Relative contribution of monsoon precipitation and pumping to changes in groundwater storage in India

Akarsh Asoka¹, Tom Gleeson², Yoshihide Wada^{3,4,5,6} and Vimal Mishra^{1*}

The depletion of groundwater resources threatens food and water security in India. However, the relative influence of groundwater pumping and climate variability on groundwater availability and storage remains unclear. Here we show from analyses of satellite and local well data spanning the past decade that long-term changes in monsoon precipitation are driving groundwater storage variability in most parts of India either directly by changing recharge or indirectly by changing abstraction. We find that groundwater storage has declined in northern India at the rate of 2 cm yr⁻¹ and increased by 1 to 2 cm yr⁻¹ in southern India between 2002 and 2013. We find that a large fraction of the total variability in groundwater storage in north-central and southern India can be explained by changes in precipitation. Groundwater storage variability in northwestern India can be explained predominantly by variability in abstraction for irrigation, which is in turn influenced by changes in precipitation. Declining precipitation in northern India is linked to Indian Ocean warming, suggesting a previously unrecognized teleconnection between ocean temperatures and groundwater storage.

30

rignificant depletion of groundwater storage in a number of regions around the world, including northwest India^{1,2}, has been shown with Gravity Recovery Climate Experiment (GRACE) observational data as well as global hydrologic and water use models^{3,4}, and attributed to groundwater pumping (abstraction) for irrigation^{1,2,5,6}. In India, irrigated agriculture produces over 70% of food grain, and groundwater plays a major role⁷, with annual groundwater abstraction increasing from 10-20 km³ yr⁻¹ to 240-260 km³ yr⁻¹ between 1950 and 2009⁸. India is a global leader in groundwater-fed irrigation due to intensive agriculture driven by multiple crops in a year⁹, especially after the green revolution^{1,2}, with the largest non-renewable groundwater abstraction (68 km³ yr⁻¹) in the world⁷. Persistent droughts can reduce groundwater recharge and enhance groundwater pumping for irrigation, leading to lowered groundwater levels. For instance, due to a continuous deficit in precipitation, 80 km³ of groundwater has been depleted in southern California since 1960⁵. Over the Gangetic Plain and other parts of north India, the monsoon season (June to September) precipitation has declined since 1950^{10–12}, which has led to increased frequency and intensity of droughts¹³, possibly contributing to enhanced abstraction and/or reduced recharge of groundwater. Using multiple data sources (GRACE, well observations, model (PCR-GLOBWB¹⁴), precipitation, and sea surface temperature (SST)) and methods (regression and dominance analysis), we explore two related hypothesis: that precipitation deficit may have an impact on declining groundwater levels in northwestern India, which have previously been largely attributed to abstraction for irrigation², and that groundwater storage variability may be partially associated with large-scale climate effects¹⁵, since weakening of the monsoon season precipitation is linked to largescale climate variability^{10,12}.

Changes in groundwater storage

We estimated groundwater storage anomalies from GRACE for 2002-2013 to evaluate the spatial patterns of changes in groundwater in north and south India (Fig. 1). Consistent with previous analysis, and further supported for the first time by comparison to a large data set of water-level observations, GRACE groundwater anomalies show significant declines $(2 \text{ cm yr}^{-1}, p\text{-value} < 0.05)$ in the majority of north India in January, May, August, and November for which observations from Central Groundwater Board (CGWB) are available (Fig. 1a-d and Supplementary Fig. 3). Moreover, changes in groundwater anomalies from GRACE show increases $(\sim 1-2 \text{ cm yr}^{-1}, \text{ change in linear units})$ in south India (Fig. 1a-d and Supplementary Fig. 3). We find that changes in groundwater level from the observation wells and GRACE are consistent for 2002-2013 (Fig. 2e-h). However, GRACE-based estimates of trends are lower than those of observation wells, as GRACE examines larger spatial domains (\sim 100 km grid), whereas well observations are for point scale and represent very local depletion, which is not visible at GRACE resolution. However, standardized anomalies of groundwater level and GRACE-based groundwater storage change showed a close correspondence for north and south India, with correlation coefficients of 0.46 and 0.77 respectively (Fig. 1i,j). GRACE groundwater anomalies show a large pattern of declining groundwater in north India, but increasing groundwater level in south India. However, it is unclear if these patterns of changes in groundwater anomalies in north and south India are driven by groundwater abstraction for irrigation or long-term changes in precipitation.

