[1] A long-standing problem in the geological evolution of the India-Asia collision zone is how and where convergence between India and Asia was accommodated since collision. Proposed collision ages vary from 65 to 35 Ma, although most data sets are consistent with collision being underway by 50 Ma. Plate reconstructions show that since 50 Ma ~2400–3200 km (west to east) of India-Asia convergence occurred, much more than the 450–900 km of documented Himalayan shortening. Current models therefore suggest that most post-50 Ma convergence was accommodated north of the Indus-Yarlung suture zone. We review kinematic data and construct an updated restoration of Cenozoic Asian deformation to test this assumption. We show that geologic studies have documented 600–750 km of N-S Cenozoic shortening across, and north of, the Tibetan Plateau. The Pamir-Hindu Kush region accommodated ~1050 km of N-S convergence. Geological evidence from Tibet is inconsistent with models that propose 750–1250 km of eastward extrusion of Indochina. Approximately 250 km of Indochinese extrusion from 30 to 20 Ma of Indochina suggested by SE Asia reconstructions can be reconciled by dextral transpression in eastern Tibet. We use our reconstruction to calculate the required size of Greater India as a function of collision age. Even with a 35 Ma collision age, the size of Greater India is 2–3 times larger than Himalayan shortening. For a 50 Ma collision, the size of Greater India from west to east is ~1350–2600 km, consistent with robust paleomagnetic data from upper Cretaceous-Paleocene Tethyan Himalayan strata. These estimates for the size of Greater India far exceed documented shortening in the Himalaya. We conclude that most of Greater India was consumed by subduction or underthrusting, without leaving a geological record that has been recognized at the surface.

1. Introduction

[2] Collision between continental lithosphere of the Indian and Asian plates has led to the largest deformed continental region in the world in Cenozoic time. The India-Asia orogen includes the Himalaya, the Tibetan Plateau, the Pamir-Hindu Kush, the Tien Shan, Mongolia, and southern Siberia (Figure 1). Effects of the collision range from development of the India-derived Himalayan fold-and-thrust belt in the south [*Gansser*, 1964; *Hodges*, 2000], to strike-slip-dominated mountain belts thousands of kilometers to the north in Mongolia and southern Siberia [*Molnar and Tapponnier*, 1975; *Cunningham*, 2005; *Jolivet et al.*, 2010; *Arzhannikova et al.*, 2011]. The Indochinese peninsula, to the east of the Himalaya, has been deformed along major strike-slip zones that accommodated southeastward translation of lithosphere, away from the collision zone [*Tapponnier et al.*, 1986]. The amount of southeastward displacement of Indochina is heavily debated in the literature and will be discussed in detail.

[3] An accurate reconstruction of the kinematic history of the collision zone is essential to assess the dynamics of the India–Asia collision. Boundary conditions for this reconstruction are derived from plate circuits constrained by marine magnetic anomaly and fracture zone–based reconstructions of the Indian and Atlantic oceans; these constrain the relative positions of the Indian and Asian plates through time. The first India–Eurasia plate circuits [Molnar and

Tapponnier, 1975; Patriat and Achache, 1984] have changed by no more than a few hundreds of kilometers over the following decades, despite the publication of new time scales and more detailed marine geophysical data [Torsvik *et al.*, 2008; Molnar and Stock, 2009; Cande *et al.*, 2010; Copley *et al.*, 2010; van Hinsbergen *et al.*, 2011]. These plate circuit models predict ~2400 and ~3200 km of convergence between cratonic India and cratonic Asia

since 50 Ma at the longitudes of the western and eastern Himalayan syntaxes, respectively [van Hinsbergen *et al.*, 2011]. Although these plate circuit estimates are robust, where this convergence was accommodated (south or north of the India-Asia suture), and the type of deformation that accommodated this convergence (thrusting/subduction or strike-slip faulting (extrusion)) remain disputed.

