medicine I and Clinical Chemistry, Heidelberg University Hospital, <sup>2</sup>Molecular Metabolic Control, German Cancer Research Center, Heidelberg, <sup>3</sup>Biogenesis & Quality Control of Proteins, Zentrum für Molekulare Biologie Heidelberg, Germany.

**Background and aims:** Current regimes for the treatment of Diabetes mellitus type 2 (DM2) can only postpone, but not prevent the development of long term diabetic complications. Therefore, the continuously earlier age of DM2 onset will dramatically increase the incidence and severity of diabetic complications in future years. The course of DM2 complications includes accumulation of damaged, misfolded and aggregated proteins, while protective heat shock proteins (HSP) are repressed. With this study we aim to identify HSP-regulated liver-to-periphery signalling pathways effecting the development and progression of long term diabetic complications.

**Materials and methods:** Livers of Streptozotocin-induced type 1 diabetic mice, obesity-induced type 2 diabetic mice (db/db), mice fed a high-fat diet

and respective control mice were analyzed for expression of HSPs by qPCR and western blot. Hepatocyte-specific reconstitution of HSPs in db/db mice was achieved via adenoviral constructs for Hsp70, DNAJB1 and DNAJA2.

**Results:** In our models of diabetes, we observed downregulations of up to 90% in the hepatic expression of central HSPs such as Hsp70. In contrast, non-diabetic mice on a high-fat diet showed no significant regulation of hepatic HSP expression. In db/db mice, two weeks of hepatocyte-specific reconstitution of Hsp70 reduced both fasting glucose and HbA1c by approx. 25% ( $p < 0.005$ ) along with improved liver histopathology. Parameters of lipid metabolism were not significantly affected. Since efficient recognition and processing of damaged and aggregated proteins requires the cooperation of HSPs from different HSP families, we also analyzed the *in vivo* effects of simultaneous reconstitution of the cooperating HSPs Hsp70, DNAJB1 and DNAJA2 in db/db mice. This combined reconstitution improved fasting blood glucose from  $444 \pm 91$  mg/dl in control mice to  $269 \pm 101$  mg/dl in HSP-treated mice ( $-40\%$ ,  $p < 0.005$ ). As a measure of overall liver pathology, serum alanine amino transferase (ALT) dropped from  $325 \pm 112$  IU/l to  $108 \pm 50$  IU/l ( $p < 0.005$ ). The response to acute glucose challenge showed a highly significant reduction of glucose tolerance ( $p < 0.001$  in two way ANOVA). Along with reduced serum insulin levels in HSP-treated mice, the improved glucose tolerance test was suggestive for a reduced insulin resistance and increased glucose uptake in periphery organs like muscle and adipose tissue. Importantly, only six days after reconstitution of cooperating HSPs, the thermal nociceptive responsiveness was significantly improved from  $32.5 \pm 11$  sec. in control mice to  $24.5 \pm 8$  sec. in HSP-treated mice ( $p < 0.01$ ). Peripheral nerve histology revealed a significant change in the number of infiltrating leukocytes, pointing towards immunological mechanisms that reduced the pre-existing diabetic neuropathy.

**Conclusion:** The hepatic reconstitution of HSPs cooperating in protein quality control resulted in a profound metabolic improvement in our *in vivo* model of DM2, affecting not only parameters of carbohydrate metabolism but also insulin resistance and the long term complication of diabetic neuropathy. Our data indicate that hepatic HSPs regulate systemic signalling pathways which direct the course of diabetes and its long term complications.

### Lipoprotein subclasses associate with hepatic glucose uptake, production, and genetic targets after bariatric surgery in morbidly obese patients

R.M. Badeau<sup>1</sup>, M.-J. Honka<sup>1</sup>, H. Immonen<sup>1</sup>, J.C. Hannukainen<sup>1</sup>, P. Soinen<sup>2</sup>, A.J. Kangas<sup>2</sup>, M. Ala-Korpela<sup>2</sup>, P. Nuutila<sup>1</sup>;

<sup>1</sup>Turku Positron Emission Tomography Centre, Turku,

<sup>2</sup>School of Pharmacy, University of Eastern Finland, Kuopio, Finland.

**Background and aims:** The cardiovascular complications arising from morbidly obese individuals remains unsettled. If lifestyle modifications are not effective in reducing weight, these individuals have a high risk for insulin resistance and diabetes. Bariatric surgery is a potent treatment to rapidly remove weight. Although absolute very-low-density lipoprotein cholesterol (VLDL) serum levels are decreased and high-density lipoprotein (HDL) cholesterol concentrations are increased after bariatric surgery, their heterogeneity/subclass distributions remain unclear. These subclasses play a major role in the extent of atherosclerosis severity. This study's objective was to map these subclasses in morbidly obese participants, both pre- and post-surgery, and to assess hepatic metabolic and genetic associations.

**Materials and methods:** Hepatic glucose uptake and production were ascertained using <sup>18</sup>F-fluorodeoxyglucose and positron emission tomography from 23 morbidly obese (BMI > 39 kg/m<sup>2</sup>) participants, before and six months after surgery. Ten healthy lean controls were also recruited. Liver biopsies were taken from 23 participants before surgery. Targeted, real-time PCR analysis was conducted to assess gene levels in the morbidly obese, on lipoprotein assembly and catabolic genes: microsomal triglyceride transfer protein, apoB, apoE, ABCA1, apoAI, LDL receptor, CD36, hepatic lipase, and LCAT. Genes involved with liver triglyceride metabolism such as glucose kinase regulatory protein, DGAT, etc. were also profiled. Lipoprotein subclass profiles, from serum, were analyzed by NMR spectroscopy. Principal component analysis explained the 95 percent variation in the dataset. After a Bonferroni correction, p-values less than 0.001041 were significant. Lipoprotein subclasses, which changed significantly, were compared to hepatic glucose uptake, production, and genetic profiles using Pearson correlations.

**Results:** After bariatric surgery, large, medium, and small VLDL-cholesterol concentrations were significantly reduced, while extra-large and large HDL cholesterol subclasses were significantly higher. Only after surgery, large

and extra-large HDL correlated positively with hepatic glucose uptake rate ( $r = 0.542$ ;  $p = 0.025$  and  $r = 0.510$  and  $p = 0.036$ , respectively) and these particles associated negatively with hepatic glucose production ( $r = -0.624$ ,  $p = 0.013$  and  $r = -0.547$  and  $p = 0.035$ , respectively). Results from the liver genetic data are in process.

**Conclusion:** We showed that surgery induced, rapid weight loss caused significant increases in antiatherogenic large HDL subclasses and that these were associated with hepatic glucose metabolism. In addition, this study used human liver samples, which are restricted based on ethical rationales. This pioneer study builds a framework for understanding hepatic lipoprotein metabolism in morbid obesity, a condition precluding insulin resistance and type 2 diabetes. With our novel findings, early prevention strategies can be induced. In summary, this report delivers an in-depth conceptualization about how liver and lipoprotein synergy dictates diabetes-induced cardiovascular risk factors.

## PS 116 Vascular calcification

1284

### Oestrogen-related receptor gamma mediates vascular calcification through up-regulation of BMP2

Y.-K. Choi<sup>1</sup>, J.-H. Kim<sup>1</sup>, M.-K. Kim<sup>2</sup>, G.-S. Jung<sup>1</sup>, K.-H. Bae<sup>1</sup>, M.-J. Kim<sup>3</sup>, E. Kim<sup>4</sup>, I.-K. Lee<sup>1</sup>, K.-G. Park<sup>1</sup>, M.-G. Choi<sup>5</sup>, K.-U. Lee<sup>6</sup>, E. Jung<sup>7</sup>;

<sup>1</sup>Division of Endocrinology and Metabolism, Department of Internal Medicine, Kyungpook National University School of Medicine, <sup>2</sup>Division of Endocrinology and Metabolism, Department of Internal Medicine, Keimyung University School of Medicine, <sup>3</sup>Pooreen Meerae Internal Medicine Clinic, <sup>4</sup>Division of Endocrinology and Metabolism, Department of Internal Medicine, Daegu, <sup>5</sup>Division of Endocrinology and Metabolism, Department of Internal Medicine, Hallym University Medical Center, Chuncheon, <sup>6</sup>Division of Endocrinology and Metabolism, Department of Internal Medicine, Asan Medical Center, Seoul, <sup>7</sup>Division of Endocrinology and Metabolism, Department of Internal Medicine, Daegu Catholic University Medical Center, Republic of Korea.

**Background and aims:** Vascular calcification, which refers to ectopic mineralization in vascular smooth muscle cells, occurs frequently in many diseases such as chronic kidney disease, atherosclerosis, and diabetes. Estrogen related receptor (ERR) $\gamma$ , a member of orphan nuclear receptor superfamily has diverse roles in regulating homeostatic and metabolic processes. However the role of ERR $\gamma$  in vascular calcification has not yet been investigated. This study was undertaken to examine the role of ERR $\gamma$  in vascular calcification.

**Materials and methods:** Rat aortic smooth muscle cells (RASMCs) were cultured and vascular cell calcification was induced by treatment with inorganic phosphate and calcium. Next we investigated effects of adenovirus-mediated overexpression of ERR $\gamma$  on phosphate-induced VSMC calcification and examined whether siRNA-mediated inhibition of endogenous expression of ERR $\gamma$  or pharmacological inhibition of ERR $\gamma$  with GSK5182 prevent phosphate-induced vascular calcification.

**Results:** Along with increased expression of bone morphogenic protein-2 (BMP2), Runx2 and Msx2, ERR $\gamma$  expression was upregulated during phosphate-induced calcification. Von-kossa staining showed that adenovirus-mediated overexpression of ERR $\gamma$  (Ad-ERR $\gamma$ ) in RASMCs accelerated Pi-induced calcification. Ad-ERR $\gamma$  increased the expression of osteogenic gene including Runx2, OPN and Msx2 but decreased alpha-SMA. ERR $\gamma$  induced BMP2 transcription through directly binding to its promoter region and increased BMP2 signaling including phosphorylation and nuclear localization of smad1/5/8. Moreover, inhibition of ERR $\gamma$  by both siRNA-mediated knockdown of endogenous ERR $\gamma$  and a selective inverse agonist, GSK5182 attenuated vascular calcification and osteogenic gene expression in vitro and in vivo.

**Conclusion:** This study demonstrated that ERR $\gamma$  mediates vascular calcification through up-regulation of BMP2 signaling. These results indicate that inhibition of ERR $\gamma$  may be a potential therapeutic strategy for prevention of vascular calcification.

1285

### Effects of high glucose on the OPG/RANK/RANKL/TRAIL system in the progression of vascular calcification in rat aortic vascular smooth muscle cells

Y. Kang, H. Choi, E. Sim, H. Lee, D. Yi, S. Son;

Internal Medicine, Pusan National University School of Medicine, Yangsan, Republic of Korea.

**Background and aims:** Diabetes mellitus is frequently complicated by cardiovascular disease, such as vascular calcification and accelerated atherosclerosis. Recently, it has been known that the OPG/RANK/RANKL/TRAIL system may play a major role in vascular calcification and atherosclerosis. However, the possible effects of long term high glucose stimulation at least 4 weeks on the OPG/RANK/RANKL/TRAIL system in the progression of vascular calcification are less clear. We attempted to evaluate the effect of high glucose on the progression of vascular calcification in rat aortic smooth muscle cells (RASMCs) and to detect the expression changes of OPG, RANK, RANKL, and TRAIL for 2 and 4 weeks. Furthermore, we used BMP-7, which has been known to attenuate vascular calcification, to detect the possible changes of OPG, RANK, RANKL, and TRAIL expressions on the calcification of RASMCs.

**Materials and methods:** The primary cultured RASMCs were stimulated with normal glucose (5.5mmol/L glucose, NG) and high glucose (30 mmol/L glucose, HG) with calcification medium. The mRNA levels and the protein expressions of OPG, RANK, RANKL, and TRAIL were measured by reverse transcription polymerase chain reaction (RT-PCR) or Western blot.

**Results:** The intensity of calcium staining was increased in HG after 2 weeks and more increased and prominent after 4 weeks compared to NG. OPG mRNA and protein expressions were not different after 2 weeks, however, after 4 weeks, OPG expressions were significantly decreased in HG. Regarding RANK, RANKL, and TRAIL expressions, there were no differences after 2 or 4 weeks of stimulation. After 4 week of rhBMP-7 co-treatment, the densities of calcium stains were attenuated and the total amount of calcium was also decreased. The mRNA and protein OPG expressions were maintained with BMP-7 after 4 weeks of stimulation. There were no differences in the expressions of RANK, RANKL, and TRAIL between with and without BMP-7 co-treatment. There was no difference in Bax mRNA expression, an apoptotic marker, between with and without BMP-7 co-treatment, however, ALP mRNA expression, a marker of mineralization, was decreased in the presence of BMP-7.

**Conclusion:** Chronic hyperglycemia may enhance vascular calcium deposition and high glucose may increase OPG mRNA and protein expression with short-term stimulation, but decrease it with long-term stimulation. The expression of RANKL, RANK, and TRAIL were maintained with long term stimulation. As the OPG expression was decreased, the increased mineralization activity may be more associated rather than apoptotic activity with the progression of long-term high glucose induced vascular calcification.

1286

### The DPP-4 inhibitor linagliptin increases plasma fetuin-A concentrations in a rat model of uraemic calcification

C. Reichetzedler<sup>1,2</sup>, A. Pasch<sup>3</sup>, K. von Websky<sup>1,2</sup>, O. Tsaprykov<sup>1</sup>, T. Klein<sup>4</sup>, B. Hocher<sup>1</sup>;

<sup>1</sup>University of Potsdam, <sup>2</sup>Centre for Cardiovascular Research / Institute of Pharmacology, Charité, Berlin, Germany, <sup>3</sup>Department of Nephrology, University of Bern, Switzerland, <sup>4</sup>Boehringer Ingelheim, Germany.

**Background and aims:** Fetuin-A is a potent inhibitor of ectopic mineralisation. An increase in fetuin-A has beneficial effects in uraemic vascular calcification, whereas fetuin-A deficiency is associated with soft tissue calcification in mice and humans. Biomarker data in diabetic and non-diabetic rodent models of chronic renal failure suggest that the dipeptidyl peptidase (DPP)-4 inhibitor linagliptin may be able to influence the pathogenesis of vascular calcification. The aim of the present study was to investigate the effect of linagliptin on uraemic vascular calcification in nephrectomised rats.

**Materials and methods:** 1,25-dihydroxyvitamin D3 (0.25  $\mu$ g/kg/day) was used to induce uraemic vascular calcification in 5/6 nephrectomised rats (5/6NxVitD). Rats were allocated to 3 treatment groups: a) sham-operated rats treated with placebo (n=10); b) 5/6NxVitD rats treated with placebo (n=14); c) 5/6NxVitD rats treated with linagliptin (n=14). Rats were treated for 6 weeks. We analysed plasma factors known to be involved in uraemic vascular calcification such as cystatin C, fibroblast growth factor 23 (FGF23), magnesium, calcium, phosphate, and fetuin-A. Blood pressure was monitored and at study end, animals were sacrificed; blood was taken and stored at -80°C for analysis.

**Results:** Blood pressure was similar in all groups. 5 of 14 animals died in the 5/6NxVitD placebo group; 3 of 14 animals died in the 5/6NxVitD linagliptin group ( $p>0.05$ ). At study end, magnesium, FGF23, and cystatin C levels were unaffected by linagliptin in 5/6NxVitD rats. The change from baseline in phosphate levels was similar with linagliptin and placebo in 5/6NxVitD rats, whereas the change from baseline in calcium levels was less with linagliptin ( $-0.062 \pm 0.255$  mmol) than placebo ( $0.961 \pm 0.439$  mmol) in 5/6NxVitD rats ( $p<0.05$ ). The change from baseline in fetuin-A levels was greater with linagliptin ( $1.278 \pm 0.125$  g/l) than placebo ( $0.919 \pm 0.072$  g/l) in 5/6NxVitD rats ( $p<0.05$ ).

**Conclusion:** The favorable change from baseline in plasma calcium after 6 weeks of linagliptin treatment in an aggressive rat model of uraemic vascular calcification may be due to an increase in fetuin-A levels. Although further studies are required, linagliptin treatment may potentially offer a new therapeutic option to reduce uraemic vascular calcification in patients with advanced stages of renal failure.

## 1287

**Below-knee arterial calcification in type 2 diabetes: association with receptor activator of nuclear factor kappa B ligand, osteoprotegerin and neuropathy**O. Bourron<sup>1,2</sup>, C.E. Aubert<sup>1</sup>, S. Liabeuf<sup>3</sup>, P. Cluzel<sup>1</sup>, M. Komajda<sup>1</sup>,S. Jacqueminet<sup>1</sup>, Z. Massy<sup>3</sup>, A. Hartemann<sup>1,2</sup>;<sup>1</sup>Pierre et Marie Curie University Paris 06 - Assistance Publique Hôpitaux De Paris, <sup>2</sup>CHU Pitié-Salpêtrière,<sup>3</sup>Picardie University - CHU Amiens, Paris, France.

**Background and aims:** Calcification of the arterial wall in diabetes contributes to the arterial occlusive process at the below knee level. The osteoprotegerin(OPG)/RANKL system is suspected to be involved in the calcification process. The aim of the study was to investigate if there is a link between arterial calcification in type 2 diabetes and 1) the conventional cardio-vascular risk factors, 2) the serum RANKL and OPG levels and 3) neuropathy.

**Materials and methods:** We objectively scored, in a cross-sectional study, infra-popliteal vascular calcification using CT-scan in 198 patients with type 2 diabetes, a high cardio-vascular risk and with glomerular filtration rate > 30mL/mn. Colour duplex ultrasonography was performed to assess peripheral arterial occlusive disease, and mediocalcosis. Peripheral neuropathy was defined by a neuropathy disability score (NDS) > 6. RANKL and OPG were measured in serum by routine chemistry.

**Results:** Below knee arterial calcification was associated with arterial occlusive disease. In multivariate logistic regression analysis, variables significantly and independently associated with the calcification score were age (OR=1.08; 95% CI=1.04-1.13; p<0.0001), male gender (OR=3.53; 95% CI=1.54-8.08; p=0.003), previous CVD(OR=2.78; 95% CI=1.39-5.59; p=0.005) and NDS (per 1 point, OR=1.21; 95% CI=1.05-1.38; p=0.006). The association with Ln OPG, significantly associated with calcification score in univariate analysis (OR=3.14; 95% CI=1.05-9.40; p=0.045), was no longer significant in multivariate analysis. RANKL and OPG/RANKL were not significantly associated with the calcification score.

**Conclusion:** Below knee arterial calcification severity is clearly correlated with peripheral neuropathy severity and several usual cardio-vascular risk factors, but not with serum RANKL level.

## 1288

**Serum fetuin levels are associated with peripheral arterial disease in patients with type 2 diabetes mellitus**I. Eleftheriadou<sup>1</sup>, P. Grigoropoulou<sup>1</sup>, I. Mourouzis<sup>2</sup>, C. Liaskos<sup>1</sup>, A. Kokkinos<sup>1</sup>, D. Perrea<sup>3</sup>, K. Makrilakis<sup>1</sup>, N. Katsilambros<sup>1</sup>, N. Tentolouris<sup>1</sup>;  
<sup>1</sup>First Department of Propaedeutic and Internal Medicine, Athens University Medical School, Laiko General Hospital, <sup>2</sup>Department of Pharmacology, Athens University Medical School, <sup>3</sup>Laboratory of Experimental Surgery and Surgical Research, Athens University Medical School, Greece.

**Background and aims:** Fetuin is a hepatic glycoprotein that inhibits arterial calcification and insulin action. Patients with type 2 diabetes mellitus (T2DM) have higher fetuin levels than non-diabetic individuals. However, increased fetuin levels have been associated with lower cardiovascular risk among non-diabetic individuals, while a trend towards the opposite direction has been demonstrated in patients with T2DM. Conflicting data exists regarding the association between fetuin and peripheral arterial disease (PAD) in diabetes. The purpose of this study was to determine the relationship of serum fetuin levels with PAD in patients with T2DM.

**Materials and methods:** A total of 71 patients (142 feet) with T2DM were recruited (mean age 67.7±8.9 years, mean diabetes duration 15.0±10.6 years, male/female 45/26). Serum fetuin levels were measured using ELISA. Diagnosis of PAD was based on the presence of either biphasic, monophasic or blunted waveforms at the pedal arteries, while ankle-brachial index (ABI) was also measured.