Previous studies^{1,2,11} reported declines in groundwater storage in north India based on GRACE data, which are available for 2002 onwards; however, quantification of groundwater storage

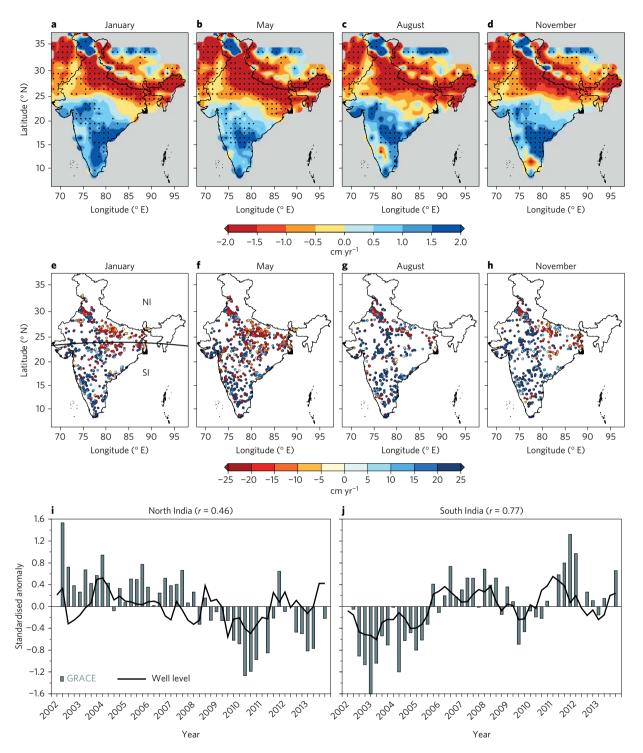

Figure 1 | **Changes in groundwater storage from observation well and GRACE data during 2002-2013. a-h**, Monthly trends in groundwater anomaly are from GRACE (in cm yr⁻¹) (**a-d**) and *in situ* well observations from the CGWB (**e-h**) for 2002-2013. Stippling in **a-d** indicates statistically significant changes at the 5% level. **e-h**, Wells that experienced significant declines and increases in groundwater levels (cm yr⁻¹) during 2002-2013. Trends were estimated using the non-parametric Mann-Kendall test and Sen's slope method. Monthly anomalies for January, May, August, and November were estimated from GRACE and *in situ* observations after removing the monthly mean. *In situ* groundwater well observations from the CGWB are available only for four months (January, May, August, and November). **i, j**, Area-averaged standardized departure (after removing mean and dividing by the standard deviation) from GRACE and *in situ* well observations for north (above 23° N) and south (below 23° N) India, respectively. Correlation coefficients between standardized anomalies of GRACE and groundwater wells for north and south India are 0.46 and 0.77, respectively.

variability in India beyond the GRACE period is limited. We
estimated changes (using linear trend) in the groundwater table
depth (m) using well observations from the CGWB for 1996–2013

⁴ and applied the non-parametric Mann–Kendall trend test and Sen's

slope method. Moreover, we used the field significance test¹⁶ to evaluate trends at a regional scale considering the influence of spatial and temporal correlations. Results show a significant decline (\sim 15– 25 cm yr⁻¹, *p*-value < 0.05) in groundwater table depth during