[4] In principle, if all convergence following the initial India-Asia collision was accommodated by crustal shortening (together with delamination and subduction of subcontinental mantle lithosphere [Willett and Beaumont, 1994; Tapponnier *et al.*, 2001; Capitanio *et al.*, 2010]), then we merely need to sum shortening via thrust and strike-slip faulting in Indian and Asian crust. In practice, however, both the age of the India-Asia collision and the magnitude of shortening of Asian and Indian crust are disputed. The map-view area of Asia that was removed by shortening and lateral extrusion after Tethyan Himalaya-Asia collision is defined here as ‘Greater Asia’, whereas the map-view area of Indian-affinity lithosphere north of the Main Frontal Thrust just prior to the Tethyan Himalaya-Asia collision is referred to as ‘Greater India.’ Estimates for the age of the collision between the Tethyan Himalaya and southern Tibet range from ~65 Ma [Ding *et al.*, 2005; Cai *et al.*, 2011] to as young as 34 Ma [Aitchison *et al.*, 2007], with most authors preferring an age of 52–50 Ma [e.g., Zhu *et al.*, 2005; Green *et al.*, 2008; Dupont-Nivet *et al.*, 2010a; Najman *et al.*, 2010; Wang *et al.*, 2011].

[5] Regardless which of the proposed collision ages is preferred, the amount of shortening in Indian-affinity rocks in the Himalayan thrust belt (450–900 km [DeCelles *et al.*, 2002; Long *et al.*, 2011]) is much less than the amount of post-collisional plate convergence. Because of this reason, and because restorations of early Mesozoic Gondwana configurations suggest a size of Greater India smaller than ~1000 km [Ali and Aitchison, 2005], most tectonic models of the India-Asia collision zone partition as much as two-thirds of India-Asia convergence into Asian lithosphere [e.g., Lee and Lawver, 1995; Tapponnier *et al.*, 2001; Replumaz and Tapponnier, 2003; Royden *et al.*, 2008]. However, geological records of the post-50 Ma shortening distributed within Tibet yield much smaller estimates of only ~600 km [Dewey *et al.*, 1988; Yin and Harrison, 2000; Johnson, 2002; Guillot *et al.*, 2003]. Until recently, we have lacked structural studies from the remote interior regions of the Tibetan Plateau to accurately test these predictions. In the last decade, however, many new kinematic constraints from Tibet, the Tien Shan, the Pamir and Mongolia have been published. Here, we provide an updated restoration of shortening and extrusion in Asia for the Cenozoic. To test the various scenarios for intra-Asian deformation, we restore the deformation from Tajikistan to Vietnam and from Siberia to the Himalaya.

[6] Finally, we use the new reconstruction of intra-Asian shortening, which is independent from the age of collision, to evaluate the size of Greater India as a function of collision age. Our results show that even the youngest proposed collision age of 34 Ma yields a significant mismatch between shortening recorded in Himalaya and contemporaneous Indian-plate subduction. We conclude with a dis-

ussion of the implications of this mismatch for the composition of Greater Indian lithosphere.

2. Approach

[7] Classic plate reconstructions use rigid plates, and localize deformation at plate boundaries [Cox and Hart, 1986]. Alternatively, Tibetan lithosphere may be modeled as a thin-viscous sheet, in which lithosphere deforms homogeneously such that there are no horizontal strain gradients within a vertical column of lithosphere [England and Houseman, 1986; England and Molnar, 1997]. We use a combination of these approaches, subdividing the Himalaya-Tibetan orogen into rigid blocks, such as the Tarim basin, where no significant Cenozoic deformation is apparent, as well as deforming blocks, such as fold-thrust belts and extending basins. Because the latter typically exhibit deformation that is partitioned across many small-scale folds or faults, we chose to treat those areas as blocks that gradually deform between known boundaries, such as strike-slip faults or boundaries of extensional basins or fold-thrust belts.