**Results:** Patients with PAD (n=35) had significantly lower serum fetuin levels in comparison with those without PAD (510.0±108.5 vs 562.3±121.2 µg/ml, p=0.008). Fetuin levels were significantly associated with ABI (r=0.236, p=0.006). Univariate logistic regression analysis showed that age (p=0.004), male gender (p=0.022), diabetes duration (p=0.001), dyslipidemia (p=0.002), arterial hypertension (p=0.008), smoking (p=0.052) and fetuin levels (p=0.010) were significantly associated with PAD. No significant associations were found with BMI and HbA1c. Multivariate logistic regression analysis,

after adjustment for age and gender demonstrated that PAD was significantly associated with diabetes duration [odds ratio (OR): 1.06, 95% confidence intervals (CI): 1.01-1.10, p=0.014], dyslipidemia (OR: 5.2, 95% CI: 1.85-14.57, p=0.002), arterial hypertension (OR: 7.0, 95% CI: 1.55-32.13, p=0.012), smoking (OR: 5.0, 95% CI: 1.27-19.55, p=0.022) and fetuin levels (OR: 0.99, 95% CI: 0.989-0.997, p=0.001).

**Conclusion:** Serum fetuin levels are lower in patients with PAD and are associated with the presence of PAD irrespective of traditional cardiovascular risk factors.

## 1289

**Relation of epicardial adipose tissue volume, microalbuminuria, thyroid hormones axis to coronary artery calcium in type 2 diabetic patients**M.M.M. Aboromia<sup>1</sup>, H.A. Elorabi<sup>2</sup>, K.M. Makbol<sup>2</sup>, Y.M. Eid<sup>2</sup>,S.A. Moharam<sup>3</sup>, A.M. Hamam<sup>3</sup>;<sup>1</sup>Internal Medicine, Diabetes Unit, Ain Shams University Hospitals,<sup>2</sup>Internal Medicine, Diabetes Unit, Ain Shams University Hospitals,<sup>3</sup>Cardiology, Military Medical Academy, Cairo, Egypt.

**Background and aims:** Cardiovascular disease (CVD) is the most significant cause of mortality in type 2 diabetes mellitus(T2DM) patients. Visceral adipose tissue (VAT) may be important in sustaining the proinflammatory background of cardiovascular disease. Epicardial adipose tissue(EAT), is a special VAT that surrounds the major branches of the coronary artery branches and myocardium. This close anatomical relationship between EAT and coronary arteries and myocardium further promotes local paracrine interactions between these tissues. Calcific deposits in coronary artery are in connection with coronary artery atheromatous plaque and is considered an indicator of atherosclerosis. Microalbuminuria has long been recognized as an important biomarker that predicts micro and macrovascular complications and mortality in patients with T2DM. Complex interplay between thyroid function and insulin resistance has been implicated in diabetic dyslipidemia. Furthermore, triiodothyronine (T3) was found to be a key signal in myocardial cells. Whether there is an association between EAT, albuminuria, thyroid hormones to coronary atherosclerosis and coronary artery calcium is a question to be further evaluated. Objective: to investigate the relation between EAT volume, thyroid hormones and microalbuminuria to coronary artery calcium in T2DM.

**Materials and methods:** Design: This study was conducted on 100 T2DM patients, they were further divided according to their calcium score into 4 groups. Gr 1: T2DM with coronary artery calcium(CAC 0-10), Gr 2 :T2DM patients with CAC (11-100), Gr 3 : T2DM patients with CAC (101-400), Gr 4 : T2DM patients with CAC >400, all patients were submitted to history taking, clinical and anthropometric evaluation, laboratory investigations (FBG, 2 h PP, lipid profile, HbA1C%, serum insulin, albumin creatinine ratio, TSH, free T3, free T4), HOMA-IR, coronary multislice CT.

**Results:** There was a high statistical significant difference between the 4 groups as regards EAT volume, being the highest (>200 cm<sup>3</sup>) among Gr 4, there was a high statistical significant difference between the 4 groups as regards HbA1C%, (10.23±1.49), Urinary albumin creatinine ratio(UACR) (109.87±52.31) mg%, (P<0.001) being the highest among GR 4, there was a significant difference between the 4 groups as regards TSH levels (3.35±0.63) being the highest among Gr 4(P<0.05). Correlation between CAC and different studied parameters showed a high statistical significant(P<0.001) direct correlation between CAC and Body mass index(r=0.396), total cholesterol (r=0.267), non HDL (r=0.274), fasting blood glucose(FBG) (r = 0.363), 2 hours Post prandial blood glucose(2H PPG) (r=0.354) HbA1C% (r = 0.510), TSH (r =0.293), UACR( r = 0.515), EAT ( r = 0.831), A statistical significant (P<0.05) direct correlation between CAC and age( r= 0.200), Serum triglycerides ( r = 0.216) HOMA-IR ( r = 0.245). A statistical significant (P<0.05) indirect correlations were found between CAC and HOMA-B( r = - 0.222) and free T3 ( r = - 0.229)

**Conclusion:** CAC score is strongly related to EAT volume, blood glucose control, insulin resistance, albuminuria and thyroid axis hormones.

## 1290

**Metabolically unhealthy non-obese subjects are at higher risk of subclinical coronary atherosclerosis than metabolically healthy obese subjects in Korea**K.-U. Lee<sup>1,2</sup>, J. Jang<sup>1,2</sup>, C. Woo<sup>1</sup>, M. Lee<sup>1</sup>, C. Jung<sup>1</sup>, W. Lee<sup>1</sup>, E. Koh<sup>1,2</sup>, J.-Y. Park<sup>1</sup>, I.-K. Lee<sup>3</sup>, M. Choi<sup>4</sup><sup>1</sup>Department of Internal Medicine, Asan Medical Center, Seoul,<sup>2</sup>Metabolism Research Unit, Asan Institute for Life Sciences, Seoul,<sup>3</sup>Department of Internal Medicine, Kyungpook National University School of Medicine, Daegu, <sup>4</sup>Department of Internal Medicine, College of Medicine, Chuncheon, Republic of Korea.

**Background and aims:** Metabolically healthy obesity (MHO) is an emerging phenotype with a cardiovascular disease (CVD) risk between healthy, normal weight and unhealthy, obese individuals. It is not yet established whether this phenotype has higher risk of CVD than nonobese subjects with metabolic abnormalities. In this study, we compared the degree of subclinical coronary atherosclerosis detected by coronary multidetector computed tomography (MDCT) in four groups defined by the state of metabolic health and obesity in an asymptomatic Korean population.

**Materials and methods:** We collected the data of 4,009 asymptomatic subjects (mean age, 53.2 yr) who participated in a routine health screening examination at a medical center in Korea. Significant coronary artery stenosis (CAS) defined as >50% stenosis, and coronary artery calcium scores (CACS) were assessed by MDCT. Participants were stratified by BMI (cut-off value, 25 mg/m<sup>2</sup>) and metabolically healthy state.

**Results:** MHO subjects (n = 589) had a significantly higher prevalence of subclinical coronary atherosclerotic burden (CAS and CACS > 0) compared with metabolically healthy non-obese (MHNO) subjects (n = 1367). However, MHO subjects had a significantly lower prevalence of subclinical coronary atherosclerotic burden (CACS > 0) compared with metabolically unhealthy nonobese (MUNO) subjects (n = 853) as well as metabolically unhealthy obese (MUO) subjects (n = 1200). The prevalence of subclinical coronary stenosis in MUNO subjects was comparable to MUO subjects.

**Conclusion:** Our data show that MHO might not be a benign disease in terms of coronary atherosclerotic burden. However, MHO subjects had a significantly lower prevalence of subclinical coronary atherosclerotic burden compared with MUO subjects. Thus, the presence of metabolic abnormalities may be more important than the presence of obesity in evaluating cardiovascular risk.

## 1291

**Contributors to mortality in high risk diabetes patients**D.W. Bowden<sup>1</sup>, F.-C. Hsu<sup>2</sup>, B.I. Freedman<sup>3</sup>, J. Carr<sup>4</sup>, A.J. Cox<sup>5</sup>;<sup>1</sup>Center for Human Genomics, <sup>2</sup>Biostatistical Sciences, <sup>3</sup>Internal Medicine,

Wake Forest University School of Medicine, Winston-Salem,

<sup>4</sup>Radiology, Vanderbilt University School of Medicine, Nashville, USA,<sup>5</sup>Griffith Health Institute, Southport, Australia.

**Background and aims:** Individuals with type 2 diabetes (T2D) exhibit substantial differences in mortality risk. Coronary artery calcium (CAC) is a powerful, well documented, predictor of mortality. In this study we examined a set of individuals at high risk for death based on CAC>1000 (40% mortality in 7.5 years) and evaluated a range of clinical measures, including modifiable cardiovascular disease (CVD) risk factors, for insights into risk for mortality.

**Materials and methods:** All-cause mortality was determined in 371 European American individuals with T2D and CAC>1000 from a larger ongoing population based cohort study of CVD in people with T2D. After 8.2 ± 3.0 (mean ± SD) years of follow-up differences in CVD risk factors, medication use, and other clinical measures were compared between living (n=218) and deceased (n=153) participants. Cox Proportional Hazards Regression models were used to quantify risk for mortality to appropriately account for time-to-event effects.

**Results:** Mean age at baseline was 65.5 years with mean duration of diabetes 12.6 years. The subjects had a mean BMI of 32.0 and were 70.1% male. Death was confirmed through the US Social Security death index. Deceased participants had a longer duration of T2D (p=0.02). Differences in cholesterol were nominal (HR 2.24 CI 1.09-4.60; p=0.03), but kidney function (HR 4.78 CI 2.38-9.62; p<4x10<sup>-3</sup>) and CRP (HR 2.14 CI 1.33-3.43; p=0.002) were more strongly associated with mortality. Strikingly, measures of blood pressure, use of anti-hypertensive and hypoglycemic medications, and prior prevalent CVD were not significantly associated with risk. Use of cholesterol-lowering

medication was strongly associated with survival (HR 1.68 CI 1.19-2.39; p=0.004). Additional measures of subclinical disease revealed that a vascular calcification score derived from three arterial beds (coronary, carotid and aortic) was associated with the greatest risk for mortality (HR 2.31; p=3.43x10<sup>-7</sup>). In multivariable models elevated HbA1c, lipids, CRP and calcified plaque and lower kidney function were associated with a 1.1-1.5-fold increased risk for mortality (3.5x10<sup>-6</sup> < p < 0.03), after adjustment for confounding factors.

**Conclusion:** Even in this high-risk group, a multi-bed assessment of vascular calcification and known CVD risk factors provide useful information for risk assessment. Importantly, even in a high risk T2D sample, patients have differential risks of death over a substantial time period and the use of cholesterol-lowering medication appeared protective for mortality.

## 1292

**A diagnostic dilemma: an investigation of non-invasive vascular assessment of the lower extremity in people with diabetes**V.H. Chuter<sup>1</sup>, P.E. Craike<sup>1</sup>, N.A. Johnson<sup>2</sup>, S.L. Casey<sup>1</sup>;<sup>1</sup>Health Sciences, University of Newcastle, Ourimbah,<sup>2</sup>Health Sciences, University of Sydney, Lidcombe, Australia.

**Background and aims:** Peripheral arterial disease (PAD) is estimated to affect 21% of people over the age of 65. Non-invasive vascular assessment of the lower extremity using the ankle brachial index (ABI) is recommended to screen for the disease in those at risk of PAD including older people and people with diabetes. It is well known that the ABI loses clinical utility in the presence of diabetes and in older age due to the presence of medial arterial calcification (MAC). The toe-brachial index (TBI) is recommended as an alternative to the ABI where elevated ABI values suggest incompressible arteries due to MAC. However there is some research to suggest the TBI may be more clinically effective in all people with diabetes due to the presence of co-existent PAD and MAC producing normal ABI values in the presence of significant arterial pathology. The aim of this study was to investigate the comparative diagnostic accuracy of the TBI and ABI for the presence of PAD in people with and without diabetes.

**Materials and methods:** Participants meeting current guidelines for lower extremity vascular screening including people with diabetes were recruited on a volunteer basis from two university podiatry teaching clinics. ABI and TBI measurements were performed on the right lower extremity of all participants. Participants subsequently underwent colour duplex Ultrasound from the abdominal aorta to the distal ankle on the right side. This was used as the reference standard to calculate sensitivity, specificity and diagnostic accuracy of both the TBI and ABI for the presence of PAD. ROC analysis was performed to determine the clinical efficacy for diagnosis of PAD of each test.

**Results:** One hundred and sixty nine people were recruited to this study including 89 people with Type 2 diabetes and 100 males, with a mean age 73.57 years (SD 7.31 years). The ABI has the highest specificity for PAD in both people with and without diabetes (specificity 93%, 95%CI 0.82 to 0.98 and 95%, 95%CI 0.84 to 0.98 respectively). The TBI had greater sensitivity than the ABI in people with and without diabetes (sensitivity with diabetes TBI: 85%, 95%CI 0.72 to 0.92, ABI: 42%, 95%CI 0.30 to 0.57, sensitivity without diabetes TBI: 89%, 95%CI 0.75 to 0.96, ABI: 61%, 95%CI 0.45 to 0.75). Overall, and, in the presence of diabetes, diagnostic accuracy was higher for the TBI (TBI: 78% and 88% respectively, ABI: 68% and 79% respectively). ROC analysis indicated the TBI had greater clinical efficacy for the diagnosis of PAD in people with diabetes and in the entire study population (ROC area:0.82 p=.0001, and 0.81 p=0.0001) than the ABI (ROC area:0.59, p=0.09, and 0.67, p=0.0001).

**Conclusion:** Our results demonstrated that the ABI had greater specificity for the presence of PAD than the TBI in people with and without diabetes. However, overall the TBI demonstrated greater diagnostic accuracy and may be more clinically effective than the ABI for diagnosing PAD in people with diabetes and those meeting current guidelines for PAD screening, particularly if PAD is suspected. Further research needs to evaluate relationships between severity and location of PAD and the relative clinical utility of the TBI and ABI in people with diabetes.

### Caveolin-1 alpha expression is decreased in the aorta of rats with glucose intolerance induced by a low dose of streptozotocin

J. Srankova, L. Pivackova, G. Doka, B. Gajdacova, L. Mensikova, E. Malikova, K. Galkova, J. Klimas, P. Krenek;  
Department of Pharmacology and Toxicology, Faculty of Pharmacy Comenius University, Bratislava, Slovakia.

**Background and aims:** Caveolae are plasma membrane invaginations of endothelial cells, which represent a predominant location of endothelial nitric oxide synthase (eNOS), important in regulation of endothelial function. Caveolin-1 (cav-1) is the main component of caveolae, but the specific role of its isoforms  $\alpha$  and  $\beta$  in regulation of eNOS activity in diabetes and glucose impaired tolerance is still not known.

**Materials and methods:** Impaired glucose tolerance was involved by streptozotocin administration (STZ, 25 mg/kg/day, i.p. injections after every 24h, n=10). Control (CON, n=10) received the vehicle. After 8 weeks, oral glucose tolerance test (OGTT) was performed. At the end of experiment (10 weeks after STZ) we measured of vascular reactivity to acetylcholine. The expressions of cav-1 $\alpha$ , cav-1 $\beta$ , eNOS, hsp90, gp91phox and MnSOD were analyzed by Western blot in aorta samples. The expressions of both isoforms of cav-1 in aorta were also determined at mRNA level by qRT-PCR.

**Results:** We observed normal fasting glucose in both groups (CON 6.15  $\pm$  0.27 mmol/l vs. STZ 6.65  $\pm$  0.97 mmol/l), but STZ group had a significantly increased glycaemia 1h after oral administration of glucose in OGTT (CON 8.06  $\pm$  0.44 mmol/l vs. STZ 16.75  $\pm$  2.58 mmol/l, P<0.05). A decreased endothelium-dependent relaxation to acetylcholine was observed in STZ animals (pD2: CON 6.71  $\pm$  0.16 vs. STZ 6.27  $\pm$  0.08, P<0.01; Emax: CON 37.07%  $\pm$  3.08 vs. STZ 29.67%  $\pm$  1.42, P<0.01), whereas endothelial-independent relaxation to nitroprusside was not changed. We found a decreased expression of eNOS in STZ group (CON 100  $\pm$  12.85 vs. STZ 39.48  $\pm$  7.14, P<0.05), while the expressions of hsp90 (CON 100  $\pm$  17.36 vs. STZ 116.26  $\pm$  11.48), gp-91phox (CON 100  $\pm$  17.09 vs. STZ 139.43  $\pm$  21.53) and MnSOD (CON 100  $\pm$  11.21 vs. STZ 108.08  $\pm$  14.34) were not altered. There were no changes in the expression of both isoforms of cav-1 at mRNA level (cav-1 $\alpha$ : CON 1.00  $\pm$  0.12 vs. STZ 1.26  $\pm$  0.2; cav-1 $\beta$ : CON 1.00  $\pm$  0.21 vs. STZ 1.39  $\pm$  0.18). However, we observed a significant downregulation of cav-1 $\alpha$  (CON 100  $\pm$  12.42 vs. STZ 32.22  $\pm$  12.06, P<0.01) and a trend of increased expression cav-1 $\beta$  at protein level in STZ group (CON 100  $\pm$  23.86 vs. STZ 149.49  $\pm$  13.86, P=0.07).

**Conclusion:** Our result showed an impaired glucose tolerance after low-dose streptozotocin, which was associated with dysfunction of endothelial-dependent relaxation and decreased expression of eNOS. Endothelial dysfunction in STZ group probably is not related to expression of gp91phox and MnSOD. It is possible, that decreased expression of cav-1 $\alpha$  in STZ group could influence activity of eNOS and contribute to endothelial dysfunction.

### Different expression of CYP enzymes generating vasoactive arachidonic acid metabolites in animal models of glucose intolerance and diabetes

L. Pivackova<sup>1</sup>, J. Srankova<sup>1</sup>, G. Doka<sup>1</sup>, B. Gajdacova<sup>1</sup>, L. Mensikova<sup>1</sup>, E. Malikova<sup>1</sup>, K. Galkova<sup>1</sup>, R. Sotnikova<sup>2</sup>, J. Klimas<sup>1</sup>, J. Navarova<sup>3</sup>, P. Krenek<sup>1</sup>;  
<sup>1</sup>Dept. of Pharmacology and Toxicology, Comenius University,  
<sup>2</sup>Dept. of Pharmacology and Toxicology, Slovak Academy of Sciences,  
<sup>3</sup>Slovak Academy of Sciences, Bratislava, Slovakia.

**Background and aims:** Epoxyeicosatrienoic acids (EETs) are synthesized by cytochrome P450 epoxygenases from arachidonic acid (AA). In addition to their cardioprotective, antiinflammatory and hypoglycaemic effects, there is strong evidence that EETs can act as endothelium-derived hyperpolarizing factors in certain vascular beds and thus contribute to the regulation of vascular tone. An alternative route of AA metabolism by cytochrome P450 omega-hydroxylases produces proinflammatory and vasoconstrictory hydroxyeicosatetraenoic acids (HETEs). EETs are degraded by soluble epoxide hydrolase to less active dihydroxyeicosatrienoic acids (DHETs). Our aim was to investigate the expression of these enzymes in 2 animal models reflecting different stages of glucose metabolism impairment accompanied by endothelial dysfunction.

**Materials and methods:** In the first model, glucose intolerance (GI) was induced in 12-13 weeks old male Wistar rats (n=6-7 for each group) by postprandial streptozotocin (STZ) injections (25 mg/kg/day, i.p.) on 3 consecutive days. To induce diabetes in the second model (D), rats received STZ (30 mg/kg/day, i.p.) after overnight fasting for 3 consecutive days. Control groups (C) for each model received vehicle. 10 weeks after last dose, OGTT or preprandial blood glucose measurements were performed and we analyzed mRNA expression of chosen epoxygenases (Cyp2j4, Cyp2c23),  $\omega$ -hydroxylases (Cyp4a2, Cyp4a3) and soluble epoxide hydrolase (Ephx2) in thoracic aortae by RT-qPCR. Data were statistically analyzed by Student's t-test or Mann-Whitney U test when appropriate and are represented as mean  $\pm$  SEM.