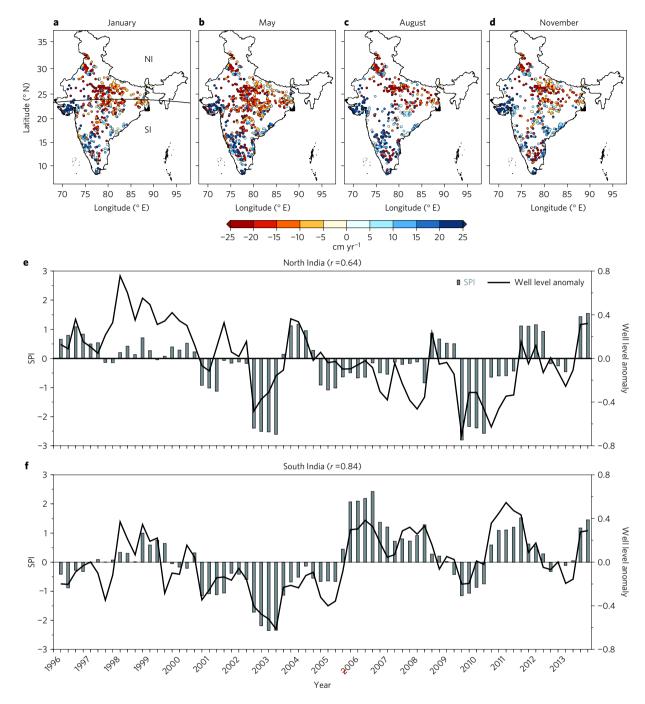

Figure 2 | Changes in groundwater level in observation wells during 1996-2013 and their linkage with precipitation. a-d, Observed trend in groundwater table for the months of January, May, August, and November for 1996-2013. Trends were estimated using the non-parametric Mann-Kendall trend test and Sen's slope (wells that show statistical significant changes at the 5% level are shown). **e,f**, Relationship between standardized groundwater table anomaly and 12-month standardized precipitation index (SPI) for January, May, August, and November for northern India (above 23° N) and for southern India (below 23° N), respectively.

1996-2013 in a majority of observation wells located in north India (23° north, Fig. 2a-d). Moreover, we find that the number 2 of wells with significant (*p*-value < 0.05) declines is higher for the 3 non-monsoon season than for the monsoon season, which may be 4 due to increased pumping during the non-monsoon season as it 5 is a major crop-growing period (Supplementary Fig. -2). In India, 6 the monsoon season overlaps with a major crop-growing season (Kharif, June to September), in which groundwater pumping may 8 be high during monsoon deficit years. In the Rabi (October to 9 April) season, however, a majority of crops (for example, wheat) 10 11 mostly rely on groundwater-based irrigation. Observation wells

with significant water-level increases (\sim 5–20 cm yr⁻¹) are mainly located in south India, which is consistent with GRACE data (Fig. 1). However, a minority of wells in each region show opposite trends of decreasing groundwater levels in southern India and increasing groundwater levels in northern India, highlighting the complexity and heterogeneity of the data and localized influence of groundwater pumping and recharge (Fig. 2).

Standardized groundwater level anomalies averaged over northwest, north-central, and south India for all four months (January, May, August, and November) represent annual variability and show a close relationship (correlation coefficients 0.55, 0.54,

increased ET is less in the dry season (Supplementary Fig. 1i).
Moreover, positive SST anomalies (El-Niño) in the central Pacific
Ocean result in precipitation deficit in the monsoon season in
north and south India (Supplementary Table 6) and precipitation
deficit in 2002 and 2009 can be partially attributed to El-Niño.

6 Precipitation and groundwater storage variability

Groundwater storage could be affected by significant declines in the
monsoon season precipitation in India after 1950¹¹⁻¹³ if changes in
precipitation lead to changes in recharge or groundwater pumping.
Declines in the monsoon season precipitation have been observed
since 1950, and have continued during 1980–2013 (Fig. 3a,b).

Moreover, cumulative deficit in the monsoon season precipitation 12 showed substantial reductions in precipitation during 2002-2013 13 in north India (Fig. 3b). Long-term changes in precipitation 14 may affect groundwater storage in north India due to high 15 groundwater persistence, as groundwater levels respond slowly 16 to recharge (Supplementary Fig. 4). We notice that parts of the 17 Gangetic Plain, semi-arid western India (including Gujarat in 18 west-central India), and peninsular India are heavily irrigated 19 with groundwater (Fig. 3b). To evaluate the role of long-term 20 changes in precipitation on groundwater storage, we separated 21 the wells located in the regions with significant increases/declines 22 in precipitation (1980-2013) and heavily irrigated (more than 23