[8] We use the freely available software package GPlates to make our reconstruction (<http://www.gplates.org>) [Boyd *et al.*, 2010]. The rotation and shape files of our reconstruction are given in the auxiliary material.¹ GPlates subdivides the surface into undeformable polygons (e.g., the Tarim basin, or the South China Block) and deformable topologies (e.g., the Tien Shan). For example, lines representing the boundaries of a deforming region move with respect to each other during the time span of deformation, changing the area in between according to geological constraints. GPlates interpolates plate or line motions with constant rates between known situations, leading to a continuously deforming plate reconstruction.

[9] The reconstruction presented here uses the India-Asia plate circuit of van Hinsbergen *et al.* [2011], which is based on the most recent plate kinematic constraints [e.g., Gaina *et al.*, 2002; Merkouriev and DeMets, 2006; Cande *et al.*, 2010]. We reconstruct Asian deformation with respect to stable Siberia. To allow comparison of our reconstructions to paleomagnetic data or mantle reference frames, Data Sets S1–S4 (rotation files) in the auxiliary material are available in a Siberia-fixed frame as shown in this paper, as well as in the paleomagnetic reference frame of Torsvik *et al.* [2008], the hybrid mantle reference frame of Torsvik *et al.* [2008] (which consists of the Indo-Atlantic hot spot frame of O’Neill *et al.* [2005] back to 100 Ma and a true polar wander-corrected paleomagnetic reference frame of Steinberger and Torsvik [2008] before 100 Ma), and finally in the slab-fitted mantle reference frame of van der Meer *et al.* [2010].

3. Review

[10] Reconstructions require a deformed pattern that is restored into an undeformed configuration. Here, crustal fragments, and their intervening sutures that built the Asian crust prior to the Cretaceous define this pattern. Available kinematic constraints from the India-Asia collision zone are summarized in Table 1 and Figures 2 and 3.

¹Auxiliary material data sets are available at <ftp://ftp.agu.org/apend/tc/2011tc002908>. Other auxiliary material files are in the HTML.

^aThe scenario number refers to the location of this estimate, as indicated in Figure 3; rl (ll) strike-slip, right- (left-) lateral strike-slip.

^bSee text for more details and references for this estimate.

^cPreferred scenario; see text for discussion.

^dA larger amount of shortening along the Great Counter thrust was used in our reconstruction to balance displacement along the Karakoram Fault; see text.