**Results:** In the first model we observed impaired glucose tolerance (total glucose AUC: 1835  $\pm$  55 vs 3079  $\pm$  415 mmol/l x 270min for C and GI group, respectively; p<0.01), but preprandial blood glucose levels remained unchanged. In the second model, rats in diabetic group had significantly higher preprandial blood glucose (6.0  $\pm$  0.2 vs 29.57  $\pm$  0.4 mmol/l for C and D group, respectively; p<0.001). The only significant change of relative mRNA expression in GI model was an upregulation of Ephx2 (1.00  $\pm$  0.16 vs 2.53  $\pm$  0.27 for C and GI group, respectively; p<0.05). On the contrary, the expression of Ephx2 in D model remained at control levels, but we observed an upregulation of Cyp2j4 (1.00  $\pm$  0.05 vs 3.16  $\pm$  0.91 for C and D group, respectively; p<0.01) and Cyp4a3 (1.00  $\pm$  0.24 vs 2.35  $\pm$  0.6 for C and D group, respectively; p<0.05). The relative expression of Cyp2c23 and Cyp4a2 was unaltered in both models. Both models had an impaired relaxation of isolated aorta to acetylcholine.

**Conclusion:** Endothelial dysfunction was observed in both models, but the alterations in expression of enzymes regulating the CYP-dependent AA metabolism suggest different pathogenic mechanisms. In the glucose intolerance model, increased Ephx2 expression could enhance EETs degradation and thus contribute to endothelial dysfunction. On the other hand, in diabetes model with hyperglycaemia, the balance between the production of vasodilatory EETs and vasoconstrictory HETEs due to changes in expression of Cyp2j4 a Cyp4a. could be more important.

### Association of endothelial progenitor cells with asymmetric dimethylarginine and cardiometabolic risk factors in prediabetes

A. Angelidi<sup>1</sup>, J. Protosaltis<sup>1</sup>, T. Sergeranis<sup>2</sup>, A. Gritzapis<sup>3</sup>, S. Matsagos<sup>1</sup>, A. Misitzi<sup>2</sup>, E. Boutati<sup>4</sup>, G. Dimitriadis<sup>5</sup>, T. Economopoulos<sup>4</sup>, S. Raptis<sup>4,5</sup>, A. Melidonis<sup>1</sup>;

<sup>1</sup>Diabetes Center, Tzanio General Hospital, Piraeus, <sup>2</sup>Department of Epidemiology and Biostatistics, Athens University Medical School, <sup>3</sup>Locus Medicus SA, Athens, <sup>4</sup>2nd Department of Internal Medicine, Research Institute and Diabetes Center, Attikon University Hospital, Athens University Medical School, <sup>5</sup>Hellenic National Center for Research, Prevention and Treatment of Diabetes Mellitus and its Complications, Athens, Greece.

**Background and aims:** It has been suggested that impaired endothelial function is present even in early states of diabetes. Endothelial Progenitor Cells (EPCs) take part in postnatal neovascularization and promote vascular homeostasis. EPCs have been considered as a potential biological marker of cardiovascular disease. Nitric oxide has been described as potential EPC mobilizing factor. Asymmetric dimethylarginine (ADMA) an endogenous inhibitor of nitric oxide synthase is a novel marker of endothelial dysfunction and atherosclerosis in humans. The aim of this study was to investigate the relation of EPC levels with several cardiovascular risk factors including ADMA among patients with prediabetes.

**Materials and methods:** 59 participants with newly diagnosed prediabetes and 32 controls were enrolled. Medical history, anthropometric and biochemical parameters, including traditional cardiometabolic risk factors and high sensitivity C-reactive protein (hsCRP), were obtained. Homeostasis model assessment of insulin resistance (HOMA-IR) was estimated. ADMA concentrations were determined by ELISA method. Flow cytometry identified and quantified EPCs (CD34+ KDR+ cells). Univariate and stepwise multivariate ordinal logistic regression analyses were performed using STATA 11.1 statistical software.

**Results:** EPCs and ADMA levels were higher in controls (p=0.027) and prediabetes (p=0.0001) group respectively. Univariate regression analyses performed separately for all estimated parameters in both groups. In control group EPC levels were significantly associated with: exercise (p=0.016), smoking (p=0.002), positive family history for diabetes (p=0.025), age

( $p=0.004$ ), c-peptide ( $p<0.0001$ ) and ADMA ( $p=0.001$ ). After stepwise multivariate ordinal logistic regression analysis EPC levels were significantly associated with: age (OR=0.85, 95%CI:0.77–0.94,  $p=0.001$ ), exercise (OR=15.99, 95%CI:2.43–105.17,  $p=0.004$ ), smoking (OR=0.01, 95%CI:0.001–0.25,  $p=0.004$ ), and family history of diabetes (OR=0.05, 95%CI:0.01–0.36,  $p=0.003$ ). Regarding prediabetes EPC levels were significantly associated with: BMI ( $p<0.0001$ ), waist circumference ( $p=0.007$ ), mean BP ( $p=0.016$ ), c-peptide ( $p=0.010$ ), hsCRP ( $p=0.041$ ), statin intake ( $p=0.039$ ) and ADMA ( $p=0.004$ ). After stepwise multivariate ordinal logistic regression analysis EPC levels were significantly associated with BMI (OR=0.89, 95%CI:0.82–0.95,  $p=0.001$ ) and ADMA (OR=0.64, 95%CI:0.45–0.9,  $p=0.01$ ).

**Conclusion:** The ADMA-induced impaired NO bioavailability may be correlated with the reduced EPC levels and the impaired endothelial function in prediabetes. The negative and independent association of BMI with EPCs indicates a possible link between obesity and endothelial dysfunction in prediabetes, and emphasizes the importance of lifestyle modification, and especially weight management, in subjects with glucose intolerance.

## 1296

### Endothelial progenitor cells show relation to asymmetric dimethylarginine (ADMA) levels and HbA<sub>1c</sub> variability in young patients with type 1 without complications

K. Nagl<sup>1</sup>, G. Gericke<sup>2</sup>, E. Duffles<sup>2</sup>, M. Fritsch<sup>1</sup>, T. Hörtenhuber<sup>1</sup>, B. Rami-Merhar<sup>1</sup>, G.-H. Schernthaner<sup>2</sup>;

<sup>1</sup>University Clinic for Pediatrics and Adolescent Medicine,

<sup>2</sup>Internal Medicine II, Department for Angiology, Medical University Vienna, Austria.

**Background and aims:** Type 1 diabetes mellitus (T1D) leads to premature cardiovascular disease. Improvement or worsening of glycemic control results in indirect proportional changes in endothelial progenitor cells (EPC) in children with T1D. Circulating EPCs play an important role in maintaining endothelial function. Asymmetric dimethylarginine (ADMA) is a competitive inhibitor of endothelial nitric oxide synthase (eNOS). ADMA is an independent marker of endothelial dysfunction and is elevated in several diseases. ADMA levels in T1D are controversial. The aim of this study is to investigate the possible association of EPCs and ADMA in T1DM.

**Materials and methods:** In 63 patients (29 female, 34 male) with T1D and a median age of 18.3 years (16.2;21.2) circulating EPCs were enumerated by flow cytometry. Different subsets were measured and labeled according their antigen expression: CD34+, CD34+CD133+, CD34+CD133+CD309+, CD34+CD309+. Serum ADMA levels were measured by commercially available ELISA. HbA<sub>1c</sub> variability was calculated as the coefficient of variation (CV) from HbA<sub>1c</sub> values measured quarterly during one year before EPC enumeration and was available in 37 patients.

**Results:** There was no significant sex-dependent difference between male and female patients in age, diabetes duration (mean 11.4±3.3 years), body mass index (24.4±3.8 kg/m<sup>2</sup>) or glycemic control (mean HbA<sub>1c</sub> 7.7±1.4 %), nor was there a significant correlation between glycemic control and the various EPC subsets. CD34+CD133+CD309+ positive EPC showed an inverse correlation with age ( $r: -0.274$ ,  $p=0.034$ ) and diabetes duration ( $r: -0.261$ ,  $p=0.044$ ), but not with HbA<sub>1c</sub>. ADMA levels (mean 0.73±0.22 micromol/l) were neither associated with HbA<sub>1c</sub> nor with age or diabetes duration, but showed a positive correlation with several of the measured EPC subsets, such as CD34+ cells ( $r: 0.394$ ,  $p=0.002$ ), CD34+CD133+ positive cells ( $r: 0.378$ ,  $p=0.03$ ) and CD34+CD133+CD309+ positive EPC ( $r: 0.360$ ,  $p=0.005$ ). Mean HbA<sub>1c</sub> variability was 5.4±3.4% (CV). ADMA was negatively associated with HbA<sub>1c</sub> variability ( $r: -0.365$ ;  $p=0.026$ ). Multiple linear regression analysis revealed that only serum ADMA levels remained independently and significantly ( $p=0.013$ ) associated with CD34+CD133+CD309+ positive circulating EPC ( $\beta=0.411$ ).

**Conclusion:** We show an independent and significant positive association of ADMA serum levels and circulating EPC in young patients with Type 1 diabetes mellitus without cardiovascular complications. In vitro studies demonstrated the role of ADMA as an endogenous inhibitor of mobilization, differentiation, and function of EPC. The paradoxical positive association of EPC counts and ADMA serum levels leads us to the assumption that due to oxidative stress and the consequently high ADMA levels EPC are mobilized to maintain endothelial integrity.

### The relationship between circulating irisin levels and endothelial function in obese patients

X. Sun<sup>1</sup>, N. Hou<sup>1</sup>, F. Han<sup>2</sup>, N. Huang<sup>1</sup>, J. Zhao<sup>1</sup>, X. Liu<sup>1</sup>;

<sup>1</sup>Department of Endocrinology, <sup>2</sup>Department of Pathology, Affiliated Hospital of Weifang Medical University, China.

**Background and aims:** Irisin is a novel hormone secreted by myocytes and could promote the browning of white adipose tissue. Some studies reported that circulating irisin levels were lower in both type 2 diabetes and obese patients compared with lean controls. Elevated NEFA levels from excess adipose tissue, which induce inflammation and oxidative stress, could account for endothelial dysfunction in obesity. It is logical to consider that irisin could ameliorate NEFA-induced endothelial dysfunction by inducing white-to-brown adipose conversion. Thus, the aim of the study was to explore the relationship between circulating irisin levels and endothelial function in obese patients.

**Materials and methods:** A total of 41 non-hypertensive, non-diabetic, obese patients, and 40 age- and sex-matched normal volunteers were involved in this study. Clinical characteristics, blood biochemistry, circulating irisin, and adiponectin of the subjects were measured. Endothelium-dependent vasodilation (EDV) and endothelial-independent vasodilation (EIV) in brachial artery were determined using high-resolution ultrasound.

**Results:** There were no significant differences in age, gender, blood pressure, total cholesterol, HDL, LDL, and fasting plasma glucose levels between two groups ( $P > 0.05$ ). Obese patients had a higher (BMI 30.8 ± 3.8 kg/m<sup>2</sup> vs 21.3 ± 1.8 kg/m<sup>2</sup>,  $P < 0.01$ ) and larger waist circumference (WC 100.7 ± 10.47 cm vs 74.3 ± 4.6 cm,  $P < 0.01$ ). Plasma NEFA, serum triglyceride, fasting insulin, high-sensitivity C-reactive protein (hs-CRP), and malondialdehyde (MDA) levels in obese patients were significantly higher compared with normal subjects (NEFA, 763.4 ± 150.5 umol/L vs 404.6 ± 96.1 umol/L; insulin, 18.7 ± 7.4 uU/ml vs 9.8±4 uU/ml; triglyceride, 1.51 ± 0.57 mmol/L vs 0.80 ± 0.24 mmol/L; hs-CRP, 2.28 ± 0.89 mg/L vs 1.21 ± 0.32 mg/L; MDA, 4.91 ± 1.02 umol/L vs 3.70 ± 0.43 umol/L,  $P < 0.01$ ). However, serum irisin and adiponectin levels were significantly lower in obese patients (irisin, 180.5 ± 22.4 ng/ml vs 194.8 ± 19.9 ng/ml; adiponectin, 6.04 ± 1.7 ug/ml vs 7.51 ± 1.64 ug/ml,  $P < 0.05$ ). Endothelial function was impaired in obese patients (maximum EDV: 8.95 ± 3.46% vs. 14.56 ± 3.90%,  $P < 0.05$ ). Bivariate correlation analysis revealed that circulating irisin was positively correlated with EDV ( $r=0.388$ ,  $P < 0.01$ ) and negatively correlated with BMI ( $r=-0.281$ ,  $P < 0.05$ ), WC ( $r=-0.298$ ,  $P < 0.01$ ), NEFA ( $r=-0.289$ ,  $P < 0.01$ ), hs-CRP ( $r=-0.244$ ,  $P < 0.05$ ), and MDA ( $r=-0.258$ ,  $P < 0.05$ ). EDV was positively correlated with adiponectin ( $r=0.381$ ,  $P < 0.01$ ) and negatively correlated with BMI ( $r=-0.510$ ,  $P < 0.01$ ), WC ( $r=-0.484$ ,  $P < 0.01$ ), triglycerides ( $r=-0.412$ ,  $P < 0.01$ ), NEFA ( $r=-0.535$ ,  $P < 0.01$ ), insulin ( $r=-0.279$ ,  $P < 0.05$ ), hs-CRP ( $r=-0.240$ ,  $P < 0.05$ ), and MDA ( $r=-0.396$ ,  $P < 0.01$ ). Multiple regression analysis was employed to study the association of EDV with BMI, irisin, adiponectin, NEFA, insulin, hs-CRP, and MDA. The model revealed that circulating irisin, adiponectin, NEFA, and BMI were independently associated with EDV after adjusting for covariates ( $R^2=0.412$ ,  $F=10.357$ ,  $P=0.000$ ).

**Conclusion:** Circulating irisin level was decreased in non-hypertensive, non-diabetic, obese patients compared with normal subjects. Lower levels of irisin are independently associated with endothelial dysfunction. Therefore, irisin may be involved in the regulation of endothelial function in obesity.

### Effects of vitamin D supplement on arterial stiffness in patients with type 2 diabetes mellitus and vitamin D deficiency

J.-H. Kim, J.-M. Lee, S.-A. Chang;

Internal Medicine, The Catholic University of Korea, Seoul, Republic of Korea.

**Background and aims:** Vitamin D deficiency has been commonly detected in Korea and well known that deficiency is closely related with increasing risk of cardiovascular disease. Especially, the rate of Vitamin D deficiency is higher in patients with type 2 diabetes mellitus and low 25-hydroxyvitamin D [25(OH)D] level was significantly associated with increased arterial stiffness in these patients. Though there were several studies which were shown the effect of vitamin D supplement on vascular condition in vitamin D deficiency population, it is still controversy up to now. This study aimed to evaluate the

effect of vitamin D supplement on arterial stiffness in patients with type 2 diabetes and vitamin D deficiency.

**Materials and methods:** This study was designed as a prospective, randomized, open-label controlled trial. A total of 40 (20 men and 20 women) patients with type 2 diabetes and vitamin D deficiency, defined as serum 25(OH)D levels < 20 ng/mL, were enrolled. A randomized-study group (10 men and 10 women) was administered daily 1000IU vitamin D3 for 6 months, and control group had no interventional drug. After 6 month of intervention, authors estimated the pulse wave velocity and the aortic augmentation index as primary endpoints in both group, and statistically analyzed the variation.

**Results:** A mean age of patients was 56.2 years old, and mean level of 25(OH)D was 11.9 ng/mL. A 25(OH)D level of study group was significantly increased for 6 months, which were 25.3 ng/mL in study group and 9.4 ng/mL in control group ( $P < 0.001$ ). However, there were no significant changes in terms of pulse wave velocity ( $-0.11 \pm 0.83$  vs  $-0.10 \pm 0.26$  m/sec,  $P = 0.258$ ) and aortic augmentation index ( $-0.9 \pm 3.7$  vs  $0.3 \pm 2.1\%$ ,  $P = 0.567$ ). Though there is no significance, an aortic augmentation index level was tended to decrease in interventional group, compared to those of control group.

**Conclusion:** There were no significant changes of arterial stiffness measurement when the patients with type 2 diabetes and vitamin D deficiency were supplemented daily vitamin D, however, vitamin D level was significantly increased. This study is shown that vitamin D supplement is not clinically effective for improving arterial stiffness in patients with type 2 diabetes and vitamin D deficiency.

### Influence of postprandial hyperglycaemia on arterial function in patients with type 2 diabetes with or without albuminuria

M. Saraheimo<sup>1,2</sup>, D. Gordin<sup>1,2</sup>, A. Soro-Paavonen<sup>1,2</sup>, C. Forsblom<sup>1,2</sup>, K. Paavonen<sup>1,3</sup>, B. Steckel-Hamann<sup>4</sup>, F. Vandenhende<sup>5</sup>, I. Pavo<sup>6</sup>, V. Koivisto<sup>7</sup>, P.-H. Groop<sup>1,2</sup>;

<sup>1</sup>Folkhälsan Institute of Genetics, Biomedicum Helsinki,

<sup>2</sup>Division of Nephrology, Helsinki University Central Hospital,

<sup>3</sup>Division of Cardiology, Helsinki University Central Hospital, Finland,

<sup>4</sup>Eli Lilly Export S.A., Vernier, Switzerland, <sup>5</sup>ClinBAY, Genappe, Belgium,

<sup>6</sup>Eli Lilly, Vienna, Austria, <sup>7</sup>Eli Lilly, Helsinki, Finland.

**Background and aims:** To determine whether postprandial hyperglycemia affects arterial stiffness, and whether pulse wave velocity (PWV) is a surrogate for macrovascular complications in patients with type 2 diabetes with or without albuminuria.

**Materials and methods:** This was a single-center, open-label study of 3 groups of males: patients with type 2 diabetes with albuminuria (N=22; mean±SD age 61±5 yrs, BMI 34±5 kg/m<sup>2</sup>, HbA1c 62±14 mmol/mol), patients with type 2 diabetes without albuminuria (N=24; age 64±5 yrs, BMI 32±6 kg/m<sup>2</sup>, HbA1c 57±12 mmol/mol) and healthy controls (N=25; age 59±7 yrs, BMI 27±3 kg/m<sup>2</sup>, HbA1c 36±3 mmol/mol). Patients were randomized to a 2-period crossover study schedule, ingesting a mixed breakfast of 500 kcal with or without insulin lispro (to induce low or high postprandial glycemia). Healthy controls were studied for 1 period with an identical breakfast. Arterial stiffness was assessed by calculating PWV and augmentation index (Alx) using applanation tonometry, and endothelial dysfunction was assessed using peripheral arterial tonometry (PAT), 30 min before breakfast and up to 240 min post-meal. These parameters were analyzed using analysis of covariance. Blood concentrations of biomarkers of inflammation, endothelial dysfunction and oxidative stress, as well as glycated proteins, were also determined.

**Results:** In the diabetic patients, least square mean±SE glucose levels at 60 min postprandial had increased by 5.3±0.3 mmol/L without lispro, and by 3.3±0.3 mmol/L with lispro, from 6.8±0.2 mmol/L before breakfast. Before breakfast, compared with controls, aortic PWV was elevated in patients with albuminuria (mean±SD 11.0±4.0 m/s vs. 8.6±2.1 m/s,  $p=0.004$ ), but not in patients without albuminuria (10.6±4.0 m/s,  $p=0.052$ ). Similarly, before breakfast, Alx was elevated in patients with albuminuria vs. controls (22.6±6.5% vs. 17.2±10.8%,  $p=0.031$ ) but not in patients without albuminuria (21±6.3%,  $p=0.111$ ). Adjusted for age and BMI, there were no significant differences pre-breakfast or postprandially in aortic PWV, Alx or PAT ratio, in patients vs. controls. Adjusted for age and BMI, brachial PWV was faster at 3 of 4 postprandial time-points (60, 180, 240 min;  $p=0.003-0.046$ ) in patients with albuminuria vs. controls, both under high and low postprandial glycemia. No changes were observed postprandially vs. pre-breakfast in the levels of asymmetric dimethylarginine, endothelin-1, soluble vascular/intercellular cell adhesion molecule-1, superoxidase dismutase, soluble extracellular domain of the receptor for advanced glycation end-products, or C-reactive protein.

**Conclusion:** In patients with type 2 diabetes and albuminuria, indices suggested that aortic stiffness was worse during fasting, relative to healthy controls. Also in patients with type 2 diabetes and albuminuria, brachial stiffness appeared to deteriorate when blood glucose increased postprandially by about 3–6 mmol/L.