40% irrigation from groundwater) with groundwater (Fig. 3c,d). We find that wells that are located in the areas that witnessed significant increases in precipitation showed positive median trends in groundwater level (1996–2013) despite these wells being located in the area that is heavily irrigated with groundwater (Fig. 3d-5 $\frac{1}{10}$ and Supplementary Fig. 5). On the other hand, wells that are located in the areas with significant declines in precipitation showed declines in groundwater tables, although there is a large variability in trends in both cases (Fig. 3e-h). The analysis was repeated for 2002-2013 with consistent results, suggesting that changes in precipitation 10 substantially influence groundwater storage in India. Positive trends 11 in groundwater storage change in south India are consistent with the 12 long-term increase in precipitation^{10,12}. 13

14 Changes in groundwater recharge

0.7

We estimated annual groundwater recharge from well data using 15 the water-table fluctuation method¹⁷ and from the PCR-GLOBWB 16 model. We found a substantial fluctuation in water-table depth in 17 the observation wells during 1996-2010, which may be associated 18 with the seasonal variability in precipitation and abstraction 19 (Supplementary Figs 6 and 7). Consistent with model results, 20 mean annual groundwater recharge estimated using the water-21 table fluctuation method for 1996-2010 showed high recharge 22 in north-central India and Gujarat (Fig. 4a,b), primarily due to 23 higher specific yields (Supplementary Fig. 8). Groundwater wells in 24 north India are located in alluvial (unconsolidated sediment) plains, 25 whereas wells in south India are primarily in bedrock (primarily 26 consolidated sediment or igneous rock), which can affect the time 27 for groundwater recharge in response to precipitation. Moreover, 28 groundwater pumping can substantially reduce the well levels 29 in the low-recharge areas, while in high-recharge areas, stream-30 aquifer interaction can also raise water levels^{15,16}. A significant 31 decline in precipitation in the north-central region (Supplementary 32 Fig. 9) resulted in reduced groundwater recharge, as shown by both 33 observation wells and model data (Fig. 4c,d). However, recharge 34 in north and south India may be variable and not always directly 35 related to precipitation. There might be other factors affecting 36 groundwater recharge in India that are not considered in our 37 analysis. For instance, groundwater systems have been modified by 38 the large-scale canal network¹⁸ for water diversions; however, the 30 influence of canals and other surface water storage structures are 40 not considered in our groundwater recharge estimates, which can /11 be substantial in the drier parts of aquifers¹⁸. Water losses from unlined and lined canals can be substantial¹⁹ in the areas where 42 43 an extensive canal network is present (for example, the Gangetic 44 Plain) contributing to groundwater recharge and water logging¹⁹. 45 Since the area irrigated by groundwater wells in north and south 46 India is far larger than that irrigated by canals (Supplementary 47 Fig. 10), recharge from canals may not be sufficient to compensate 48 groundwater declines due to abstraction²⁰. Moreover, in north India 10 (especially in the Indo-Gangetic Plain), the contribution of glacier 50 melt to streamflow is within only 5-10% (refs 21,22); therefore, **0.8** 51 groundwater recharge due to stream-aquifer interactions may not 52 be sufficient to balance the losses due to groundwater abstraction 53 for irrigation in downstream regions. 54

55 Relative importance of precipitation and abstraction

We analysed 12-month SPI and standardized abstraction index 56 (SAI, estimated using recharge from the PCR-GLOBWB model) 57 to investigate the relative contributions of precipitation and 58 groundwater abstraction on changes in groundwater storage 59 (Supplementary Fig. 11B). We separated observation wells located 60 in northwest, north-central, and south India, which showed field 61 significant declines (northwest and north-central) and increases 62 (south) in groundwater level during 1996–2013 (Supplementary 63 64 Fig. 11A). Long-term mean groundwater abstraction for 1996–2010 was substantially high (\sim 50 cm yr⁻¹) in northwestern India, which is consistent with the findings of Rodell and colleagues². We found significant increases (5-10 cm) in groundwater abstraction in northwest India for 1996-2010, whereas significant declines in the monsoon season precipitation (Supplementary Fig. 9) and groundwater recharge (Fig. 4) can be noticed in the northcentral India (Supplementary Fig. 9), indicating different driving factors such as the monsoon season precipitation, recharge, and groundwater abstraction in the northwest, north-central, and south India (Supplementary Fig. 9 and Fig. 4). Annual SPI and SAI are strongly related in northwest and south India, with correlation coefficients of -0.80 (*p*-value < 0.05) and -0.72 (*p*-value < 0.05), respectively. However, a relatively weaker (correlation = -0.46, p-value < 0.05) relationship between annual SPI and SAI was found in the north-central region (Supplementary Fig. 12 and Supplementary Table 1). Our results show that a precipitation deficit can lead to higher groundwater abstraction in India, as modelled abstraction is strongly related to precipitation (Supplementary Fig. 11B). Correlation between annual SAI and groundwater level anomalies from observation wells is strong in northwest and south India, with correlation coefficients of -0.62 (*p*-value < 0.05) and -0.55 (*p*-value < 0.05), respectively (Supplementary Fig. 12D,F). However, we did not find a strong relationship (correlation = 0.31) between groundwater abstraction and groundwater levels in northcentral India.