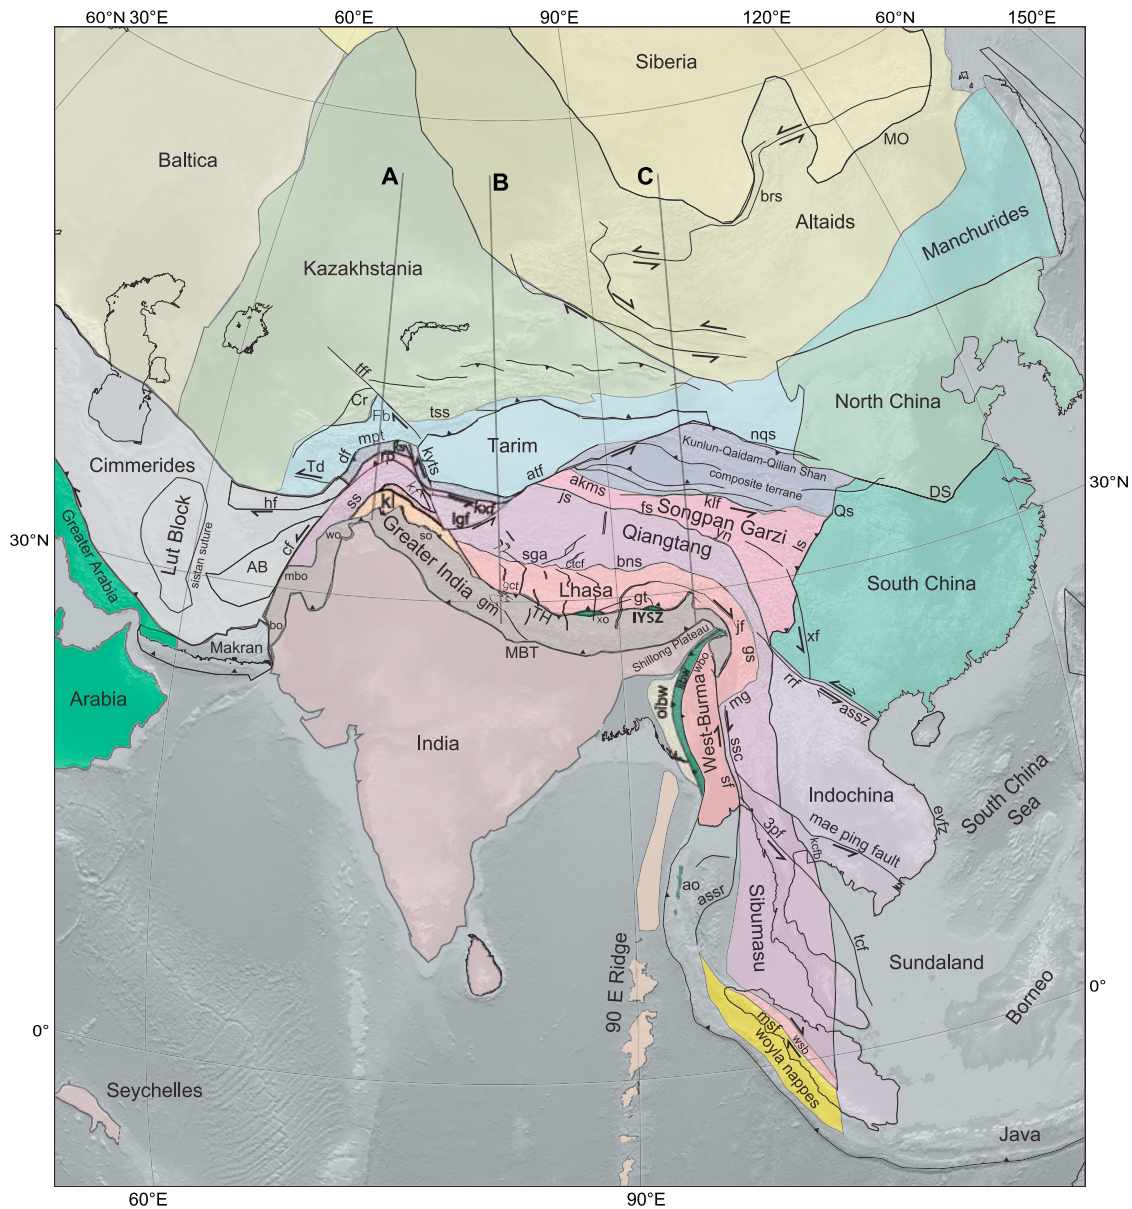

Figure 2. Simplified tectonic map of Asia, showing the main faults and boundaries of deforming regions discussed in this paper. Terranes and sutures of central and East Asia are modified after *Yin and Harrison [2000]*, *Cocks and Torsvik [2007]*, *Pubellier [2008]* and *Torsvik and Cocks [2009]* in a 3D Globe projection. Abbreviations are 3pf, Three Pagodas fault; AB, Afghan block; ao, Andaman ophiolite; akms, Ayimaqin–Kunlun–Muttag suture; assr, Andaman Sea spreading ridge; assz, Ailao Shan shear zone; atf, Altyn Tagh fault; bns, Bangong–Nujiang suture; bo, Bela ophiolite; brs, Baykal rift system; cf, Chaman fault; Cr, Chatkal range; ctcf, Central Tibetan Conjugate fault system; df, Darvaz fault; DS, Dabie Shan; evfz, East Vietnam fault zone; Fb, Ferghana basin; gm, Gurla Mandhata metamorphic complex; fs, Fenguo Shan fold-and-thrust belt; gct, Great Counter Thrust; gs, Gaoligong shear zone; gt, Gangdese thrust; hf, Helmand