### Endothelial glycocalyx is impaired in diabetic patients and first-degree relatives and is linked to abnormal aortic elastic properties and myocardial deformation

V.A. Lambadiari<sup>1</sup>, F. Kousathana<sup>1</sup>, I. Ikonomidis<sup>2</sup>, G. Pavlidis<sup>2</sup>, H. Triantafyllidi<sup>2</sup>, G. Matsaggouras<sup>1</sup>, M. Varoudi<sup>2</sup>, J. Lekakis<sup>2</sup>, G. Dimitriadis<sup>1</sup>;

<sup>1</sup>2nd Dept. of Internal Medicine, Research Institute and Diabetes Center, Attikon University Hospital, <sup>2</sup>2nd Cardiology Dept., University of Athens, Attikon Hospital, Athens, Greece.

**Background and aims:** The integrity of endothelial glycocalyx plays a vital role in vascular permeability, inflammation and elasticity. The association between damage of endothelial glycocalyx, impaired arterial elastic properties, and LV function in diabetics and first degree relatives has not been explored.

**Materials and methods:** In 40 untreated patients (age: 51±12 years) with newly diagnosed type II diabetes, 20 first degree relatives with normal oral glucose tolerance test and 25 controls of similar age and sex and no atherosclerotic risk factors we measured: a) carotid-femoral pulse wave velocity (PWVc m/sec-Complior SP ALAM), central systolic blood pressure (cSBP -mmHg), augmentation index (AI %), reflection time (RT-ms) and diastolic reflection area (DRA) of the aortic pulse wave, an index of coronary perfusion (Arteriograph TensioMed) b) S'E' (m/sec) and E'/A' of mitral annulus by Tissue Doppler c) LV longitudinal strain (GLS -%), systolic (LongSr-l/sec) and diastolic (LongSrE-l/sec) strain rate, using speckle tracking echocardiography d) perfusion boundary region (PBR- micrometers) of the sublingual arterial microvessels (ranged from 5–25 micrometers) using Sideview, Darkfield imaging (Microscan, Glycocheck). The PBR in microvessels is the cell-poor layer which results from the phase separation between the flowing red blood cells (RBC) and plasma. The PBR includes the most luminal part of glycocalyx that does allow cell penetration. Increased PBR is considered an accurate index of reduced endothelial glycocalyx thickness because of a deeper RBC penetration in the glycocalyx

**Results:** Compared to controls, diabetics and relatives had higher PBR (2.1±0.25 vs. 2.05±0.25 vs. 1.89±0.1) AI (27±16 vs. 24±15 vs. 17±14) and DRA (44±12 vs. 49±13 vs. 68±27,) ( $p < 0.05$  for all comparisons). Diabetics and relatives had similar PBR, AI and DRA ( $p=ns$ ). Compared to controls, diabetics had also higher PWV (10.9±2 vs. 8.9±2), cSBP (137±19 vs. 116±17), reduced RT (118±26 vs. 151±14), GLS (-16±4 vs. -20±3), LongSr (-0.8±0.2 vs. -1.1±0.3), LongSrE (0.8±0.2 vs. 1.3±0.5), S' E' and E'/A' ( $p < 0.05$  for all comparisons). Reduced endothelial glycocalyx thickness as assessed by increased PBR was related with increased PWV ( $r=0.35$ ), reduced RT ( $r=-0.42$ ) and DRA ( $r=-0.36$ ) in diabetics ( $p < 0.05$  for all associations). These associations were more prominent for PBR measured in the microvessels ranged from 20–25 micrometers. Increased PWV were related with reduced S' ( $r=-0.48$ ), E' ( $r=-0.63$ ), E'/A' ( $r=-0.63$ ), GLS ( $r=0.48$ ), LongSr ( $r=0.35$ ), LongSrE ( $r=-0.51$ ) respectively ( $p < 0.05$  for all associations)

**Conclusion:** Endothelial glycocalyx is impaired in newly diagnosed diabetics and first degree relatives and is related to abnormal aortic elastic properties leading to impaired LV longitudinal deformation in diabetics.

#### Evaluation of a glyoxalase 1 mutant mouse

A. Shafie, M. Xue, P.J. Thornalley, N. Rabbani;  
WMS, CSRL, University of Warwick, Coventry, UK.

**Background and aims:** Glyoxalase 1 plays an important role in the metabolism of reactive dicarbonyl metabolites, glyoxal and methylglyoxal, to less reactive products and prevention of dicarbonyl-derived advanced glycation endproduct formation. Glo1 deficient mice and transgenic mice overexpressing Glo1 provide valuable models to study control of change in extent of dicarbonyl glycation in mammalian systems. The aim of this study is to characterise the genotype and phenotype of the Lexicon Glo1 mutant mouse. **Materials and methods:** The Glo1 mutant mice (+/- breeding pair), Glo1Lex were obtained from the European Mutant Mouse Archive, Heidelberg, Germany. We maintain a colony of Glo1Lex heterozygotes and sibling wild type controls. The mice were produced by Lexicon Pharmaceuticals, Inc, USA. In a C57BL/6 genetic background, mutation was produced by retroviral insertion of a DNA cassette between coding exons 1 and 2 (LEXKO-1493). Genotyping Forty-four offspring were genotyped from ear punch samples. For PCR, the three pairs of primers were used to discriminate between wild-type: heterozygote and homozygote mutant mice. Phenotyping Nineteen mice, 12 Glo1Lex (+/-) (6 male, 6 female) and 7 wild type control siblings (5 male, 2 female) were sacrificed at 7 months old, tissues (brain, heart, liver, spleen, kidney, pancreas and skeletal muscle) collected and stored at -80°C until analysis. Aliquots of tissue were homogenised and Glo1 enzymatic activity was determined in cytosolic extracts by spectrophotometric assay, protein by Western blot and mRNA by RT-PCR. Protein advanced glycation endproduct (AGE) residues of liver were analysed in 10 Glo1Lex (+/-) (5 male, 5 female) and 10 wild type control siblings (5 male, 5 female) by LC-MS/MS and normalized to the corresponding unmodified amino acid residue.

**Results:** In the genotyping of Glo1Lex mutant mice we found only Glo1Lex (+/-) heterozygote and wild type siblings. No homozygous Glo1Lex (-/-) mice have been born to date. No significant impairment in fertility was found for Glo1Lex (+/-) mice. The activity of Glo1 was not significantly different between wild-type controls and Glo1Lex (+/-) mice ( $P < 0.05$ , Mann Whitney-U). For brain, Glo1 activity (U/mg protein; median (lower - upper quartile)) was: wild type 1.77 (1.53 - 2.00), Glo1Lex (+/-) 2.05 (1.55 - 2.27). For heart, Glo1 activity was: wild type 0.95 (0.85 - 1.05), Glo1Lex (+/-) 0.98 (0.87 - 1.04). Other tissues similarly gave no significant difference in Glo1 activity between wild-type controls and Glo1Lex (+/-). The expression of Glo1, as judged by protein and mRNA, in Glo1Lex mice was not significantly different from wild-type controls. AGE residue contents of liver were not significantly different between wild type controls and Glo1Lex (+/-) mice ( $P < 0.05$ , Mann Whitney-U). MG-H1 residue content of liver was: wild type 0.330 (0.276 - 0.417) mmol/mol arg and Glo1Lex (+/-) 0.309 (0.276 - 0.360) mmol/mol arg. G-H1 residue content of liver was: wild type 0.125 (0.105-0.152) mmol/mol arg and Glo1Lex (+/-) 0.140 (0.112- 0.166) mmol/mol arg. Other protein glycation, oxidation and nitration adduct residue contents of liver were also not significantly different between wild type controls and Glo1Lex (+/-).

**Conclusion:** Glo1Lex mutant mouse appears embryonically lethal for homozygous inheritance; cf. mutant human GLO1 gene with no viable homozygous offspring. It has compensatory increased Glo1 expression with normal fertility. The mutant mouse appears to have been incorrectly genotyped in preliminary characterisation by the originator.

#### Knockdown of glyoxalase 1 leads to collagen overproduction in human aortic endothelial cells

N. Klusmeier<sup>1</sup>, J. Tiemann<sup>1</sup>, B. Espelage<sup>1</sup>, Y. Mattern<sup>1</sup>, D. Hendig<sup>2</sup>,  
C. Knabbe<sup>2</sup>, D. Tschöpe<sup>1</sup>, B. Stratmann<sup>1</sup>;

<sup>1</sup>Diabetes Center, <sup>2</sup>Institute for Laboratory and Transfusion Medicine,  
Heart and Diabetes Center NRW, Bad Oeynhausen, Germany.

**Background and aims:** Chronic hyperglycaemia is an important predictor of diabetic complications and associated metabolic derangements are accompanied by accumulation of high glucose levels as well as rising methylglyoxal (MG) concentrations. MG is a highly reactive, cytotoxic carbonyl compound which is formed as a side product during glycolysis and other metabolic path-

ways. The main detoxification mechanism of MG is the glyoxalase system which consists of the enzymes glyoxalase 1 (Glo1) and glyoxalase 2 (Glo2). The aim was to analyse the impact of MG on selected proteins in human aortic endothelial cells (HAECs) under hyperglycaemia.

**Materials and methods:** Detection of protein and mRNA expression levels were carried out by western blot and quantitative real time PCR (qRT-PCR) analyses following siRNA mediated knockdown of Glo1 or direct stimulation experiments with exogenously added MG.

**Results:** Following Glo1 knockdown a significant accumulation of MG was detected by rising modifications of arginine in terms of arg-pyrimidine. Furthermore, an elevated collagen-4 and collagen-5 synthesis was detected in combination with a reduced expression of the cross-linking enzymes PLOD2 and LEPREL2. Levels of collagen-8 and collagen-18 remained unchanged in this experimental setting. In addition, an up-regulated expression of the proteoglycan metabolism associated enzymes xylosyltransferase 1 and 2 (XT1, XT2) was verified. MMP-2, TIMP-2 and TIMP-4 were elevated non-significantly. A decreased expression of Glo1 under hyperglycemia and MG stimulation (1 $\mu$ M) was clearly shown. MG stimulation significantly induced the expression of extracellular matrix components (collagen-4, -5, -8, -18), and the ECM-molecules TIMP-2, TIMP-4, MMP-2, TGF- $\beta$  under hyperglycaemia. Comparable to the knockdown experiments the expression of proteoglycan metabolism associated enzyme XT2 was significantly elevated. Comparable to the knockdown experiments MG stimulation led to an enhanced endothelial-mesenchymal transition measured by increased expression of ACTA-2 which is in close relation to the observed overall increase in extracellular matrix components production.

**Conclusion:** The results of this experimental research emphasize the effect of MG on composition and stability of the extracellular matrix. This may, at least partially, explain the molecular basis of the effect of hyperglycaemia on endothelial function seen in patients with diabetes mellitus.

### 1303

#### Methylglyoxal induced protein damage in diabetes is handled by the quality control system conserved from yeast to humans

J. Tyedmers<sup>1</sup>, L. Schmidt<sup>1</sup>, T. Fleming<sup>1</sup>, E. Herpel<sup>2</sup>, S. Kaden<sup>3</sup>, H.-J. Gröne<sup>3</sup>,  
P.P. Nawroth<sup>1</sup>;

<sup>1</sup>Innere Medizin I und Klinische Chemie, Universität Heidelberg,

<sup>2</sup>Pathologisches Institut, Universitätsklinikum Heidelberg,

<sup>3</sup>Zelluläre und Molekulare Pathologie, DKFZ, Heidelberg, Germany.

**Background and aims:** Increased concentrations of reactive metabolites such as methylglyoxal (MG) are thought to be involved in the development of late diabetic complications by causing intracellular protein damage through posttranslational protein modifications. We aim to reveal cellular mechanisms and molecular pathways that are involved prevention and remission of protein damage by MG.

**Materials and methods:** We have established a yeast system to study protein damage and aggregate formation by increased intracellular concentrations of MG within physiological ranges. Results obtained in yeast were validated in endothelial cells in cell culture and tested in immunohistologic stains of tissue samples from patients with diabetic complications.

**Results:** We found that yeast forms aggregates upon increased MG concentrations. A mass spectroscopy approach to identify potential targets of MG induced protein damage revealed several molecular chaperones and metabolic enzymes. Aggregates are handled by the cellular protein quality control system. Induction of the heat shock response in general and Hsp70 in particular increased the tolerance towards increased MG levels. We next translated our findings to mammals by demonstrating that an intracellular increase of MG in mouse endothelial cells in cell culture also leads to the formation of aggregates which can be visualized with EM and are bound by Hsp70 chaperones. Pharmacological inhibition of Hsp70 rendered the cells more sensitive towards MG. Finally, staining of kidney tissue from patients with severe diabetic complications revealed drastically increased levels of Hsp70 in the glomeruli.

**Conclusion:** The cellular protein quality control system including Hsp70 handles MG induced protein damage from simple eukaryotes to mammals. It's up-regulation renders cells more resistant towards MG induced cell damage. These similarities between diverse species such as yeast and humans allow to exploit the high-throughput and large scale analysis tools available for simple eukaryotes such as yeast to better understand cellular responses to increased levels of reactive metabolites.

## 1304

**Nuclear RAGE, a regulator of DNA integrity in diabetic lung fibrosis**V. Kumar<sup>1</sup>, T. Fleming<sup>1</sup>, E. Schleicher<sup>2</sup>, H.-U. Häring<sup>2</sup>, P.P. Nawroth<sup>1</sup>;<sup>1</sup>Internal Medicine I and Clinical Chemistry, University of Heidelberg,<sup>2</sup>Department of Internal Medicine, University of Tübingen, Germany.

**Background and aims:** The receptor for advanced glycation endproducts (RAGE) is a member of the immunoglobulin super-family of cell receptors, whose activation has been suggested to contribute to various pathologies. Recent studies have suggested that the localization of RAGE is not restricted to the cell-surface but also inside the nucleus interacting either directly or indirectly with DNA. However, the role that nuclear RAGE services in the nucleus remains unclear. In this study, we have investigated the ligand-independent localization of RAGE to nucleus and its role as a DNA repair protein.

**Materials and methods:** Pulmonary fibroblasts were isolated from the lungs of RAGE-deficient (RAGE<sup>-/-</sup>) and aged-matched wild-type (C57Bl/6; male) mice. RAGE and DNA repair proteins were detected by immunofluorescence. DNA damage was assessed by single-cell gel electrophoresis (COMET) assay. Micro-irradiation of cells was performed using a FluoView1000 confocal microscope, using 355nm laser. Laser settings were chosen to generate detectable double-strand breaks (DSBs) within the path of the laser, without induction of major cytotoxic effects

**Results:** Pulmonary phenotyping in RAGE<sup>-/-</sup> mice showed that these mice had a reduced lung volume as compared to aged-matched control, consistent with a restrictive lung disease, such as fibrosis. This was confirmed by trichrome staining which showed that RAGE<sup>-/-</sup> mice had a greater accumulation of collagen and other extracellular matrix. Analysis of the subcellular localization of RAGE within the lung showed that the majority of the protein was in the nucleus. The localization of RAGE to the nucleus was confirmed in vitro, using wild-type lung fibroblasts transiently transfected with GFP-tagged RAGE. It was observed that RAGE<sup>-/-</sup> lung fibroblasts has a significantly altered growth rate and morphology. Further analysis showed that RAGE<sup>-/-</sup> lung fibroblasts had significantly higher levels of DNA damage as compared to wild-type fibroblasts treated with and without bleomycin. The level of DNA damage could be increased in wild-type fibroblasts by transient transfection with a shRNA vector specific for RAGE. Conversely, transfection of the GFP-tagged RAGE into RAGE<sup>-/-</sup> lung fibroblasts could significantly reduce the level of DNA damage by ca.80%. This would suggest, that within the context of the lung, nuclear RAGE is responsible for maintain DNA integrity. Following laser-induced DSBs, it was found that nuclear RAGE is phosphorylated by ATM, the main protein kinase sensor of DSBs, leading to its association with a variety of repair proteins, including MRN11, Rad50 and Nba1, which are involved in the formation of the MRN complex. It was subsequently shown that post-translational modification of RAGE by methylglyoxal, a reactive metabolite elevated in diabetes, leads to loss of function with respect to DNA resectioning and binding, an effect which was not observed following oxidative modification.

**Conclusion:** Loss of nuclear RAGE in the lung may provide a new mechanism for the development diabetic lung fibrosis; inactivation of nuclear RAGE by reactive metabolite driven post-translational modifications would prevent the correct formation and function of the MRN complex, leading to increased DNA damage via a reduced repair capacity, analogous to the molecular phenotype observed in the RAGE<sup>-/-</sup> mice.

## 1305

**Soluble receptor for advanced glycation end-products (sRAGE) relates to oxidative stress index in patients with diabetes**J. Škrha jr.<sup>1</sup>, J. Soupal<sup>1</sup>, M. Kalousova<sup>2</sup>, R. Mikova<sup>1</sup>, M. Prazny<sup>1</sup>, J. Škrha<sup>1</sup>;<sup>1</sup>Third Department of Medicine, First Faculty of Medicine, Charles University in Prague, General University Hospital,<sup>2</sup>Institute of Medical Biochemistry and Laboratory Diagnostics,

First Faculty of Medicine, Charles University in Prague,

General University Hospital, Czech Republic.

**Background and aims:** Oxidative stress is one of the most important factors in the development of vascular damage in patients with diabetes. Novel findings support the idea of advanced glycation end-products involvement in the pathophysiology of diabetic angiopathy. The aim of our study was to evaluate relationship between oxidative stress and soluble receptor for advanced glycation end-products (sRAGE) in patients with diabetes.

**Materials and methods:** Total 121 persons were included within the study - 45 patients with Type 1 diabetes (T1DM; aged 52 ± 15 yrs), 59 patients with Type 2 diabetes (T2DM; aged 65 ± 11 yrs) and 17 healthy controls (47 ± 15 yrs). Oxidative stress was measured by Free Radical Analytical System (FRAS4; H&D, Italy) and evaluated by two blood tests: reactive oxygen metabolites test (d-ROMs) and by biological antioxidative potential test (BAP). Oxidative stress index (OSi) expressing the total oxidative status was calculated (OSi = d-ROMs/BAP). In all patients routine biochemical parameters, glycated hemoglobin (expressed in mmol/mol acc. EFCC), sRAGE, cell adhesion molecules (VCAM, ICAM), von Willebrand factor, (micro)albuminuria (expressed as albumin/creatinine ratio UACR), and anthropometrical data were measured.

**Results:** Oxidative stress index was similar between groups (T1DM: 0.25 [0.13 - 0.47], T2DM: 0.25 [0.13 - 0.42], controls 0.24 [0.18 - 0.34]; NS) and also sRAGE did not differ significantly (T1DM: 1352 ± 514, T2DM: 1179 ± 814, controls: 1177 ± 564 ng/l, NS). Significantly lower d-ROMs were observed in patients with T1DM and T2DM without albuminuria (UACR<2.5 g/mol creatinine) as compared to patients with albuminuria (368 ± 105 vs. 432 ± 134 U; p=0.009). Significant positive relationship of OSi and sRAGE was found both in T1DM (r=0.39; p<0.01) and T2DM (r=0.33; p<0.02), and similarly of OSi and VCAM (T1DM: r=0.47, p<0.005; T2DM: r=0.35, p<0.05).

**Conclusion:** This is the first study describing significant relationship between oxidative stress expressed by oxidative stress index and sRAGE concentration in patients with diabetes. Similar relationship was observed between OSi and marker of vascular activation - adhesion molecule VCAM. Oxidative stress, apart from direct effect, likely participate in the development of endothelial activation also by other mechanisms - e.g. RAGE activation. Though, more studies will be necessary for better understanding of these processes.

## 1306

**One-compartment kinetic model predicts dicarbonyl modification influence half-life and functionality of HDL in high risk CVD group**N. Rabbani<sup>1</sup>, L. Godfrey<sup>1</sup>, N. Yamada-Fowler<sup>1</sup>, J. Smith<sup>2</sup>, P.J. Thornalley<sup>1</sup>;<sup>1</sup>Clinical Sciences Research Institute, University of Warwick,<sup>2</sup>Bruker UK Ltd, Coventry, UK.

**Background and aims:** Decreased plasma concentration and anti-atherogenic properties of high density lipoprotein cholesterol (HDL-C) is implicated in increased CVD risk. The cause is unknown and under intense investigation. The extent of modification of HDL by methylglyoxal, a reactive dicarbonyl metabolite, in patients with diabetes and related functional effects is also unknown. Dicarbonyl modification of HDL may be linked to the reported 20% and 37% decrease in half-life of HDL in type 2 diabetes and renal failure. The aim of this study was to: (i) to construct a one-compartment model of HDL influx and clearance from plasma in human subjects, and (ii) from the effect of minimal modification of HDL by methylglyoxal on HDL plasma clearance, predict how dicarbonyl glycation influences plasma HDL concentration in patients with diabetes, renal failure and the ageing population.