Linear regression was performed for 1996-2010 using 90 groundwater levels from observation wells, SPI and SAI to 91 evaluate the relative importance (contribution) of precipitation 92 and abstraction on groundwater variability. We find that SPI 93 (12-month) explains 29, 30, and 64% of total groundwater 94 storage variability in northwest, north-central, and south India, 95 respectively (Supplementary Table 2). Annual groundwater 96 abstraction (12 month-SAI) explains 38, 10, and 30% of total 97 groundwater storage variability in northwest, north-central, 98 and south India (Supplementary Table 2). However, looking 99 at individual contributions (in total variability of groundwater 100 storage) of annual (12-month) precipitation and abstraction, we 101 find groundwater abstraction (SAI) explains more variability 102 (38%) in northwest India, whereas SPI explains more variability 103 in the north-central (30%) and south India (64%) (Supplementary 104 Table 2). To understand if the groundwater abstraction is driven by 105 precipitation in India, we estimated the fraction of total variability 106 in annual abstraction (SAI) explained by annual precipitation 107 (SPI). Our results showed that 65% variability of groundwater 108 abstraction (SAI) in northwest India is explained by the annual 109 precipitation (SPI), indicating that groundwater abstraction for 110 irrigation is higher during precipitation deficit. It is important to 111 note that about 35% of the variability of groundwater abstraction in 112 northwestern India is contributed by other factors (such as choice 113 of crops, intensive agriculture, subsidized electricity, and market 114 driven prices). Moreover, the model results for abstraction may 115 have a relatively higher uncertainty in the north-central region than 116 in southern India²³. We evaluated the relative importance of SPI 117 and SAI using dominance analysis²⁴ to predict groundwater level 118 anomalies because SPI and SAI are correlated. Results from linear 119 regression and dominance analysis were consistent, indicating a 120 larger role of SPI in groundwater storage variability in south and 121 north-central India (Supplementary Tables 2 and 3). Similar to 122 groundwater storage; we estimated the relative importance of SPI 123 and SAI in groundwater recharge for all three regions. We found that 124 annual precipitation (12-month SPI) explains 50, 91, and 83% of the 125 total variability of annual groundwater recharge in northwestern, 126 north-central, and south India (Supplementary Table 4). Our 127 results from the regression and dominance analysis showed that 128 the relative contribution from SPI in annual groundwater recharge 129 is higher than SAI in all three regions (northwest, north-central, 130

and south) (Supplementary Table 4 and Supplementary Table 5),
which further highlights the importance of the role of precipitation
on groundwater recharge and abstraction in India.