fault; iibw, inner Indo-Burman wedge; IYSZ, Indus-Yarlung Suture Zone; jf, Jiali fault; js, Jinsha suture; kcf, Khmer-Chanthaburi fault belt; kf, Karakoram fault; kl, Kohistan-Ladakh arc; klf, Kunlun fault; ks, Kongur Shan; kxf, Karakax fault; kyts, Kashgar-Yecheng transfer system; lgf, Longmu-Goza fault; ls, Longmen Shan; mbo, Muslim Bagh ophiolite; nqs, North Qilian suture; MBT, Main Boundary Thrust; mg, Mogok metamorphic belt; MO, Mongol-Okhotsk suture; mpt, Main Pamir thrust; msf, Mentawai and Sumatra faults; oibw, outer Indo-Burmese wedge; Qs, Qinling Shan; rp, Rushan Pshart; rrf, Red River fault; sf, Sagaing fault; sga, Shiquanhe-Gaize-Amdo thrust system; so, Spontang ophiolite; ss, Shyok suture; ssc, Shan Scarp; tcf, Tho Chu fault; Td, Tadjik Depression; tff, Talas-Ferghana fault; TH, Tethyan Himalaya; tss, Tien Shan suture; wo, west Burma ophiolite; wsb, West Sumatra block; xf, Xianshuihe fault; xo, Xigaze ophiolite; yn, Yushu-Nangqian fold-and-thrust belt.