**Materials and methods:** The extent of dicarbonyl glycation of HDL - modification by methylglyoxal and related metabolites glyoxal and 3-deoxyglucosone - was assessed by quantitation of dicarbonyl-derived AGEs in HDL protein. We constructed a one-compartment model of HDL release into and clearance from plasma assuming that dicarbonyl-modified HDL is preferentially cleared. We measured the change in clearance of HDL when modified minimally by methylglyoxal in rats. The mathematical model of HDL influx and clearance from plasma in human subjects was defined by published estimates of values of apolipoprotein (ApoA1) synthesis (14 mg kg<sup>-1</sup>day<sup>-1</sup>) and HDL half-life (4.47 days), and validated experimentally by measurement of plasma HDL and methylglyoxal-modified HDL in human subjects. HDL kinetics were computed for 2 - 4 fold increase in dicarbonyl concentration typical of old-age, diabetes and renal failure using the COPASI programme.

**Results:** Dicarbonyl-modified HDL accounted for ca. 2.6% HDL in healthy people. Experimental studies in rats showed that clearance of HDL from plasma increased 2-fold when modified minimally by methylglyoxal. Input of a 2 - 4 fold increase in plasma dicarbonyl concentration into the one compartment model of plasma HDL predicted a 2 - 6% decrease in plasma total HDL. ApoA1 concentration correlates strongly with HDL-C (r = 0.83) and so this translates to a predicted ca. 3 - 9% increased risk of CVD. The model also predicted a greater decrease in functional HDL (4.5 - 12.5%). Suggested validity of the model came from experimental confirmation of the predicted negative association of plasma HDL-C to the level of methylglyoxal modified

HDL in healthy people. From the correlation coefficient,  $r = -0.42$ ,  $P < 0.05$  ( $n = 22$ , Pearson), glycation of HDL by methylglyoxal accounts for 18% of the variation in HDL-C.

**Conclusion:** The kinetic model predicted dicarbonyl modification contributes significantly to decreased half-life and dysfunction of HDL, and through this to increased CVD risk in high risk populations such as elderly and patients with type 2 diabetes and renal failure. Therapeutic interventions to counter dicarbonyl glycation of HDL may decrease risk of CVD.

### Protection from diabetes-induced atherosclerosis and renal disease by octyl-D-carnosine: evidence for a role of AGEs in hyperglycaemic memory

S. Menini, C. Iacobini, C. Ricci, C. Blasetti Fantauzzi, G. Pugliese; Department of Clinical and Molecular Medicine, La Sapienza University, Rome, Italy.

**Background and aims:** The advanced glycation end-products (AGEs) are involved in the pathogenesis of vascular and renal complications of diabetes and are considered as a putative mechanism for “hyperglycaemic memory”. Octyl-D-carnosine (ODC) was shown to attenuate AGE formation as well as vascular and renal injury induced by high fat diet in ApoE null mice. This study was aimed at verifying the protective effect of ODC in atherosclerosis and renal disease induced by experimental diabetes and the role of AGEs in “hyperglycaemic memory”.

**Materials and methods:** To this end, ApoE null mice were rendered diabetic by multiple injections of streptozotocin and divided in 4 groups: untreated (DIAB) or treated with ODC for 20 weeks (ODC-Extended) or for first 11 weeks only, starting immediately after diabetes induction (ODC-Early) or at week 9 (ODC-Late). Non-diabetic ApoE null mice served as controls. Metabolic parameters were assessed using standard methods. Aortic and renal lesions were evaluated by morphometry. Protein and gene expression of relevant disease markers were assessed by immunohistochemistry and RT-PCR, respectively.

**Results:** Treatment ODC-Extended was effective in reducing the size of atherosclerotic lesions ( $48,496 \pm 5,501$  vs.  $90,545 \pm 4,267 \mu\text{m}^2$ ), and plaque content of macrophages ( $11.9 \pm 3.2$  vs.  $39.9 \pm 3.3$  % lesion area, and  $1.46 \pm 0.36$  vs.  $3.4 \pm 0.69$  UA), MCP-1 ( $1.74 \pm 0.58$  vs.  $3.61 \pm 0.63$  UA), RAGE ( $10.4 \pm 1.6$  vs.  $37.3 \pm 3.3$  % lesion area, and  $1.12 \pm 0.31$  vs.  $2.41 \pm 0.44$  UA), N<sup>ε</sup>-carboxymethyllysine (CML,  $16.6 \pm 3.1$  vs.  $64.0 \pm 6.2$  % lesion area), nitrotyrosine ( $11.4 \pm 2.7$  vs.  $37.1 \pm 4.5$  % lesion area), and apoptotic cells ( $24.8 \pm 4.4$  vs.  $88.8 \pm 6.8$  n/mm<sup>2</sup>). Conversely, plaque content of collagen ( $42.3 \pm 3.3$  vs.  $26.4 \pm 2.5$  % lesion area) and smooth muscle cells ( $13.4 \pm 2.1$  vs.  $4.9 \pm 1.1$  % lesion area) was increased, as compared with DIAB. ODC treatment for 11 weeks afforded partial protection from atherosclerotic lesions, which however was significantly higher in ODC-Early than in ODC-Late for most of the above parameters. In fact, ODC-Early plaques were smaller as compared with ODC-Late plaques and showed reduced content of CML, which was associated with less inflammation and oxidative stress markers, smaller necrotic cores, increased deposition of collagen and thicker fibrous caps. In addition to quantitative differences, also qualitative differences were observed. In particular, immunohistochemistry staining for CML, macrophage, apoptosis and oxidative stress markers was restricted to the luminal side of the ODC-Early plaques, at variance with what observed in plaques from ODC-Late and untreated DIAB mice, which covered the entire depth of the atherosclerotic intima. Also renal disease was attenuated in ODC-Extended than in DIAB and partial protection was observed in mice treated for 11 weeks, with no significant difference between ODC-Early and ODC-Late.

**Conclusion:** These data show that therapy with ODC protects from vascular and renal disease induced by experimental diabetes and early treatment is more effective than late treatment on atherosclerosis, thus suggesting that inhibition of AGE formation and accumulation within early plaques might slow down post-treatment atherosclerosis progression and favour development of more stable lesions. This is consistent with the hypothesis that AGEs could represent the underlying mechanism responsible for the „hyperglycaemic memory“.

#### Glucagon-like peptide-1 reduces intestinal lipoprotein production by peripheral pathways and central melanocortin-4 receptor signalling

S.L. Farr, C. Baker, M. Naples, J. Taher, K. Adeli; Molecular Structure and Function, The Hospital for Sick Children, Toronto, Canada.

**Background and aims:** The intestinal overproduction of chylomicron particles is a common feature of insulin resistance and the metabolic syndrome, resulting in postprandial dyslipidemia and heightened levels of atherogenic particle remnants. Recently, the anti-diabetic hormone glucagon-like peptide-1 (GLP-1) has gained attention not only as an insulin secretagogue, but also as a modulator of intestinal lipoprotein metabolism in the periphery. GLP-1 can additionally be produced within the brain to regulate neuronal activity in regions like the arcuate nucleus of the hypothalamus, and through sympathetic pathways GLP-1 has been shown to modulate peripheral lipid metabolism. Here we investigated the involvement of both peripheral and central GLP-1 in regulating intestinal chylomicron production.

**Materials and methods:** Healthy hamsters received an oral gavage of olive oil followed by an acute intraperitoneal (IP) or intracerebroventricular (ICV) injection of the GLP-1 receptor (GLP-1R) agonist exendin-4 (5nmol/kg and 250ng, respectively) or vehicle. The postprandial production of triglyceride (TG)-rich lipoproteins (TRL) was then assessed over 6h by measuring levels of TRL-TG and -apolipoprotein B48 (apoB48). This study was repeated with 3μg ICV MK-0626, an inhibitor of endogenous GLP-1 degradation, in the presence or absence of the GLP-1R antagonist exendin9-39. To characterize the central pathways of GLP-1 action, the effects of ICV exendin-4 on TRL production were assessed during ICV melanocortin-4 receptor (MC4R) antagonism and in the presence or absence of α and β adrenergic receptor blockers given intravenously.

**Results:** Both IP and ICV exendin-4 treatment induced prolonged reductions in the rate of TRL-TG accumulation (IP 72%  $p < 0.05$  and ICV 56.5%  $p < 0.01$ ). A similar trend was seen in apoB48 accumulation. The effects of central exendin-4 were mirrored by ICV administration of MK-0626 and negated by ICV pre-treatment with the GLP-1R antagonist exendin9-39. This indicates that GLP-1 produced in the brain can act on central GLP-1Rs to modulate chylomicron production in the periphery. In accordance with satiety studies supporting the notion that central GLP-1 may signal through the MC4R system, central MC4R antagonism prevented ICV exendin-4 from lowering TRL-TG levels. An infusion of adrenergic receptor antagonists also prevented the reduction in TRL-TG levels seen with exendin-4 treatment alone, suggesting that the GLP-1-sensitive brain-gut axis modulating chylomicron production is likely via sympathetic pathways. Finally, to study the interplay between central and peripheral pathways of GLP-1R signaling, exendin-4 was given IP while exendin9-39 was given ICV and vice-versa. IP exendin-4 maintained its ability to diminish TRL-TG levels during central antagonism; however, IP exendin9-39 prevented the action of ICV exendin-4. This suggests that central stimulation may potentiate peripheral GLP-1Rs, and that peripheral GLP-1Rs can act independently of central signaling to modulate intestinal lipoprotein metabolism.

**Conclusion:** Our results demonstrate an important role for central GLP-1R signaling in modulating chylomicron production, which has critical implications for diabetic dyslipidemia. In line with previous studies showing that exendin-4 activates neurons in the arcuate nucleus, this brain-gut axis appears to involve MC4Rs and sympathetic outflow to the periphery.

**Serum paraoxonase-1 activity is more closely related to HDL particle concentration and large HDL particles than to HDL cholesterol in type 2 diabetic and non-diabetic subjects**R.P.F. Dullaart<sup>1</sup>, J.D. Otvos<sup>2</sup>, R.W. James<sup>3</sup>;<sup>1</sup>Endocrinology, University Medical Center, Groningen, Netherlands,<sup>2</sup>LipoScience Inc., Raleigh, USA, <sup>3</sup>Internal Medicine, Division of Endocrinology, Diabetology, Hypertension and Nutrition, University Hospital Geneva, Switzerland.

**Background and aims:** We determined relationships of the anti-oxidative enzyme, paraoxonase-1 (PON-1), with high density lipoprotein (HDL) sub-fractions, and tested whether these relationships are stronger than those with HDL cholesterol and apolipoprotein A-I (apoA-I) in subjects with and without type 2 diabetes mellitus (T2DM).

**Materials and methods:** Serum PON-1 (arylesterase activity) and HDL sub-fractions (nuclear magnetic resonance spectroscopy) were determined in 67 T2DM patients and in 56 non-diabetic subjects.

**Results:** PON-1 activity, HDL cholesterol and apoA-I were decreased in T2DM (all  $p < 0.05$ ). The HDL particle concentration was unaltered, but large HDL particles, medium HDL particles and HDL particle size were decreased, whereas small HDL particles were increased in T2DM (all  $p < 0.05$ ). PON-1 was more closely related to HDL cholesterol than to apoA-I ( $p = 0.001$ ). In turn, the positive relationship of PON-1 with the HDL particle concentration and with large HDL particles was stronger than that with HDL cholesterol (both  $p < 0.01$ ). The inverse relationship of PON-1 with T2DM was only modestly attenuated by HDL cholesterol or HDL particle characteristics. Multi-variable linear regression analyses demonstrating relationships of serum paraoxonase-1 activity with mutually adjusted high density lipoprotein (HDL) variables and apolipoprotein A-I (apoA-I) in 63 subjects with Type 2 diabetes mellitus (T2DM) and in 56 non-diabetic subjects. HDL variables are given in standard deviation scores (Z-scores). Independent statistical determined as assessed by subsequent backward elimination are shown in bold print.  $\beta$ : standardized regression coefficient. Model 1: HDL cholesterol + apoA-I; model 2: HDL cholesterol + HDL particle concentration; model 3: HDL cholesterol + large HDL particles.

**Conclusion:** PON-1 activity is more closely related to the HDL particle concentration or large HDL particles than to HDL cholesterol. Impaired PON-1 activity in T2DM is not to a considerable extent explained by altered HDL subfraction levels.

## 1310

**HDL and blood glucose correlations in patients with familial hypercholesterolemia**M. Walus-Miarka<sup>1</sup>, B. Idzior-Walus<sup>1</sup>, M. Małeck<sup>1</sup>, P. Miarka<sup>2</sup>, E. Wozniakiewicz<sup>2</sup>;<sup>1</sup>Metabolic Diseases, CMUJ, <sup>2</sup>Nephrology, CMUJ, Krakow, Poland.

**Background and aims:** Familial hypercholesterolemia is characterized by markedly increased LDL-cholesterol concentration due to mutation in LDL-receptor, apo B 100 and PCSK9 genes and, in consequence, premature coronary artery disease. Typically HDL-C and triglyceride concentrations are within normal limits. Accumulating data suggest that cholesterol homeostasis is a major regulator of beta cell function. Intra-cellular cholesterol accumulation leads to islet dysfunction and impaired insulin secretion. There is also evidence suggesting that the different lipoprotein classes have varying effects on beta cell apoptosis and proliferation. The aim of our study was to assess blood glucose correlates in patients with familial hypercholesterolemia (FH), familial combined hyperlipidemia (FCH) and healthy controls (C).

**Materials and methods:** Material included patients from outpatient lipid clinic, referred for treatment of resistant hyperlipidemia. Familial hypercholesterolemia was diagnosed according to Simon Broome register criteria. In each patient standardized questionnaire, anthropometric examinations and lab test were performed. Serum lipids and glucose were examined in fasting state by enzymatic methods, using Roche reagents.

**Results:** We examined 241 patients with FH, 124 patients with FCH and 45 controls. Mean age and BMI values in FH, FCH and C groups were as follows: 41.1 +/-18.4, 41.8 +/-15.0 and 32.5 +/-15 years; 24.7 +/-5, 26 +/-4.4 and 22.4 +/-4.4 kg/m<sup>2</sup>. Mean values of serum concentrations of LDL-cholesterol in FH, FCH and controls were 4.6 +/-1.6, 3.5 +/-0.7 and 2.5 +/-0.6, while of HDL-cholesterol; 1.6 +/-2.2, 1.5 +/-0.4, and 1.5 +/-0.5 mmol/l respectively. In

FH patients serum glucose concentration significantly correlated with age and obesity parameters (BMI and waist circumference) and blood pressure values. We also found significant correlation between serum glucose and creatinine ( $r = 0.15$ ,  $p = 0.02$ ), GGTP ( $r = 0.13$ ,  $p < 0.05$ ) and a strong negative correlation with HDL-cholesterol ( $r = -0.26$ ,  $p < 0.001$ ). In FCH group apart from correlation with age, obesity indices, blood pressure and creatinine, significant association between glucose and serum triglyceride, insulin resistance syndrome component, was found ( $r = 0.18$ ,  $p < 0.05$ ). In healthy persons only significant positive correlations between serum glucose and CRP and negative with serum creatinine were observed. Multiple regression analysis with serum glucose as dependent variable revealed that in FH patients serum HDL-C concentration ( $p = 0.0009$ ) and waist/hip ratio ( $p = 0.014$ ) were significant associates. In statin treated FH patients serum glucose concentrations were associated with the same variables as in the whole group of patients with exception of lack of correlation with HDL-C, similarly like in healthy controls, and the presence of negative correlation between LDL-C ( $r = -0.18$ ,  $p < 0.05$ ). In FH patients not taking statins only the negative correlation between HDL-C and serum glucose was observed.

**Conclusion:** The results of the study suggest that HDL-C and WHR are significant correlates of blood glucose levels in FH patients, while HDL-C is associated with blood glucose levels only in patients not treated with statin. These results might be of importance in development of carbohydrate metabolism disturbances in statin treated FH patients.

## 1311

**Diet induced fat storage in the ApoE knockout rat: a novel animal model**S. Skovso<sup>1</sup>, I. Rune<sup>1,2</sup>, X.A. Wolf<sup>2</sup>, B. Rolin<sup>2</sup>;<sup>1</sup>University of Copenhagen, <sup>2</sup>Translational Pharmacology, Novo Nordisk A/S, Måløv, Denmark.

**Background and aims:** Apolipoprotein E (ApoE) is highly expressed in adipose tissue and plays a pivotal role in lipoprotein and triglyceride metabolism in adipocytes. The role of ApoE in site-specific fat storage remains poorly understood. The contribution of ApoE in adipocyte triglyceride accumulation has previously been described in ApoE knockout mice, but not in ApoE-deficient rats. Moreover, the effect of dietary gluten as a potential accelerator of site specific fat accumulation has not been thoroughly examined. Fat distribution and cardiovascular risk are highly associated. Thus, we investigated site specific fat storage in rats with systemic knockout of the ApoE gene, fed either a cholesterol enriched Western Diet or a normal Low Fat diet in combination with or without gluten.

**Materials and methods:** ApoE knockout rats were fed either: 1) a Western Diet (WD) high in cholesterol, fat and sucrose; 2) a WD with gluten (WD+G); 3) a Low Fat diet (LF); or 4) LF and gluten (LF+G) from 10 days of age. At 20 weeks of age body weight, whole body fat, visceral fat and subcutaneous fat were measured. Fat distribution was measured by MRI and CT scanning

**Results:** We compared rats fed either WD or LF diets in combination with or without gluten at 20 weeks of age. The greatest differences were observed between rats fed WD+G diet or LF+G diet. When compared to LF+G fed rats, WD+G fed rats had significantly higher body weight ( $352 \pm 14$  g versus  $293 \pm 11$  g;  $p < 0.001$ ), whole body fat/body weight ratios ( $0.26 \pm 0.081$  versus  $0.17 \pm 0.010$ ;  $p < 0.001$ ), visceral fat ( $13.4 \pm 0.9$  versus  $7.1 \pm 0.7$  g;  $p < 0.01$ ), and subcutaneous fat ( $5.1 \pm 0.3$  g versus  $2.5 \pm 0.4$  g;  $p < 0.001$ ). No significant differences were observed between LF and WD, between WD and WD+G or between LF and LF+G for any of the above mentioned parameters. However, the visceral fat was significantly increased in WD+G fed rats, when compared to WD fed rats ( $13.4 \pm 0.9$  g versus  $10.8 \pm 0.7$  g;  $p < 0.05$ ). Finally, the liver density, an inverse measure of liver fat, was observed to be significantly lower in the WD+G fed rats, when compared to the WD rats ( $-46.1 \pm 3.6$  Hounsfield Units (HU) versus  $-19.9 \pm 5.1$  HU,  $p < 0.01$ ) at week 20.

**Conclusion:** Our data suggest that WD in combination with gluten, but not alone, increases deposition of fat in the visceral compartment rather than the subcutaneous compartment in ApoE knock out rats when the different diets are introduced from 10 days of age. The differences observed in body weight, whole fat and the site of fat deposition between the group fed WD combined with gluten and the group fed LF diet combined with gluten also suggest that it is the interaction between gluten and the cholesterol-enriched WD, rather than gluten per se, that promotes the early signs of the metabolic syndrome.

### The synergistic effect of two mtDNA point mutations in complexes of the respiratory chain promote age-dependent hyperglycaemia and mitochondrial ROS production

S. Schröder, J. Niemann, F. Koch, C. Johne, M. Tiedge, S. Baltrusch; Institute of Medical Biochemistry and Molecularbiology, Rostock, Germany.

**Background and aims:** Mutations in complexes of the respiratory chain, which are encoded in the mitochondrial genome (mtDNA), can mediate an increase in production of reactive oxygen species (ROS). Thus, mtDNA mutations are proposed to evoke mitochondrial dysfunction and to contribute to the pathogenesis of type 2 diabetes mellitus. In this study we investigated ROS production and the expression of antioxidative enzymes in liver and muscle from conplastic mice carrying a mtDNA point mutation in the cytochrome c oxidase (complex IV) or a combined mutation in the cytochrome c oxidase (complex IV) and the NADH dehydrogenase (complex I).

**Materials and methods:** Blood glucose was measured in the conplastic mouse strains C57BL/6NTac-mtBPL/1J (NADH dehydrogenase mutation und cytochrome c oxidase mutation, mtBPL), C57BL/6NTac-mtNOD/LtJ (cytochrome c oxidase mutation, mtNOD) and C57BL/6NTac-mtAKR/J (control; mtAKR). For analysis of mitochondrial ROS production MitoSox was injected in living animals. Thereafter mice were killed and tissues were analyzed for accumulated ROS by fluorescence microscopy. Gene expression of the antioxidative enzymes catalase, SOD1, SOD2 was investigated by quantitative PCR analyses.