4 Year-to-year variability in the monsoon season precipitation is linked to the large-scale climate^{10,12}, suggesting large-scale climate 5 may also influence groundwater variability in India. Annual changes 6 in the groundwater anomaly from GRACE showed significant 7 $(\sim 2 \text{ cm yr}^{-1}, p$ -value < 0.05) declines in north India and increases 8 in south India (Fig. 5). The leading mode obtained from the 9 empirical orthogonal function (EOF-1), which explained about 46% 10 of total squared covariance, exhibited a similar spatial structure 11 to that obtained from trend analysis (Fig. 5a,b). The principal 12 component (PC-1) of the leading mode obtained from the EOF 13 analysis showed consistent declines during 2002-2013, indicating 14 the leading mode represents the trend in groundwater anomaly. 15 Negative correlation between PC-1 and SST anomalies indicates 16 that warmer SST anomalies in the Indian Ocean result in declines 17 in groundwater levels in northern India (Fig. 4d), which can be 18 explained on the basis of the relationship between rainfall and 19 SST^{12,13}, and rainfall and groundwater levels, as shown above. 20 Moreover, the ENSO affects the Indian monsoon rainfall in India¹⁰ 21 which can also indirectly lead to enhanced warming over the Indian 22 Ocean^{10,25}. Consistent with previous studies^{10,26,27}, we found that 23 a positive SST anomaly over the central Pacific Ocean results in 24 a similar impact (decline in precipitation) in north and south 25 India (Supplementary Table 6), indicating that contrasting trends 26 in groundwater storage in north and south India are more strongly 27 linked to the SST variability in the Indian Ocean. The role of 28 ENSO on groundwater storage variability, which affects SST over 29 the Indian Ocean^{10,25,28}, can be separated²⁹ if long-term GRACE data 30 are available. 31

Significance of untangling impacts on groundwater storage 32 Groundwater storage plays a key role in Indian agriculture, on 33 which a large population rely directly or indirectly⁸. Although 34 groundwater-based irrigated area has increased in northwest, north-35 central, and south India during 2002–2013 (Supplementary Table 7), 36 contrasting trends in groundwater storage in north and south 37 India highlight the importance of precipitation variability. Our 38 results show that the contributions of anthropogenic pumping 39 and precipitation to groundwater variability vary regionally in 40 India-in north-central and south India precipitation is the major 41 contributing factor, whereas in northwest India groundwater 42 43 pumping is more important. We show that precipitation variability controls groundwater storage and recharge directly or indirectly 44 in the majority of India, which has implications for water 45 management in current and projected climate conditions³⁰⁻³². 46 47 Although groundwater-based irrigated area has increased in northwest, north-central, and south India (Supplementary Table 7), 48 contrasting trends in groundwater storage in north and south India 49 highlight the importance of precipitation variability. Importantly, 50 other factors impacting groundwater storage (choice of crops, type 51 52 of irrigation methods, intensive agriculture, subsidized electricity, and increasing trend in irrigated area) and groundwater recharge 53 (aquifer characteristics¹⁶, depth of water table, presence of canals 54 and surface storage structures^{23,33}, pumping-induced recharge³⁴ 55 and abstraction¹⁸, and stream-aquifer interaction¹⁶ of glacier-fed 56 rivers²²) may affect the linkage between groundwater storage and precipitation in India. Moreover, several other factors related to 58 irrigation practices and methods, uncertainties in recharge^{23,33–35}, 59 60 and management practices related to agriculture can influence 61 variability of groundwater storage in the current and future climate²⁸. For instance, improving irrigation methods (for example, 62 sprinkler, drip) possibly reduces the return flow from irrigation 63 to groundwater and baseflow, which may be another important 64 factor for irrigation development and groundwater storage change 65

in India. Understanding the relative contribution from precipitation and anthropogenic pumping provides insight into better water management approaches for food and water security in India.

Acknowledgements

The authors acknowledge funding from the ITRA-Water project. Data availability from the Central Groundwater Board (CGWB), Gravity Recovery and Climate Experiment (GRACE), and India Meteorological Department (IMD) is greatly appreciated.

Author contributions

V.M. conceived the idea. A.A. collected, analysed the data and developed the methodology. T.G. and Y.W. contributed to discussions of the findings. Y.W. provided groundwater recharge and abstraction data from the PCR-GLOBWB model. V.M. and A.A. wrote the manuscript with contributions from T.G. and Y.W.

Additional information

Supplementary information is available in the online version of the paper. Reprints and permissions information is available online at www.nature.com/reprints. Correspondence and requests for materials should be addressed to V.M.