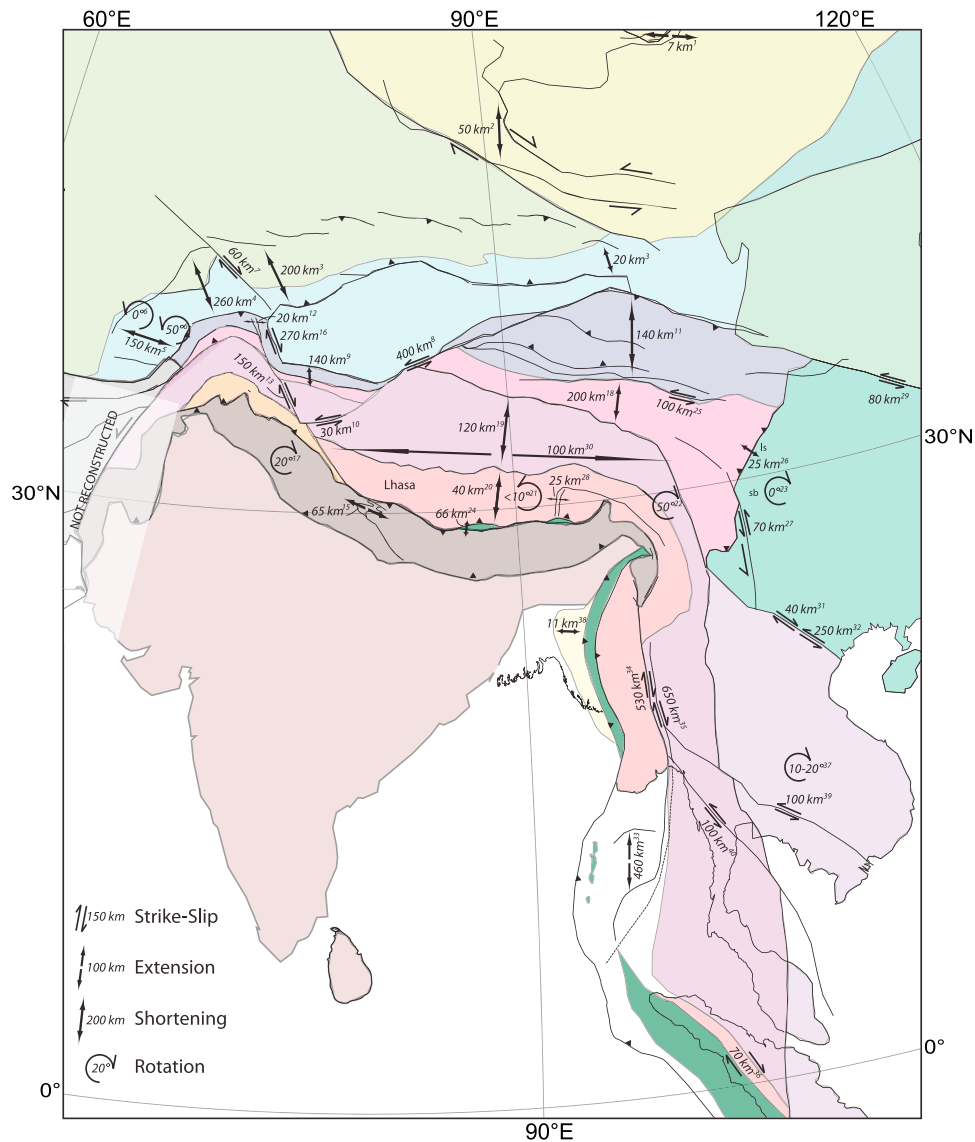

Figure 3. Summary of the kinematic constraints used as input in this reconstruction. Numbers in superscript refer to Table 1. See Figure 2 for explanation of basement blocks and structures.

3.1. Continental Fragments of Asia

[11] We study the region of Asia that underwent intense Cenozoic deformation. This area is surrounded by and (partly) includes the Kazakhstan block to the northwest, the Altaid collage and the Siberian craton to the north, the Manchuride collage and the North and South China blocks to the east, and cratonic India south of the Main Frontal Thrust to the south [Şengör *et al.*, 1993; Şengör and Natal'in, 1996; Cocks and Torsvik, 2007; Pubellier, 2008; Torsvik and Cocks, 2009] (Figure 2).

[12] The youngest collisions in central and east Asia are the Triassic collision between the North and South China blocks, forming the Dabie Shan and the Qinling ranges [Zhao and Coe, 1987; Ratschbacher *et al.*, 2003; Hacker *et al.*, 2006], the late Triassic collisions between Sibumasu and Indochina, and Indochina and South China [Metcalf, 1996; Zhou *et al.*, 2008; Ferrari *et al.*, 2008; Barber and Crow, 2009; Cai and Zhang, 2009; Roger *et al.*, 2010] and

the latest Jurassic closure of the Mongol-Okhotsk Ocean and collision of the Mongolian Altai (also called Amuria) with Siberia [Enkin *et al.*, 1992; Van der Voo *et al.*, 1999b; Cogné *et al.*, 2005; Metelkin *et al.*, 2010]. Early Cretaceous (~125 Ma) paleomagnetic poles from Mongolia coincide with Eurasian reference poles [Hankard *et al.*, 2007; van Hinsbergen *et al.*, 2008]. These collision zones have been tectonically reactivated due to Cretaceous far-field tectonic stresses or internal body forces [Graham *et al.*, 2001; Meng *et al.*, 2003; Ratschbacher *et al.*, 2003], but they can be considered as stable Eurasian continent, while major tectonic activity was dominated by collisions along the Eurasian margins. Below we review the crustal structure and available kinematic constraints for each area.

3.2. Mongolia

[13] Mongolia and southern Siberia contain strike-slip dominated regions including the Western Altai and the Gobi