**Results:** At the age of 6 months mtBPL mice (7.5 mmol/l) showed significantly higher blood glucose levels compared to mtNOD mice (6.1 mmol/l) and mtAKR control mice (6.2 mmol/l). In liver and muscle of mtNOD and mtAKR mice an age-dependent increase in ROS was observed between month 3 and 12. In contrast, mtBPL mice showed a significant 20-fold peak increase in ROS at the age of 6 months, which normalized at the age of 12 month. At this time point the ROS level in muscle and live was comparable to mtAKR control mice. In dependence of age mtNOD mice showed a comparable or higher expression of antioxidative enzymes than mtAKR control mice, whereas in mtBPL mice the expression of all antioxidative enzymes and in particular the expression of catalase was significantly reduced.

**Conclusion:** The coincidence of mtDNA point mutations in the cytochrome c oxidase and NADH dehydrogenase resulted in higher blood glucose levels in 6 month old mtBPL mice. At this age mtBPL mice showed a significant increase of ROS production in liver and muscle. Thus, mtDNA mutations confer high ROS production in liver during adolescence with inadequate adaptation of the antioxidative system. This scenario could be a pathogenic trigger for insulin resistance with progressive ageing and contribute to the development of type 2 diabetes mellitus.

## 1313

### Streptozotocin-induced diabetes does not affect mitochondrial structure and function

N. Volk<sup>1</sup>, T.H. Fleming<sup>1</sup>, A.S. Hidmark<sup>1</sup>, E.-M. de Villiers<sup>2</sup>, P.P. Nawroth<sup>1</sup>; <sup>1</sup>Department of Medicine I and Clinical Chemistry, University of Heidelberg, <sup>2</sup>Division for the Characterization of Tumorviruses, Deutsches Krebsforschungszentrum, Heidelberg, Germany.

**Background and aims:** A central mechanism underlying the development and progression of late diabetic complications is increased production of reactive oxygen species (ROS). Mitochondria, and specifically the electron transport chain (ETC), are considered to be the main source for intracellular ROS. During hyperglycemia, ROS production is increased leading to changes in the function of mitochondria including decreased activity of the ETC complexes, reduced ATP production, as well as changes in morphology. Unpublished data from our research group have shown discrepancies between hyperglycemic conditions and elevated ROS levels. To estimate whether mitochondria dysfunction is associated with diabetes, the structure and functional properties of mitochondria were studied in the organs of streptozotocin-induced diabetic mice, using high-through put screening assays.

**Materials and methods:** Diabetes was induced in healthy, wild-type mice (C57Bl/6; male), by low-dose streptozotocin treatment. After four months, the hearts, kidneys, and livers from control and diabetic mice were collected, and mitochondria isolated by differential centrifugation. Purity of the isolated mitochondria was determined by electron microscopy (EM) and FACS. Morphology of the mitochondria within the tissue was also assessed by EM. The abundance of ETC complexes was analyzed by western blot (WB) and

the activity of the complexes was tested using specific activity assays. Total oxygen consumption, ATP, and ROS production were analyzed during state 3 and state 4 respiration.

**Results:** After four months of diabetes, both blood glucose (158.8 ± 4.1 mg/dl vs 467.8 ± 75.7 mg/dl, P-value = 0.0002) and HbA1c (2.9 ± 0.1 % vs 9.5 ± 0.4 %, P-value < 0.0001) were significantly increased in the diabetic group, and body weight was significantly decreased (36.1 ± 1.2 mg vs 23.8 ± 2.0 mg, P-value < 0.0001). The mitochondria fraction isolated from the organs of each group had a purity of more than 95 %. No gross morphological changes between control and diabetic groups were observed in either the isolated mitochondria or within the tissue. No differences were observed with respect to the abundance of the ETC complexes, ATP, and ROS production. However, during state 3 respiration, both heart- and liver-derived mitochondria from diabetic mice showed increased oxygen consumption. During state 4 respiration, oxygen consumption was increased in liver-derived mitochondria from diabetic mice. No changes could be observed at either state 3 or 4 for kidney-derived mitochondria.

**Conclusion:** This study describes a methodology not only for the isolation of high purity mitochondria from tissue, but also high-through put screening of mitochondrial function. Utilizing this methodology, it was found that at four months of streptozotocin-induced diabetes, there were little or no changes in the structure and function of mitochondria. Additional studies are required to determine whether mitochondria dysfunction is observed at later stages of diabetes and is associated with increased ROS production.

## 1314

### Pyruvate kinase isoenzyme M2 shows increased expression in diabetes

S. Vittas, S. Kopf, N. Volk, A. Hidmark, D. Oikonomou, T.H. Fleming, P.P. Nawroth; Department of Medicine I and Clinical Chemistry, University of Heidelberg, Germany.

**Background and aims:** Pyruvate kinase (PK) catalyzes the conversion of phosphoenolpyruvate (PEP) to pyruvate, generating ATP as the last step of glycolysis. PK is expressed in 3 different isoforms named M1, M2 and LR. PKM1 and PKM2 show different activity levels, with PKM2 being highly expressed in cancer where enables cells to use aerobic glycolysis instead of oxidative phosphorylation. mRNA expression of the different isoforms (M1-M2) was investigated using specific primers and siRNAs in control and diabetic material from mouse and human in order to investigate whether PKM isoforms show differential expression in diabetes and how this balance affects late diabetic complications.

**Materials and methods:** Hearts, kidneys, sciatic nerves (SN) and dorsal root ganglia (DRG) derived from 3-6 months control and diabetic mice and human peripheral blood mononuclear cells (pBMCs) derived from healthy aged matched control and type 2 diabetic individuals were used for RNA extraction, cDNA preparation and subsequent real-time PCR using specific primers for the different PKM isoforms (M1-M2). Additionally, in vitro experiments were performed by the use of siRNA specific for either both or M2 PK isoform in order to measure metabolic dysfunction with respect to glycolysis and the electron transport chain.

**Results:** PKM isoforms show differential expression in diabetic tissues and cells in compare to the respective controls. PK M1/M2 ratio is significantly decreased in hearts, kidneys, SN and DRG derived from diabetic mice in compare to age matched control mice. The same ratio is also decreased in human pBMCs derived from diabetic individuals in compare to control ones with a positive correlation being found between the levels of PKM2 isoform and the neuropathy symptom score (NSS) in the diabetic group.

**Conclusion:** PK as the last enzyme of glycolysis plays an important role in cell metabolism. This study reveals a differential expression of the two major PK isoforms (M1-M2) in diabetes. The increased PKM2 expression in diabetic tissue can be correlated with the ability of cells to use aerobic glycolysis instead of oxidative phosphorylation. These findings reveal new aspects in development of late diabetic complications, thereby providing new opportunities for therapeutic interventions.

#### Treatment with divalent copper chelation reverses defective myocellular copper transport in the heart of diabetic rat

S. Zhang<sup>1</sup>, H. Liu<sup>1</sup>, G. Amarsingh<sup>1</sup>, C.C.H. Cheung<sup>1</sup>, S. Hogg<sup>1</sup>, U. Narayanan<sup>1</sup>, L. Zhang<sup>1</sup>, S. McHarg<sup>2</sup>, J. Xu<sup>1</sup>, D. Gong<sup>1</sup>, J. Kennedy<sup>3</sup>, B. Barry<sup>3</sup>, Y. Choong<sup>1</sup>, A.R.J. Phillips<sup>1</sup>, G.J.S. Cooper<sup>1,2</sup>;

<sup>1</sup>School of Biological Sciences, University of Auckland, New Zealand,

<sup>2</sup>Institute of Human Development, University of Manchester, UK,

<sup>3</sup>National Isotope Centre, GNS Science, Wellington, New Zealand.

**Background and aims:** Heart disease is the leading cause of death in diabetic patients, and defective copper metabolism could play important roles in the pathogenesis of diabetic cardiomyopathy. This study was to determine how myocardial copper status and myocellular copper chaperon proteins become impaired by diabetes, and how they respond to treatment with the Cu(II)-selective chelator triethylenetetramine (TETA).

**Materials and methods:** Experiments were performed using streptozotocin (STZ)-induced diabetic rats with and without TETA treatment. Cardiac function were analysed in isolated, *ex-vivo* perfused working hearts and myocardial copper content measured using particle-induced x-ray emission spectroscopy coupled with Rutherford backscattering spectrometry. The expression (mRNA and proteins) and/or activity of key protein components involved in copper binding and transport were analysed using combination of RT-qPCR, western blotting, immunofluorescence staining and enzyme activity assays.

**Results:** Left-ventricular (LV) copper levels and LV function were markedly deficient (~50%,  $p < 0.01$ ) in rats following 16-weeks' diabetes in STZ-rats, but both were unexpectedly normalized after 8-weeks' treatment with TETA. Localized myocardial copper deficiency was accompanied by decreased expression (~40–50%,  $p < 0.05$ ) and increased polymerization of the copper-responsive transition-metal-binding metallothionein proteins (MT1/MT2), consistent with impaired anti-oxidant defences and elevated susceptibility to pro-oxidant stress. Levels of the high-affinity copper transporter-1 (CTR1) were depressed (~30%,  $p < 0.01$ ) in diabetes, consistent with impaired membrane copper uptake, and were not modified by TETA which, contrastingly, renormalized myocardial copper and increased levels (~1.5 fold,  $p < 0.05$ ) and cell-membrane localization of the low-affinity copper transporter-2 (CTR2). Diabetes also lowered indexes (~30%,  $p < 0.01$ ) of intracellular copper delivery via the copper chaperone for superoxide dismutase (CCS) to its target cuproenzyme, superoxide dismutase-1 (SOD1): this pathway was restored by TETA treatment, which normalized SOD1 activity with consequent bolstering of anti-oxidant defences. Furthermore, diabetes depressed levels (~20%,  $p < 0.01$ ) of additional intracellular copper-transporting proteins, including antioxidant-protein-1 (ATOX1) and Cu(II)-transporting-ATPase-2 (ATP7B), whereas TETA elevated copper-transporting-ATPase-1 (ATP7A) (~20%,  $p < 0.01$ ).

**Conclusion:** Myocardial copper deficiency and defective cellular copper transport/trafficking are revealed as key molecular defects underlying LV impairment in diabetes, and TETA-mediated restoration of copper regulation provides a potential new class of therapeutic molecules for diabetic heart disease.

#### Exendin-4 counteracts palmitate-induced autophagy in human cardiac progenitor cells by inhibiting p38 MAPK phosphorylation and de novo production of ceramide

A. Leonardini, R. D'Oria, M. Incalza, C. Caccioppoli, V. Andrulli Buccheri, M.R. Orlando, A. Natalicchio, S. Perrini, L. Laviola, F. Giorgino; Endocrinology & Metabolic Diseases, University of Bari, Italy.

**Background and aims:** Increased autophagy of cardiomyocytes has been proposed as a mechanism of myocardial damage and dysfunction. Glucagon-like peptide-1 (GLP-1) and GLP-1 analogs exert protective effects on cardiac cells. In this study, the effects of exendin-4 (Ex-4) on lipotoxicity-induced autophagy were investigated in human cardiac progenitor cells (hCPC).

**Materials and methods:** hCPCs were isolated from right auricle biopsies of patients undergoing elective heart surgery and exposed to palmitate (0.25 mM up to 16 h). Autophagy was evidenced by monodansyl cadaverine and autophagolysosome labeling, and by immunoblotting of microtubule-associated protein 1 light chain 3 (LC3)-II and beclin1. p38 expression and phosphorylation was detected by immunoblotting. The expression of ceramide synthase 5 (CerS5) was studied by RT-PCR and immunoblotting. Intracellular ceramide content was evidenced by immunofluorescence.

**Results:** Palmitate induced an increased autophagy in hCPC, evidenced by monodansyl cadaverine and autophagolysosome labeling, and confirmed by increased levels of microtubule-associated protein 1 light chain 3 (LC3)-II and beclin1, respectively ( $p < 0.05$ ). Palmitate also stimulated p38 MAPK phosphorylation ( $p < 0.05$ ), and pretreatment with the p38 MAPK inhibitors SB203580 and SB202190 significantly inhibited palmitate-induced autophagy. In palmitate-exposed hCPC, intracellular ceramide content, evaluated by immunofluorescence, was concomitantly augmented, in parallel with increased expression of ceramide synthase 5 (CerS5), a critical enzyme in ceramide generation. Co-incubation of hCPCs with fumonisins-B1, a specific CerS5 inhibitor, partially prevented palmitate-induced autophagy. However, the inhibition of CerS5 with a specific siRNA did not prevent p38 MAPK phosphorylation induced by palmitate. When hCPC were pretreated with Ex-4, the palmitate-induced increase in LC3-II and beclin1 and p38 MAPK phosphorylation were abrogated ( $p < 0.05$ ), and so was the increase in CerS5 and ceramide levels ( $p < 0.05$ ).

**Conclusion:** Palmitate-induced hCPC autophagy is mediated both by p38 MAPK activation and de novo ceramide synthesis in parallel, and the GLP-1 analog Ex-4 can counteract these responses. GLP-1 mimetics may thus protect the myocardium from lipotoxic damage in type 2 diabetic and/or obese subjects with elevated free fatty acid levels.

#### Cardiac immuno-inflammatory response to dietary sodium restriction in rats with insulin resistance and hypertension

B. Jover, C. Guzman, A.-D. Lajoix, C. Rugale, C. Desmetz; EA<sup>7288</sup>, University, Montpellier, France.

**Background and aims:** Controversial influence of dietary sodium restriction was reported in rats with insulin resistance. We have recently observed that low sodium (LS) diet prevents renal damages in rats fed high fructose. In the present study, we aimed at verify whether LS diet may also prevent fructose-induced modifications in the heart, even in presence of a moderate arterial hypertension. In addition, the involvement of the immuno-inflammatory response in the beneficial effect of a low sodium diet was assessed in cardiac tissue.

**Materials and methods:** At the age of 8 weeks, Sprague-Dawley rats received three different regimens for 8 weeks. Low sodium (LS, <0.01% NaCl) or normal sodium (NS, 0.65% NaCl) diets were proposed to rats made insulin resistant with high fructose consumption (60%, n=20) and hypertensive by chronic infusion of Angiotensin II (AngII, 200 ng.kg<sup>-1</sup>.min<sup>-1</sup>, sc, n=20). After 4 weeks of the fructose diet, AngII was infused or not during an additional 4-week period on fructose. A regular rat chow with NS content was given to control rats. Tail-cuff pressure (TCP) was measured before and after AngII. Heart weight index (HWI, mg HW / g BW) as well as the cardiomyocytes size (histology) were determined at the end of study. Insulin resistance was determined through the use of an insulin tolerance test (ITT, 0.6 UI/kg, ip). Cardiac expression of various genes was assessed by real-time PCR (qPCR). Presence of monocytes/macrophages was evidenced by immunostaining and expression of CD68. Transcription factor, NF-kBp65, and the presence of CD4+ and CD8+ T cells or B cells (CD20) were evaluated by qPCR.

**Results:** As expected, AngII induced a clear rise in TCP in rats fed NS fructose diet (40±5% from basal value of 139±2 mmHg,  $P < 0.01$ ). TCP rose to a lesser extent (20±4%,  $P < 0.05$ ) in rats fed LS fructose diet. The response to ITT was similar in NS and LS rats fed high fructose and infused with AngII. When compared to standard rats, fructose induced a cardiac hypertrophy with a HWI of 2.80±0.05 vs 2.44±0.07 mg/g,  $P < 0.05$ . HWI was lower in rats fed the LS- than the NS-fructose diet (~ 8% vs 15%). HWI further increased in AngII-infused rats on both diets (HWI of 3.01±0.28 in NS and 2.89±0.07 mg/g in LS); yet the rise was less marked in LS- than NS-fed rats (~ 9 vs 23% compared to control group). The rise in cardiomyocytes size was prevented by the LS diet. In the heart, macrophages infiltration (CD68 staining and expression) during fructose feeding was reduced by the LS diet in absence (9.5±0.8.10-2 vs 7.1±0.5.10-2,  $P < 0.05$ ) and in presence of AngII (10.6±1.5.10-

2 vs 5.6±0.4.10<sup>-2</sup>, P<0.01). Similarly, expression of CD4 and CD8 in cardiac tissue was lower in LS-fed rats with or without AngII infusion. No significant changes were detected for CD20. Expression of NF-κBp65 was reduced in rats fed the low sodium diet in absence or presence of AngII infusion.

**Conclusion:** Reduction of sodium consumption has a beneficial effect on cardiac morphology in insulin resistance alone or associated with a clear arterial hypertension. This beneficial effect is not related to improvement of insulin resistance. Beside a reduction in the level of hypertension, sodium deprivation seems to act through the blunting of local cardiac inflammation response and the reduction of immune cells (not B cells) infiltration in the heart.

### HDL and signals of endothelial inflammation in type 2 diabetes mellitus

R.F.H. Lemmers<sup>1</sup>, S. Shagiwal<sup>2</sup>, A.J.M. Verhoeven<sup>2</sup>, M. van Hoek<sup>2</sup>, A.G. Lieveise<sup>1</sup>, E.J.G. Sijbrands<sup>2</sup>, M.T. Mulder<sup>2</sup>, W.A. Dik<sup>3</sup>;

<sup>1</sup>Internal Medicine, Máxima Medical Center, Eindhoven, <sup>2</sup>Internal Medicine, <sup>3</sup>Immunology, Erasmus Medical Center, Rotterdam, Netherlands.

**Background and aims:** In type 2 diabetes (T2D), structural as well as compositional changes of HDL have been observed. HDL usually attenuates inflammation, but can under certain conditions become pro-inflammatory. We hypothesized that pro-inflammatory HDL contributes to vascular complications in T2D. In an ongoing study, we compare the effects of HDL from T2D patients on endothelial signals of different human endothelial cells. Here, we report our preliminary results with retinal endothelial cells (REC).

**Materials and methods:** Anti-inflammatory properties of HDL isolated with iodixanol Gradient centrifugation were measured as TNF-α induced cytokine production and adhesion molecule expression by human retinal endothelial cells (REC). IL-6 and IL-8 production were measured with ELISA and vascular cell adhesion molecule-1 (VCAM1) expression with fluorescence-activated cell sorting (FACS) using fluorescent antibodies. HDL was isolated from T2D patients with both micro- and macrovascular complications (HDL<sub>T2D+C</sub>, n=3), T2D patients without complications (HDL<sub>T2D</sub>, n=3) and healthy control subjects (HDL<sub>Healthy</sub>, n=3).

**Results:** Pre-incubation of REC with HDL did not alter basal IL-6 and IL-8 production or VCAM1 expression. TNF-α increased IL-6 production from 31.6ng/ml (SD 5.7, n=3) to 75.0ng/ml (SD 12.2, n=3). After pre-incubation with HDL, TNF-α-induced IL-6 production decreased significantly (p<0.0001) to 42.7ng/ml (SD 7.7, n=9). TNF-α increased IL-8 production from 245.1ng/ml (SD 10.8; n3) to 3618.1ng/ml (SD 728.1; n=3). When pre-incubated with HDL, TNF-α stimulated IL-8 production decreased significantly (p<0.0001) to 2676.1ng/ml (SD 474.0; n=9). The median fluorescent intensity (MFI) of VCAM1-expression on REC was 604.0 units (range 594.2-642.1; n=3) and increased to 7612.8 (range 7331.0-7894.6; n=2) after TNF-α stimulation. Pre-incubation with HDL decreased TNF-α-induced VCAM1 expression significantly (p<0.0001) to 3414.1 units (range 2203.9-4246.2; n=9). The groups were too small for subgroup analyses and comparisons.

**Conclusion:** We were able to observe inhibitory effects of HDL on TNF-α induced VCAM-1 expression and IL-6 and IL-8 production by Retinal Endothelial Cells. Our ongoing recruitment and testing will increase the power of the study and enable comparisons between the subgroups.

## 1319

### Soluble dipeptidyl peptidase 4 induces inflammation and proliferation of human vascular smooth muscle cells via protease-activated receptor 2

N. Wronkowitz<sup>1</sup>, S.W. Görgens<sup>1</sup>, T. Romacho<sup>1</sup>, L.A. Villalobos<sup>2</sup>, C.F. Sánchez-Ferrer<sup>1</sup>, C. Peiro<sup>1</sup>, H. Sell<sup>1</sup>, J. Eckel<sup>1</sup>;

<sup>1</sup>Paul-Langerhans Group for Integrative Physiology, German Diabetes Center, Düsseldorf, Germany, <sup>2</sup>Department of Pharmacology and Therapeutics, Universidad Autónoma de Madrid, Spain.