Methods

1

We used Gravity Recovery Climate Experiment (GRACE) groundwater anomaly, 2 groundwater well observations from the Central Ground Water Board (CGWB), 3 daily precipitation³⁶ from India Meteorological Department (IMD), and irrigated 4 5 area map from the Food and Agriculture Organization (FAO) to understand the driving factors of groundwater variability in India. We derived the groundwater 6 anomaly (GWA) at 1° spatial resolution after subtracting surface water storage 7 (sum of soil moisture, canopy storage, and surface water) from GRACE terrestrial 8 water storage anomaly (TWSA) for 2002-2013. Monthly TWSA version 0537,38 was 0 10 obtained from the Centre for Space Research (CSR) at the University of Texas, 11 Austin. A 300 km Gaussian filter was applied to reduce the random errors in the 12 data³⁷. We applied scaling factors to minimize the attenuation caused due to sampling and post processing. We used monthly surface water storage from the 13 Noah, CLM, VIC, and MOSAIC land surface models, which are available from the 14 Global Land Data Assimilation System (GLDAS)³⁹. The ensemble of groundwater 15 anomalies based on GLDAS models (Noah, CLM, VIC, and MOSAIC) was used for 16 17 the analysis. We used observations from more than 19,000 groundwater wells from 18 CGWB, which are available for the months of January, May, August, and November 19 (frequency of measurements is four times a year) for 1996-2013. However, there are significant data gaps and inconsistencies in the observed records. We selected 20 groundwater observation wells for the analysis that have long-term data and are 21 free from substantial missing data and inconsistencies. We finally selected 2,458 22 wells with a minimum 15 yr (out of the entire record of 17 yr) of observations in 23 each month (January, May, August, and September). Gridded daily precipitation³⁶ **0.14** 24 at 0.25° was obtained from IMD for 1980-2014. For areas outside India, monthly 25 precipitation data were obtained from the Tropical Rainfall Measurement Mission 26 (TRMM 3B43 V7)⁴⁰. To understand groundwater variability in irrigated regions, 27 the fraction of total area irrigated with groundwater was obtained from the 'Global 28 Map of Irrigation Areas' (GMIA) version 541. The water-table fluctuation method 29 as suggested by the CGWB was used for recharge estimation using the difference 30 between maximum and minimum depths (or fluctuation) of the water table at the 31 32 observation wells and specific yield (recharge = fluctuation in water table \times 33 specific yield). Specific yield for aquifers in India was obtained by digitizing a map provided by the CGWB^{17,42}. 34

We used the satellite-derived volumetric soil moisture product from the 35 36 European Space Agency Climate Change Initiative (ESACCI SMv02.1)43 for 1980-2013. Soil moisture trends using the ESACCI data were evaluated with the 37 other products, and consistent results were found⁴³. We estimated the evaporative 38 stress index (ESI), which is a ratio of evapotranspiration (ET) and potential 39 evapotranspiration (PET), using data from the Moderate Resolution Imaging 40 Spectroradiometer (MODIS) monthly ET and PET (MOD16) products⁴⁴ at 5 km 41 spatial resolution for 2002-2013. Higher ESI indicates water-stressed conditions as 42 43 ET approaches PET.

We performed trend analysis based on the non-parametric Mann-Kendall 44 trend test⁴⁵ with Sens's slope estimator⁴⁶. For groundwater level anomalies, trends 45 were estimated for each month for which observations were available to avoid the 46 influence of seasonality. Spatial and temporal correlations in the data set in trend 47 48 analysis were considered, and a field significance test was performed to evaluate changes at regional scales using the methodology described in Yue and Wang¹⁶ 49 50 Please note that trend analysis can be influenced by the start and end year as well as 51 length of the record. Changes for 2002-2013 in the selected variables were estimated by multiplying the trend slope by the number of years. Changes in 52 groundwater anomaly from GRACE, groundwater table from the CGWB, 53 precipitation, soil moisture, maximum temperature, and ESI were estimated for 54 55 2002-2013 as well as for the other periods based on the data availability. To represent meteorological drought, the standardized precipitation index (SPI)47 was 56 57 used after fitting the Gamma distribution to monthly precipitation data. Similarly, we estimated the standardized abstraction index (SAI) using the model 58 59 (PCR-GLOBWB) simulated abstraction data (in linear units) considering 60 cumulative abstraction for a given period. For instance, an *n*-month SPI or SAI represents a standardized anomaly for cumulative precipitation or abstraction for 61 the same period (that is, n months). Daily abstraction data were simulated from the 62 PCR-GLOBWB14 model for 1950-2013. The PCR-GLOBWB model simulates 63 water storage for each grid cell at 0.5° spatial and daily temporal resolutions using 64 two soil layers and an underlying groundwater layer. The model considers 65 groundwater recharge from precipitation and irrigation water, while abstraction is 66 estimated using requirements for irrigation and other sectors. 67