Altai, and the E-W extensional Lake Baykal basin, which can be viewed as an extensional step-over in a left-lateral strike-slip system (Figure 2). Total strike-slip displacements here are within tens of kilometers. The Lake Baykal rift system, which may have a pre-Cenozoic history unrelated to the India-Asia collision [Jolivet *et al.*, 2009], accommodated ~7 km of extension since 11–7 Ma [San'kov *et al.*, 2000; ten Brink and Taylor, 2002]. The Western Altai accommodated ~20–30 km of right lateral displacement since the Oligocene [Howard *et al.*, 2003; Cunningham, 2005]. The Gobi Altai accommodated at least 15 km of sinistral strike-slip along the northern Bogd fault system since 5 ± 3 Ma [Vassallo *et al.*, 2007; Cunningham, 2010]. Because many of the mountain ranges have not been studied in detail (W. D. Cunningham, personal communication, 2010), we assume a total intra-Mongolian shortening of 50 km, twice as much as documented by Cunningham [2005], and assume a constant shortening rate since the onset of deformation around 23 Ma [Howard *et al.*, 2003]. Pre-Oligocene deformation of Mongolia and northwestern China dates back to the Mesozoic [Graham *et al.*, 2001; Davis *et al.*, 2002; Meng *et al.*, 2003; Yuan *et al.*, 2006; Darby and Ritts, 2007; Vassallo *et al.*, 2007; Jolivet *et al.*, 2007], and does not fall within the scope of our restoration.

3.3. Tien Shan

[14] The Tien Shan is developed on the upper Paleozoic to lower Mesozoic suture between the Tarim block and Kazakhstan [Allen *et al.*, 1993; Şengör *et al.*, 1993] (Figures 1 and 2). The Tarim basin has behaved as a stable sedimentary basin, with deformation localized along its margins [Graham *et al.*, 1993; Yang and Liu, 2002]. The Tien Shan is bounded in the north and south by Neogene to Recent thrust faults [Avouac *et al.*, 1993; Molnar, 1994; Yin *et al.*, 1998; Burbank *et al.*, 1999]. The range becomes narrower to the east, where it structurally connects to the Gobi Altai sinistral transpressional system [Cunningham *et al.*, 1996] and accommodated 20–40 km of Cenozoic shortening [Yin *et al.*, 1998]. Avouac *et al.* [1993] assumed that the Tien Shan is in isostatic equilibrium (but see Kosarev *et al.* [1993]) and estimated that Cenozoic N-S shortening increased from near-zero in the east to ~200 km in the west. This lateral variation in shortening predicts a vertical axis rotation of the Tarim block with respect to Kazakhstan of ~7° around a pole at the eastern end of the Tien Shan [Avouac *et al.*, 1993]. Low-temperature thermochronology demonstrates a phase of rock uplift around 65–60 Ma in the Tien Shan [Jolivet *et al.*, 2010]. This age predates most estimates for the India-Asia collision and kinematic data associated with this phase remain undocumented, so this deformation is not specifically included in our reconstruction. Sedimentological, stratigraphic and low-temperature thermochronological data indicate a significant increase of exhumation in the southern Tien Shan at ~23 Ma [Hendrix *et al.*, 1994; Yin *et al.*, 1998; Yang and Liu, 2002; Sobel *et al.*, 2006; Heermance *et al.*, 2007; Jolivet *et al.*, 2010]. Rock (and probably surface) uplift in the northern and eastern Tien Shan may have followed later, may have occurred in pulses, and the shortening rate may have increased through time [Bullen *et al.*, 2003; Charreau *et al.*, 2009; Sun and Zhang, 2009; Li *et al.*, 2011]. Rock uplift and shortening rates are not necessarily proportionally linked, however, and no kinematic data are available

to quantify shortening rate changes in the Tien Shan in the Miocene. For simplicity, we assume that shortening of the Tien Shan since 23 Ma has been continuous between the modern range-front thrusts.