**Background and aims:** Dipeptidyl peptidase 4 (DPP4) is a ubiquitously expressed cell-surface protease and a novel adipokine, as shown by us. Due to DPP4-mediated degradation of the incretin hormone glucagon-like peptide (GLP)-1, inhibition of DPP4 is now widely used as a therapeutic approach for type 2 diabetes mellitus treatment. In addition, DPP4 inhibitors display beneficial cardiovascular effects that are not only GLP-1 mediated. However, nothing is known about direct cellular effects of soluble DPP4 (sDPP4), the circulating form of this enzyme. Previously, we showed that sDPP4 directly induces inflammation and proliferation in human vascular smooth muscle

cells (hVSMC). The aim of the present study was to identify a responsible receptor for the sDPP4-induced effects in hVSMC.

**Materials and methods:** Primary hVSMC from three distinct donors were exposed to protease-activated receptor 2 (PAR2) specific siRNA or the antagonist GB83. Cells were then treated with sDPP4 for 6 and 24h and the impact of PAR2 on the sDPP4-induced effects was investigated. The sDPP4-induced signaling pathways were assessed by Western blot analysis. To analyze the expression of different cytokines mRNA were measured by real-time PCR. Effects on proliferation were detected by ELISA.

**Results:** Bioinformatic analysis and signaling signature induced by sDPP4 suggest that sDPP4 might be an agonist for PAR2. Indeed, we found a potential PAR2 binding site in the cysteine-rich region of DPP4 responsible for partner binding. When we aligned the potential PAR2 binding site with the sequence of the crystallized DPP4, we could locate it on the surface of DPP4. Interestingly, PAR2 protein level was significantly higher in hVSMC compared to endothelial cell, adipocytes or skeletal muscle cells. After silencing of PAR2, the sDPP4-induced ERK activation (2.5-fold) as well as the proliferation (1.7-fold) was totally abolished. Additionally, the same effect was observed by the PAR2 antagonist GB83. In accordance to that the sDPP4-induced NF-κB activation (1.5-fold) as well as the upregulation of the pro-inflammatory cytokines IL-6 and IL-8 (2-fold and 1.9-fold, respectively) could completely be prevented by PAR2 silencing.

**Conclusion:** In conclusion, in this study we characterized a novel sDPP4-induced signaling cascade in hVSMC. sDPP4 directly and markedly activates the MAPK- and NF-κB signaling pathway in a PAR2 dependent manner leading to pro-atherogenic changes in hVSMC like increased proliferation and inflammation. Considering the increased circulating levels of sDPP4 in obesity and the upregulation of PAR2 in atherosclerotic lesions, our proposed sDPP4-PAR2 interaction might play an important role in linking obesity to cardiovascular disease.

### Inflammatory stimulation transforms glucose into a deleterious agent in human vascular smooth muscle cells

C.F. Sanchez-Ferrer<sup>1</sup>, C. Peiro<sup>1</sup>, T. Romacho<sup>1</sup>, V. Azcutia<sup>1</sup>, L. Villalobos<sup>1</sup>, E. Fernandez<sup>2</sup>, J.P. Bolanos<sup>3</sup>, S. Moncada<sup>3</sup>;

<sup>1</sup>Farmacologia, Universidad Autonoma de Madrid,

<sup>2</sup>Instituto de Biología Funcional y Genética, Salamanca, Spain,

<sup>3</sup>Wolfson Institute for Biomedical Research, London, UK.

**Background and aims:** Although hyperglycemia is recognized as an independent risk factor for cardiovascular diseases, the links between glucose metabolism and the development of atherosclerosis still require elucidation. We have previously shown that normal vascular cells, which have the capacity to regulate the entry of glucose, are not damaged by high glucose concentration unless they are primed with an inflammatory stimulus such as interleukin (IL)1β.

**Materials and methods:** In cultured human vascular smooth muscle cells (VSMC) submitted to normal or high glucose (5.5 or 22 mmol/L), inflammation (1 to 10 ng/mL IL1β), and/or infection with the glucose transporter GLUT1, the following parameters were analysed: (1) glucose uptake and consumption, as well as lactate production; (2) characterization of GLUT1 by flow cytometry, RT-PCR, and immunofluorescence; (3) determination of inflammatory parameters, such as the expression of inducible nitric oxide synthase (iNOS) and the activity of nuclear factor-κB (NF-κB); (4) NADPH oxidase activity; (5) expression of glucose-6-phosphate dehydrogenase (G6PD) and activity of the pentose phosphate pathway (PPP) and; (6) determination of total and reduced glutathione.

**Results:** In VSMC submitted to high glucose, we show that excess glucose uptake and utilization only occurs in the presence of IL1β. However, we demonstrate that the simple entry of glucose is not enough to be deleterious in these cells since over-expression of GLUT1 or increased glucose uptake following inhibition of mitochondrial oxidative phosphorylation with sodium azide are not sufficient to trigger inflammatory mechanisms. Our results indicate that, besides allowing glucose entry, IL1β enhances G6PD expression and activates the PPP in VSMC, thus permitting some of the excess glucose to be metabolized by this route. Such activation provides additional substrate for the enzyme NADPH oxidase and results in increased generation of free radicals. These are necessary intermediates for the inflammatory response since they are required for the activation of iNOS and NF-κB. The higher the concentration of glucose the more the PPP pathway is activated, giving rise to an increased inflammatory condition which cannot be counterbalanced by

the simultaneous regeneration of reduced glutathione that occurs following activation of the PPP.

**Conclusion:** A pro-inflammatory stimulus such as IL1 $\beta$  transforms excess glucose into a deleterious agent in VSMC by causing an increase in glucose uptake and its subsequent diversion into the PPP. This action ultimately promotes the pro-oxidant conditions required for the exaggeration of pro-inflammatory pathways. Interestingly, all these pathways were blunted by the blockade of IL1 receptors with anakinra. These findings can improve our understanding of the mechanisms for the development of diabetic vascular complications and suggest the combination of anti-inflammatory strategies together with glycaemic control for a more efficient prevention of such diseases.

### Nitric oxide hyperproduction and markers of DNA damage in the early phase of diabetic nephropathy in rat streptozotocin diabetes mellitus model

J. Sokolovska<sup>1</sup>, E. Rostoka<sup>1</sup>, O. Sugoka<sup>2</sup>, S. Isajevs<sup>3</sup>, L. Baumane<sup>1</sup>, J. Sharipova<sup>1</sup>, I. Kalvinsh<sup>1</sup>, N. Sjakste<sup>1</sup>;

<sup>1</sup>Latvian Institute of Organic synthesis, Riga, <sup>2</sup>University of Latvia, Institute of Biology, Salaspils, <sup>3</sup>University of Latvia, Riga, Latvia.

**Background and aims:** Reactive oxygen species (ROS) production due to intracellular hyperglycaemia is an important factor that initiates inflammatory pathways leading to diabetic nephropathy. NO hyperproduction in the kidney might lead to nitrosative stress with resulting DNA damage. However, data on NO, nitric oxide synthases (NOS) in the diabetic nephropathy are contradictory. Other enzymes like xantine oxidoreductase (XOR) might be involved. The aim of this work was to study changes and mechanisms of NO production in the kidneys of rats with streptozotocin (STZ) diabetes mellitus model, along with expression of poly ADP ribose polymerase (PARP) and histone gamma H2AX as markers of DNA damage. In order to modify NO production, we have used 1,4-dihydropyridine (1,4-DHP) class compounds, synthesized in the Latvian Institute of Organic Synthesis.

**Materials and methods:** Diabetes mellitus in rats was induced by streptozotocin (STZ) 50 mg/kg, i.v. Production of NO in kidneys was monitored by means of ESP spectroscopy of Fe-DETC-NO complex. Different inhibitors of NO synthesis (GdCl<sub>3</sub>, aminoguanidine, 1400W, allopurinole) have been applied. 1,4-DHP class drugs have been administered 0,5 mg/kg for 3 days per os. Kidney iNOS, eNOS, XOR, PARP and H2AX mRNA and protein expression were detected by qRT-PCR and immunohistochemistry correspondingly, 12 days after diabetes mellitus induction and after 3 days of treatment with DHP class drugs.

**Results:** NO production increase in kidneys was stable and potent (from 2.64  $\pm$  0.97 to 15.04  $\pm$  2.04 ng/g tissue). Application of non-selective NOS inhibitor aminoguanidine and XOR inhibitor allopurinol resulted in a significant decrease of NO hyperproduction. Further, 1,4-DHP class compounds etaforon, cerebrocrast and fenoforon significantly decreased NO production. iNOS and XOR protein expression was upregulated in STZ rat kidney and decreased under etaforon treatment (iNOS: control 11  $\pm$  4 cells/mm<sup>2</sup>, STZ: 29  $\pm$  15 cells/mm<sup>2</sup>, STZ+etafaron; 13  $\pm$  6 cells/mm<sup>2</sup> p<0.05) and (XOR: control 8  $\pm$  2 cells/mm<sup>2</sup>, STZ 27  $\pm$  7 cells/mm<sup>2</sup>; STZ+etafaron 9  $\pm$  3 cells/mm<sup>2</sup>, p<0,05.). In kidneys of STZ rats, PARP expression was significantly elevated, and normalized by 1,4-DHP drug AV153. H2AX expression also significantly increased in kidneys of diabetic rats, AV153 did not affect this parameter.

**Conclusion:** We report increased NO production in kidneys of STZ diabetic rats, along with increased markers of DNA damage, after short duration of severe hyperglycaemia. 1,4-DHP class compounds could normalize increased NO production, iNOS, XOR and PARP hyperexpression in STZ rat kidneys. NO production in the kidney might become a therapeutic target to decrease oxidative stress and progression of diabetic nephropathy.

### Early intervention with GLP-1 analogue prevents memory impairment and tau hyperphosphorylation in diabetic db/db mice

Y. Yang, S. Shao;

Department of Endocrinology, Tongji Hospital, Tongji Medical College, Huazhong University of Science and Technology, Wuhan, China.

**Background and aims:** Recent studies have shown that type 2 diabetes mellitus (T2D) is a risk factor for Alzheimer's disease (AD), and hyperphosphorylated tau protein is a pathophysiological change in hippocampus on the early set of AD, which is called AD associated tau change. Insulin resistance is often associated with T2D and can induce defective insulin signaling in the central nervous system. Glucagon like peptide-1 (GLP-1) stimulates insulin secretion and has been employed in the treatment of T2D. Unlike insulin, GLP-1 and its analogs could cross the brain blood barrier freely. In this study, we investigated the potential effects on AD associated tau protein with treatment with a GLP-1 analog in db/db mice.

**Materials and methods:** A total of 80 male db/db mice at the age of 2-2.5 weeks were randomly divided into three groups: GLP-1-treated, insulin-treated and control-treated groups. After being acclimatized and received daily subcutaneous saline injections for 1 week, all mice received daily subcutaneous injection of GLP-1 analog, insulin or, as a control, saline right before the dark cycle each day. Five to seven mice from each group were sacrificed every two weeks. Blood, cerebrospinal fluid (CSF) and brain tissues were collected at the second, fourth, sixth and eighth weeks separately after GLP-1 analog or insulin administration for analyses.

**Results:** We found that GLP-1 analog promoted more beneficial effects on learned memory in db/db mice compared with insulin treatment. The drug reduced hyperphosphorylated tau protein by activating insulin signaling pathway in the hippocampus. On the contrary, insulin peripheral administration had no effects on AD associated tau protein changes. Neither GLP-1 analog nor insulin could stimulate neuronal degeneration.

**Conclusion:** In summary, our data indicate that early GLP-1 analog intervention improves cognition in db/db mice, an effect likely driven by increasing the activity of insulin signaling pathway in the T2D brain, which leads to the reduction of AD associated tau hyperphosphorylation.

### Effect of hyperglycaemia on the expression of aquaporins in diabetic rat testis

A. Kannan, C. Prahalthan;

Biochemistry, Bharathidasan University, Tiruchirappalli, India.

**Background and aims:** Diabetes mellitus (DM) is one of the greatest public health threats in modern societies. DM is a well-recognized cause of male sexual dysfunction and impairments of male fertility. Sustained hyperglycemic and hypoinsulinemic states is considered as a major cause of sexual, ejaculatory and erectile dysfunction in human population. Water and solute movement across the epithelium of the male reproductive tract is responsible for balancing the luminal environment for spermatogenesis and plays a pivotal role for establishment of male fertility. Aquaporins (AQPs) are a family of integral membrane proteins allowing the transcellular transport, maintaining water homeostasis and is strongly associated with female and male reproductive systems. In the testis, AQPs play an indirect role in maintaining spermatogenesis, while in the efferent ducts and epididymis; provide environment for the transport and maturation of sperm. The main aim of this study is to determine the effect of hyperglycemia on expression of AQPs in testis of diabetic rats.

**Materials and methods:** Experimental animals were handled according to the University and institutional legislation, regulated by the Committee for the Purpose of Control and Supervision of Experiments on Animals (CPCSEA), Ministry of Social Justice and Empowerment, Government of India (BDU/IAEC/2011/28/29.03.2011). Experimental diabetes in rats was induced by a single intraperitoneal injection of streptozotocin (65 mg/kg body weight). Plasma glucose was measured using glucometer. The mRNA expressions of AQPs (1, 7, 8, 9 & 11) in testis from control and diabetic rats were examined by RT-PCR after a time interval of 4weeks. All statistical analysis was carried out using GraphPad Prism4 software. All data were presented in mean ( $\pm$ ) standard deviations (SD).

**Results:** Plasma glucose was significantly higher in diabetic groups than in controls ( $P < 0.05$ ). The RT-PCR detection of the aquaporins (1, 7, 8, 9 & 11) considered in this study is illustrated in Fig. 1. The level of expression of AQP 1 in diabetic testis was similar to that of control groups. The levels of expression of AQPs 7, 8, 9 and 11 in diabetic testis were significantly higher compared to controls ( $P < 0.05$ ).

**Conclusion:** In summary, this work describes the expression of AQPs 7, 8, 9, & 11 in testis of diabetic rats were altered compared to controls. Alteration of AQPs expression leads to disruption of water homeostasis and affects spermatogenesis. Recent studies shows that AQPs 7, 8 & 11 plays an important role in spermatogenesis and physiological sperm volume regulation. AQP9 plays a specific role in the transport of water and non-charged solutes in Leydig cells. Furthermore, altered expression and regulation of AQPs have already been demonstrated to be the cause of several disorders of the male reproductive system. The full enlightenment of these molecular interactions and mechanisms may point towards possible therapeutic targets to counteract diabetes induced male subfertility/infertility.

**Fig. 1** Expression of AQPs 1, 7, 8, 9, 11 in testis of control and diabetic rat. The gene expression was determined by RT-PCR. Values represent mean  $\pm$  S.D (\* $P < 0.05$ ; \*\* $P < 0.005$ )

### 1324

#### Decreased use of experimental animals through optimisation of experimental design for efficacy studies

R. Stoop, A.M. van den Hoek, R. Hanemaaijer, S. van Buuren, A.-M. Zuurmond;

Metabolic Health Research, Netherlands Organization for Applied Scientific Research (TNO), Leiden, Netherlands.

**Background and aims:** Well-designed studies provide the maximum of information from the minimal number of experimental animals. Aim of this study was to explore whether asymmetric experimental designs can reduce number of animals needed without affecting statistical power of the study.

**Materials and methods:** Data from several efficacy studies in bleomycin-induced lung fibrosis in mice were combined to make tentative estimates of the expected outcomes for newly planned studies. Classically, these types of studies comprise a PBS control group, a bleomycin-induced (bleo) group, and several treatment groups with the same number of animals in all groups. Instead of comparing all groups to each other using ANOVA and post-hoc testing,  $k + 1$  planned comparisons were defined in advance: bleo versus PBS control, and bleo versus  $k$  treatments (in total  $k + 1$  comparisons). Since the bleo group appears in both the comparison with the PBS control and the treatment group, changing the size of this group will have most effect on the statistical power. Since the direction of the effects was anticipated, only one-sided t-tests were used. For fixed type I error, statistical power of the Student t-test was calculated for all combinations of group sizes of 2–30 animals. The optimal asymmetric design achieves the desired statistical power for each planned comparison with the minimum of animals needed.

**Results:** We calculated that the best asymmetric designs required about 20–25% fewer animals than the best symmetric design.

**Conclusion:** This demonstrates that substantial reduction of animal use is possible by smarter choices on group size without loss of power. To aid researchers to optimize their experimental design, we developed a freely available sample size calculator (available at [www.tno.nl/3R](http://www.tno.nl/3R)) to compare symmetric and asymmetric designs.

### 1325

#### Twice-daily hyperglycaemic spikes accelerate atherosclerotic lesion formation in C57BL/6 mice

Y. Shuto, A. Asai, M. Nagao, M. Kawahara, H. Sugihara, S. Oikawa; Endocrinology, Diabetes and Metabolism, Nippon Medical School, Tokyo, Japan.

**Background and aims:** Increasing epidemiological evidence indicates that postprandial hyperglycemia in individuals with impaired glucose tolerance (IGT) is a risk factor for atherosclerotic cardiovascular disease. A number of studies have demonstrated the possible roles of acute glucose fluctuations, a hallmark of IGT, in atherogenesis in cell culture models; e.g., intermittent high glucose exposure-induced oxidative stress, inflammatory response, and subsequent proatherogenic changes in vascular endothelial cells, smooth muscle cells, and macrophages. However, there is little convincing experimental evidence that repetitive glucose fluctuations can actually result in accelerated atherosclerosis in vivo. Hence, the in vivo mechanism underlying IGT-induced atherogenesis is not yet fully understood. In this study, we demonstrated the effect of long-term repetitive hyperglycemic spikes on atherosclerotic lesion formation in mice.

**Materials and methods:** Female C57BL/6 mice were fed an atherogenic diet (AD; 1.25% w/w cholesterol, 0.5% w/w sodium cholate, 36% energy fat) from 8 to 28 weeks of age. During the 20-week AD feeding period, the mice received 20% glucose solution (50 mg glucose/mouse) (G) or distilled water (W) twice daily by oral gavage (6 days a week). The post-challenge blood glucose changes were monitored on a day in the week 2, 11, and 20. OGTT and insulin tolerance test were performed in the week 19 and 20, respectively. After the AD feeding, serial frozen sections (10  $\mu$ m thickness, spanned 450  $\mu$ m) of aortic sinus were prepared and the atherosclerotic lesion size was quantitated from the oil red O-stained area (mean of 9 sections, each separated by 50  $\mu$ m). Gene expression levels in the thoracic aorta and the plasma

lipid profiles were also analyzed. Data are expressed as mean±SEM (n=8). Differences between G and W were assessed by Student's *t* test.

**Results:** Blood glucose levels in G increased by ~5 mmol/l above W at 20 min after the glucose ingestions and returned to similar levels to W within 60 min. There are no significant differences in body weight, plasma lipid profiles (total cholesterol, HDL-cholesterol, non-HDL-cholesterol, triacylglycerols, and NEFA), and blood glucose levels in OGTT and insulin tolerance test between G and W. Aortic sinus atherosclerotic lesion size in G was 3.8-fold greater than that of W ( $22.2\pm 5.7$  vs  $5.8\pm 1.8 \times 10^3 \mu\text{m}^2$ ,  $p=0.025$ ). Gene expression levels of an adhesion molecule *Icam-1* (1.26-fold,  $p=0.036$ ) and a macrophage marker *Cd68* (1.27-fold,  $p=0.036$ ) in thoracic aorta were significantly higher in G relative to those in W.

**Conclusion:** These results demonstrate that repetitive hyperglycemic spikes can accelerate atherosclerotic lesion formation *in vivo* independent of basal blood glucose levels, insulin resistance, or plasma lipid profiles, possibly via proatherogenic changes in arterial wall. The repetitive glucose ingestion in mice on AD would be a simple and useful method for studying the pathogenesis, prevention, and treatment of IGT-induced atherosclerotic vascular disorders.

### 1326

#### Cardiac magnetic resonance imaging evaluation after experimental myocardial infarction in streptozotocine induced diabetic rats with high glycaemic variability

M. Joubert<sup>1</sup>, J. Hardouin<sup>1</sup>, K. Blanchart<sup>2</sup>, S. Allouche<sup>3</sup>, A. Manrique<sup>3</sup>;

<sup>1</sup>Endocrinology Unit, <sup>2</sup>Cardiology Unit, University Hospital of Caen, <sup>3</sup>EA4650, Caen, France.