To evaluate the influence of climate variability and human intervention on 68 69 groundwater, we selected the regions with increasing and declining trends in 70 precipitation and significant groundwater-based irrigation. Areas were selected that are irrigated more than 40% with groundwater and have significant increasing 71 or declining trends in the monsoon season rainfall. Groundwater wells falling in 72 these areas were selected and their median trends were evaluated to understand if 73 the monsoon season precipitation is a major driver of groundwater variability in 74 India. To check consistency between groundwater anomalies from GRACE and 75 observation wells, we used aggregated standardized departure fields (standardized 76 anomaly) for wells located in northern (above 23°) and southern India (below 23°). 77

We used GRACE groundwater anomalies to estimate persistence (autocorrelation) for northern and southern India, which may influence estimated recharge rates during precipitation deficit years.

To evaluate the relative contribution of SPI and SAI on groundwater storage variability, linear regression was used. The relative contribution was estimated on the basis of the fraction of total variability (R^2) in groundwater storage (represented by well level anomalies) explained by SPI or SAI. The relative contribution of SPI or SAI on groundwater storage variability was estimated by using just one of these (SPI or SAI) as a predictor of groundwater storage anomaly. The relative contribution of SPI and SAI was estimated for 3-24-month accumulation periods for precipitation and abstraction (using 3-24-month SPI for the same month for which groundwater anomaly was used) on groundwater storage anomaly. Similarly, we estimated the relative contribution of SPI and SAI on model-simulated groundwater recharge for north-central, northwestern, and south India. Since SPI and SAI may be correlated, we used dominance analysis^{24,48,49} to estimate the relative importance of SPI and SAI on groundwater storage or recharge (where both are estimated using linear units rather than volumes). In dominance analysis the overall coefficient of determination (R^2) of a predictor variable is computed after evaluating all the possible (p-1) sub-models. The conditional dominance of a variable for each sub-model (0 to p-1) is evaluated and the predictor with highest average conditional dominance is identified as the largest contributor^{24,48,49}.

To evaluate the role of large-scale climate variability on groundwater, we used empirical orthogonal function (EOF) analysis¹⁰ using GRACE groundwater anomaly for 2002–2013. The leading mode obtained from the EOF analysis (EOF-1) and the corresponding principal component (PC-1) were obtained. Correlation between the detrended PC-1 of annual groundwater anomalies from GRACE and SST anomalies over the Indian Ocean was estimated. SST data were obtained from the National Climatic Data Center's Extended Reconstructed SST (ERSSTv3b)⁵⁰. We also estimated the correlation between precipitation in north and south India and the Nino 3.4 ENSO index.

Data availability The data used in the study are publicly available and can be directly obtained from the source websites. For instance, GRACE TWS data were obtained from JPL NASA (ftp://podaac-ftp.jpl.nasa.gov/allData/tellus/L3/ land_mass/RL05). GLDAS surface water storage data are available from GSFC NASA (http://disc.sci.gsfc.nasa.gov/services/grads-gds/gldas). Data of satellite (TRMM) and gridded precipitation were obtained from GSFC NASA (http://disc. gsfc.nasa.gov/uui/datasets/TRMM 3B43 7/summary) and India Meteorological Department (IMD, http://www.imd.gov.in/Welcome%20To%20IMD/Welcome. php), respectively. Soil moisture data used in this study can be obtained from European Space Agency's Climate Change Initiative (ESACCI, http://www.esasoilmoisture-cci.org). Satellite-based evapotranspiration from MODIS (MOD 16) can be obtained from the University of Montana (http://www.ntsg.umt.edu/project/ mod16). Groundwater well data from CGWB are available through Water Resources Information System of India (India-WARIS, http://www.india-wris.nrsc. gov.in/wris.html). Global Map of Irrigation Area (GMIA v5) can be obtained from Food and Agricultural Organization (FAO, http://www.fao.org/nr/water/aquastat/ irrigationmap), while state-level irrigated area information can be obtained from India Stat (http://www.indiastat.com/default.aspx).