**Background and aims:** During acute myocardial infarction (MI) in type 2 diabetic (T2D) patients, both hyperglycemia and hypoglycemia (at admission and/or during the hospital stay) are associated with poor outcome. In addition, the impact of glycemic variability in these patients is also discussed: several *in vitro* and *in vivo* studies have suggested a deleterious effect of glycemic variability on endothelial function through an increase in oxidative stress. However, there is actually no data concerning the direct impact of this glucose metric on MI morbidity. We address here this question in a rodent diabetic model.

**Materials and methods:** Twenty-six adult male Wistar rats ( $315 \pm 41$  g), synchronized to a reverse 12 hours dark-light cycle were divided in three groups: control (C) (n=7), sham (S) (n=5) and diabetes (D) (n=14). Rats from group D received 70 mg/kg of intraperitoneal (IP) streptozotocin (STZ). Rats from group C and S received vehicle only 70 mg/Kg IP. Group D was divided in two subgroups: diabetes hyperglycemia (Dh) (n=6) and diabetes variability (Dv) (n=8). Glargine was introduced 48 hours after STZ injection: 5 UI/kg/j subcutaneously (SC) at 9:00 AM for Dh rats and 15 UI/kg/j SC at 9:00 AM for Dv rats. Blood glucose monitoring was performed to confirm that glycemia was maintained above 250 mg/dl in Dh sub-group and presented swings below 150 and above 250 mg/dl in Dv sub-group. After 4 weeks, all rats (except in group S) were subjected to ischemia (30 min of transient coronary artery ligation) followed by reperfusion. Cardiac magnetic resonance imaging (CMR) was performed 1 and 3 weeks (w1 and w3) after surgery to assess left ventricular function [end-diastolic volume (EDV), end-systolic volume (ESV), ejection fraction (LVEF), wall motion score (WMS)] and myocardial edema.

**Results:** Mean blood glucose was  $140\pm 24$ ,  $130\pm 28$  and  $265\pm 88$  mg/dl in group C, S and D (global  $p<0.001$ ). Glycemic standard deviation, a glycemic variability index, was higher in Dv compared to Dh group ( $205$  vs.  $94$  mg/dl;  $p=0.021$ ). LVEF (%) at w1/w3 was  $47.5\pm 11.5/46.5\pm 7.7$ ;  $59.5\pm 8.5/55.7\pm 3.7$  and  $51.1\pm 9.3/47.4\pm 10.7\%$  for group C, S and D, respectively (ns). Likewise, no inter or intra group difference was found for ESV and EDV. However, WMS was increased (indicating abnormal wall motion) after ischemia in group C and D vs S at w1/w3 ( $1.40\pm 0.20/1.35\pm 0.20$  and  $1.56\pm 0.15/1.50\pm 0.27$  vs  $1\pm 0$ ;  $p<0.0001$ ). Myocardial edema decreased in infarct zone between w1 and w3 in group C ( $20.3\pm 5.0$  vs  $14.5\pm 3.2$ ;  $p<0.001$ ) but not in group D ( $20.4\pm 5.9$  vs  $21.2\pm 6.3$ ; ns). In subgroup analysis, myocardial edema also decreased in infarct zone between w1 and w3 in group Dh ( $20.6\pm 5.7$  vs  $18.6\pm 4.1$ ;  $p<0.05$ ) but not in group Dv ( $20.3\pm 6.0$  vs  $22.4\pm 6.8$ ; ns). In the remote territory, myocardial edema decreased in group Dh but increased in group Dv between w1 and w3 (Dh:  $19.3\pm 5.5$  vs.  $16.7\pm 4.1$ ; Dv:  $17.7\pm 4.8$  vs.  $18.9\pm 6.1$ ; all  $p<0.05$ ).

**Conclusion:** Myocardial edema, reflecting myocardial injuries, does not improve over time in diabetic rats compared to control animals after an experimental MI. This effect is due to the sole subgroup with high glycemic

variability. Furthermore, in this particular subgroup, prolonged edema was also observed in the remote territory. These results suggest that glycemic variability might be more deleterious than persistent hyperglycemia after MI.

#### Cardioprotective effect of decorin in type 2 diabetes

F. Chen<sup>1</sup>, J. Tang<sup>2</sup>, D. Wang<sup>2</sup>;

<sup>1</sup>Department of Endocrinology, <sup>2</sup>Department of Internal Medicine and Institute of Hypertension, Tongji Hospital, Tongji Medical College, Huazhong University of Science, Wuhan, Hubei, China.

**Background and aims:** Cardiomyopathy in diabetes is the leading cause of increased mortality in diabetes patients. In the present studies, we investigated the effect of decorin (DCN) gene therapy on left ventricular function, cardiac inflammation and fibrosis in high-fat diet (HFD) and streptozotocin (STZ)-induced type 2 diabetes.

**Materials and methods:** Type 2 diabetes was induced in male Wistar rats by HFD (60% of calories as fat) and injection of low-dose STZ, (20 mg/kg, intravenously). Diabetic rats were divided into (n=6 for each group) the control group, the GFP-treated group and the DCN-treated group, received intravenous injection of saline solution, recombinant adeno-associated viral (rAAV)-GFP and rAAV-DCN, respectively. We investigated cardiac inflammation, fibrosis, left ventricular (LV) function at 6 months after gene delivery.

**Results:** rAAV-DCN Treatment attenuated diabetic cardiomyopathy with improved LV function, cardiac inflammation and fibrosis compared with control animals. These protective effects were associated with increased expression of PKC- $\alpha$  and Hsp70, decreased activation state of IGF-IR, pERK, TGF- $\beta$ 1 and  $\alpha$ -SMA and NF- $\kappa$ B pathways.

**Conclusion:** Our results show that rAAV-mediated DCN therapy may be beneficial in the treatment of diabetic Cardiomyopathy.

#### Hyperglycaemia does not affect restenosis development after percutaneous transluminal angioplasty in a diabetic rabbit model

J.X. Zhou<sup>1</sup>, L. Zhang<sup>2</sup>, W.Z. Zhang<sup>1</sup>, L. Liao<sup>1</sup>, J.J. Dong<sup>3</sup>;

<sup>1</sup>Department of Endocrinology, <sup>2</sup>Department of Sonography, Affiliated Qianfoshan Hospital of Shandong University, <sup>3</sup>Department of Endocrinology, Qilu Hospital of Shandong University, Jinan, China.

**Background and aims:** It is clear that hyperglycemia aggravates the development of atherosclerosis. However, whether hyperglycemia promotes prevalence of restenosis remains unknown. In the studies, we investigated the effect of hyperglycemia on restenosis.

**Materials and methods:** Restenosis was evaluated in two sets of diabetic rabbits models: (1) diabetic restenosis (DR) versus non-diabetic restenosis (NDR); and (2) diabetic atherosclerosis (DA) versus non-diabetic atherosclerosis (NDA).

**Results:** Our study showed no difference in restenosis rates between the diabetic and the non-diabetic rabbits ( $92.33\pm 5.46\%$  versus  $89.17\pm 7.14\%$ ,  $P>0.05$ ). However, the prevalence of stenosis was significantly increased in the DA group compared with NDA group ( $72.37\pm 24.55\%$  versus  $35.54\pm 40.97\%$ ,  $P<0.05$ ). Similarly, intima-media thickness and cell proliferation were remarkably higher in the DA group than that of the NDA group, while no difference was found between the DR and NDR groups.

**Conclusion:** Our results provide evidence that hyperglycemia is an independent risk factor for atherosclerosis, but it does not promote restenosis, and different mechanisms are involved in the development of atherosclerosis and restenosis.

**Figure**  
Arteries of rabbits were harvested at day 28 post-surgery. Arteries were plastic embedded and cross sections were stained. A) Cross sections stained with HE, Masson and VGF. B) Stenosis rate of the right iliac artery of rabbits treated with atherosclerotic lesion (group 1, n=6), atherosclerotic lesion+hyperglycemia (group 2, n=4), restenotic lesion (group 3, n=6), restenotic lesion + hyperglycemia (group 4, n=7). C) Intima/Media ratio of the right iliac artery of rabbits treated with atherosclerotic lesion (group 1, n=6), atherosclerotic lesion+hyperglycemia (group 2, n=4), restenotic lesion (group 3, n=6), restenotic lesion+hyperglycemia (group 4, n=7). HE: Hematoxylin and eosin stain, EVG: Elastic Van-Gieson stain, NDM: non-diabetes, DM: diabetes. Magnification 40 $\times$ . A significant ( $P<0.05$ ) from respective control is denoted by \*\*\*. Scale bar=1000  $\mu$ m.

**Effect of glucose level on the size of myocardial infarction in pigs**  
S.S. Diemar<sup>1,2</sup>, A.-S. Sejling<sup>1,3</sup>, K.K. Iversen<sup>1</sup>, T. Engström<sup>4</sup>, J.L. Hønge<sup>5</sup>, N. Tønder<sup>1</sup>, N. Vejstrup<sup>4</sup>, K. Ekström<sup>1,2</sup>, U. Pedersen-Bjergaard<sup>1,2</sup>, M. Dalsgaard<sup>1</sup>, B. Thorsteinsson<sup>1,2</sup>

<sup>1</sup>Department of Cardiology, Nephrology and Endocrinology, Nordsjællands Hospital, Hillerød, <sup>2</sup>Faculty of Health Sciences, University of Copenhagen, <sup>3</sup>Faculty of Health Sciences, University of Southern Denmark, Odense, <sup>4</sup>Department of Cardiology, Rigshospitalet, Copenhagen, <sup>5</sup>Department of Cardiothoracic and Vascular Surgery, Aarhus University Hospital, Skejby, Denmark.

**Background and aims:** Patients with diabetes and acute myocardial infarction (MI) have a two- to five-fold increased in-hospital mortality compared with non-diabetic patients. Concomitant hypoglycaemia or hyperglycaemia is suggested to worsen the acute prognosis of MI. Mortality after MI is associated with necrotic damage to the myocardium. Consequently, minimising the necrotic area is warranted. Our aim was to investigate the effect of the acute plasma glucose level on the size of MI in a closed-chest pig model.

**Materials and methods:** 38 non-diabetic Danish/Landrace female pigs were randomised to three different plasma glucose levels: hypoglycaemia ( $2.1 \pm 1.0$  mmol/l; 15 pigs (mean $\pm$ SD)); normoglycaemia ( $5.8 \pm 1.6$  mmol/l; 12 pigs) and hyperglycaemia ( $21.5 \pm 2.9$  mmol/l; 11 pigs). After 30 minutes of steady state with plasma glucose levels within target (1.8–2.2 mmol/l, 5–7 mmol/l, 22–23 mmol/l, respectively) MI was induced. Using a closed-chest model a balloon catheter was inserted via the internal carotid artery to the left anterior descending coronary artery and inflated for 30 minutes. Afterwards the heart was reperfused while the plasma glucose level remained in target for 2 hours. Following sternum split an in-vivo staining with Evans Blue was performed. The heart was subsequently taken out and in-vitro stained with TTC to delineate the necrotic tissue from the viable tissue (area at risk (AAR)).

**Results:** Twenty-five (66%) pigs developed ventricular fibrillation (VF) during the reperfusion period. Of these 7 pigs died. There was no difference in incidence of VF ( $p=1.0$ ) or death ( $p=0.22$ ) between the glycaemic groups. No

significant differences in infarction size, AAR or infarction/AAR ratio were detectable between the groups.

**Conclusion:** In a closed-chest pig model the acute glucose level did neither affect cardiac morbidity or mortality nor the size of the myocardial infarction.

**Table 1.**

|                                 | VF (N) | Mortality (N) | Infarction (mm <sup>2</sup> ) (mean $\pm$ SD) | AAR (mm <sup>2</sup> ) (mean $\pm$ SD) | Infarct/AAR ratio (mean $\pm$ SD) |

**Dipeptidyl peptidase-4 inhibition in a rat model of ischaemia-reperfusion injury may accelerate tubular regeneration but does not improve glomerular filtration rate**

B. Hocher<sup>1</sup>, C. Reichzeder<sup>1</sup>, K. von Websky<sup>1</sup>, O. Tsuprykov<sup>1</sup>, T. Klein<sup>2</sup>; <sup>1</sup>University of Potsdam, <sup>2</sup>Boehringer Ingelheim, Biberach, Germany.

**Background and aims:** Dipeptidyl peptidase (DPP)-4 inhibitors have been shown to have protective effects on ischaemia-reperfusion injury (IRI) of the heart and lung. As the DPP-4 enzyme and its substrates are also expressed in the kidney, we studied the effects of the DPP-4 inhibitors linagliptin, vildagliptin, and sitagliptin on the outcome of IR-induced acute kidney injury in uninephrectomised rats.

**Materials and methods:** Male Wistar rats obtained from Charles River (Germany) weighing 150–170 g were subjected to uninephrectomy. Two weeks later, the remaining kidney was exposed to IRI by clamping the renal artery for 30 min; sham surgery was performed without clamping. The rats (n=10–14 per group) received DPP-4 inhibitor treatment once-daily with either linagliptin (1.5 mg/kg/day), vildagliptin (8 mg/kg/day), sitagliptin (30 mg/kg/day), or vehicle via gavage on the 3 consecutive days prior to IRI. An additional group was treated with sitagliptin until study end in order to inhibit DPP-4 activity during the entire experiment. This group was treated initially with sitagliptin 30 mg/kg/day; after induction of IRI, the dose was adjusted to 15 mg/kg/day because of renal failure. Levels of plasma cystatin C (a biomarker of glomerular filtration rate) and clusterin (a biomarker of tubular regeneration) were measured at 0, 24, 48, 72, and 168 hours after IRI or sham operation.

**Results:** Levels of active GLP-1 increased 3–4 fold in all DPP-4 inhibitor treatment groups versus the placebo group, up to 24 hours after clamping ( $p<0.05$  for all comparisons). Levels of plasma cystatin C peaked 48 hours after clamping and increased from  $1454 \pm 320$  ng/ml in the sham-operated group to  $1728 \pm 323$  ng/ml in the placebo-treated group with IRI ( $p=0.059$ ). This increase was unaffected by treatment with either linagliptin, vildagliptin, or sitagliptin. Similarly, the area under the curve for plasma cystatin C (0 to 168 hours after IRI) was comparable across all treatment groups. At study end, levels of plasma clusterin were lowest in the placebo-treated group ( $97.14 \pm 15.71$   $\mu$ g/ml) and significantly higher in all treatment groups (linagliptin:  $116.53 \pm 25.28$   $\mu$ g/ml; vildagliptin:  $111.28 \pm 17.78$   $\mu$ g/ml; sitagliptin:  $113.53 \pm 16.45$   $\mu$ g/ml; extended sitagliptin treatment:  $114.99 \pm 16.00$   $\mu$ g/ml;  $p<0.05$  for all comparisons).

**Conclusion:** In rats with acute IRI of the kidney, DPP-4 inhibition does not alter the glomerular filtration rate but may enhance tubular regeneration. These findings were observed when DPP-4 activity was inhibited prior to IRI and for one week following IRI.

**Morphometric characteristics of the air-blood barrier in experimental diabetes mellitus**O. Pivovarova<sup>1</sup>, E. Rozova<sup>2</sup>, B. Mankovsky<sup>3</sup>;<sup>1</sup>State Establishment „Lugansk State Medical University, Lugansk,<sup>2</sup>Bogomoletz Institute of Physiology, Kyiv, <sup>3</sup>P.L. Shupyk National Medical Academy of Post-Graduate Education, Kyiv, Ukraine.

**Background and aims:** Respiratory diseases contribute significantly to mortality and morbidity in patients with diabetes mellitus. However, the mechanisms underlying the lung damage in diabetic patients are not fully understood. The air-blood barrier (ABB) performs an important role in functioning of the respiratory system but its structure in diabetes was not studied in detail. Therefore, the aim of this study was to investigate specific histological features of the ABB in the streptozotocin (STZ)-induced diabetes.

**Materials and methods:** The study was performed on 47 STZ-induced diabetic and 43 control male Wistar rats. Diabetes was induced by single intraperitoneal injection of STZ (SIGMA, USA) 60 mg/kg in 0.1 M citrate buffer, pH 4.5. The tissue for the further evaluation was collected after 18 weeks of diabetes. The diabetic rats were not treated with insulin. The morphometric assessment was performed using the electron microscope PEM-125K and the data were analyzed using the software Image Tool Version 3 (USA). The thickness of arithmetic average ( $\tau$ ) and harmonic average ( $\tau_h$ ) were calculated.

**Results:** We found the significant increase of thicknesses of  $\tau$  and  $\tau_h$  of ABB in STZ-induced diabetic rats compared to control group -  $\tau$  were  $302,7 \pm 11,4$  nm and  $163,4 \pm 6,8$  nm,  $\tau_h$  were  $289,5 \pm 12,5$  nm and  $155,6 \pm 5,4$  nm, respectively, in diabetic and control animals,  $p < 0,01$ . These changes could indicate the hyperhydration. Also,  $\tau$  and  $\tau_h$  of epithelial layer of ABB in the STZ-induced diabetic rats were significantly elevated ( $98,6 \pm 2,2$  nm and  $91,5 \pm 1,7$  nm, respectively), compared to controls ( $71,6 \pm 3,5$  nm and  $65,1 \pm 2,1$  nm),  $p < 0,05$ . The values of  $\tau$ ,  $\tau_h$  of the interstitium of ABB in the STZ-induced diabetic rats were significantly higher than in non-diabetic animals -  $92,4 \pm 4,3$  nm,  $97,6 \pm 5,2$  nm in diabetes and  $49,2 \pm 3,1$  nm and  $46,1 \pm 3,3$  nm, in controls, respectively,  $p < 0,001$ . In the STZ-induced diabetic rats,  $\tau$  and  $\tau_h$  of endothelium of ABB were  $118,8 \pm 7,1$  nm and  $121,7 \pm 4,2$  nm, whereas in the controls there were  $63,9 \pm 3,3$  nm and  $50,1 \pm 3,2$  nm respectively,  $p < 0,001$ .

**Conclusion:** We found the significant thickening of all layers of the ABB, including epithelial, which may underlie the development of intraalveolar edema in the STZ-induced diabetic rats. Permeability changes caused by hyperhydration of ABB can lead to the disturbance of the oxygen transport and the development of hypoxia in diabetic rats.

## 1332

**Adipose tissue mitochondrial dysfunction triggers a lipodystrophic syndrome with insulin resistance, hepatosteatosis and cardiovascular complications**C. Vernochet<sup>1</sup>, F. Damilano<sup>1</sup>, A. Mourier<sup>2</sup>, O. Bezy<sup>1</sup>, M.A. Mori<sup>1</sup>, G. Smith<sup>1</sup>, A. Rosenzweig<sup>3</sup>, N.-G. Larsson<sup>2</sup>, R.C. Kahn<sup>1</sup>;<sup>1</sup>Joslin Diabetes Center, <sup>2</sup>Department of Mitochondrial Biology, Max Planck Institute for Biology of Ageing, <sup>3</sup>Cardiovascular Division of the Beth Israel Deaconess Medical Center and Harvard Medical School, Boston, USA.

**Background and aims:** Mitochondrial dysfunction in adipose tissue occurs in obesity, type 2 diabetes and some forms of lipodystrophy, but whether this dysfunction contributes to or is the result of these disorders is unknown.

**Materials and methods:** To investigate the physiological consequences of severe mitochondrial impairment in adipose tissue, we generated mice deficient for the mitochondrial transcription factor TFAM in adipocytes by using mice carrying Adiponectin-Cre and TFAM floxed alleles.

**Results:** These Adipo-TFAM KO mice had a 75-81% reduction of TFAM in subcutaneous and intra-abdominal white adipose tissue (WAT) and interscapular brown adipose tissue (BAT), and this resulted in decreased expression and enzymatic activity of proteins in complexes I, III, and IV of the electron transport chain (ETC). This mitochondrial dysfunction led to adipocyte death and inflammation in WAT and a “whitening” of BAT. As a result, Adipo-TFAM KO mice were resistant to weight gain, but exhibited insulin resistance, on both normal chow and high fat diets.

**Conclusion:** These lipodystrophic mice also developed hypertension, cardiac hypertrophy and cardiac dysfunction. Thus, isolated mitochondrial dysfunction in adipose tissue can lead a syndrome of lipodystrophy with metabolic syndrome and cardiovascular complications