[15] The gradual westward increase in Tien Shan elevation stops abruptly at the trans-crustal, dextral Talas-Ferghana strike-slip fault [Burtman, 1975; Trifonov *et al.*, 1992; Burtman *et al.*, 1996; Li and Chen, 2006; Korjenkov *et al.*, 2010], which continues northward to faults that have not been active in the Cenozoic [Allen *et al.*, 2001; Alexeiev *et al.*, 2009]. The Talas-Ferghana fault has a post-late Cretaceous, dextral displacement of 60 km [Burtman *et al.*, 1996]. West of the Talas-Ferghana fault, the Chatkal range in the north and the Alai range (or Southern Tien Shan) in the south are separated by the intervening Ferghana Basin, which is overthrust by both ranges (Figure 1) [Cobbold *et al.*, 1993; Burtman *et al.*, 1996]. The Alai valley separates the Alai Range in the north from the Trans-Alai Range and the Main Pamir Thrust further to the south. The Main Pamir Thrust forms the boundary with the Pamir fold-and-thrust belt [Skobolev, 1977; Leith and Alvarez, 1985; Bourgeois *et al.*, 1997; Burtman, 2000; Coutand *et al.*, 2002] (Figures 1 and 2). Neogene thin-skinned folding and thrusting deformed sediments in the Tadjik Depression west of the Pamir salient (Figure 2). We adopted the map-view restoration of the Tadjik depression of Bourgeois *et al.* [1997] in our reconstruction. This restoration used structural geological data in combination with paleomagnetic constraints that demonstrate counterclockwise rotations that increase from 0° in the western part of the Tadjik Depression to ~50° in the eastern part near the Darvaz fault at the boundary with the Pamir salient [Bazhenov *et al.*, 1994; Thomas *et al.*, 1994]. Bourgeois *et al.* [1997] showed that ~150 km of WNW-ESE shortening in the Tadjik depression can be reconciled with the vertical axis rotation pattern assuming 240 km of NNW-ward indentation of the Pamir salient. Approximately 60 km of this shortening was accommodated in the Peter the First range (Figure 1), a south-verging fold-and-thrust belt to the northwest of the Pamir [Hamburger *et al.*, 1992]. Thomas *et al.* [1993] used paleomagnetic results from Eocene to lower Miocene sediments to demonstrate a $20 \pm 11^\circ$ counterclockwise rotation of the Ferghana Basin, and inferred 110 ± 60 km of shortening in the Chatkal range. Sediments in the Alai Valley have been shortened by ~20 km in the Neogene [Coutand *et al.*, 2002]. We assume that the remaining 50 ± 60 km of shortening of the 240 km inferred by Bourgeois *et al.* [1997] is partitioned in the Alai Range.

3.4. Tibet and the Pamir-Hindu Kush

3.4.1. Terranes and Subdivisions

[16] Most intra-Asian Cenozoic deformation was accommodated south of the Tarim block in the Tibetan Plateau to the southeast, and the Pamir-Hindu Kush region to the west and southwest (Figure 1). The Tarim block is separated from the Tibetan Plateau by the sinistral Altyn Tagh strike-slip fault and the western Kunlun Shan fold-thrust belt [e.g., Molnar and Tapponnier, 1975] (Figure 2). The western Tarim basin is separated from terranes of the Pamir region by the Kashgar-Yecheng dextral strike-slip system [Cowgill, 2010]. The dextral Karakoram strike-slip fault separates Tibet and the Tarim basin in the east, from the Pamir-Hindu Kush region in the west [Molnar and Tapponnier, 1975].

[17] The Tibetan Plateau and Pamir-Hindu Kush regions exhibit a series of suture zones and intervening crustal fragments that collided in Paleozoic to Mesozoic time [Sengör, 1987; Dewey et al., 1988; Hsü et al., 1995; Yin and Harrison, 2000; Roger et al., 2010]. To the northeast of the Tibetan Plateau, the Qilian Shan–Nan Shan ranges, the Qaidam Basin and the eastern Kunlun Shan contain several Paleozoic sutures. We refer the reader to *Gehrels et al.* [2003] for details. Here, we only show the northernmost, North Qilian suture, and the southernmost, Ayimaqin–Kunlun–Mutztagh suture [Yin and Harrison, 2000] and treat this region as a composite Kunlun–Qaidam–Qilian Shan terrane. The latter suture forms the northern boundary of the Songpan–Ganzi terrane (Figure 2). The Songpan–Ganzi terrane is comprised largely of Triassic turbidites that were deposited in Paleo-Tethyan oceanic basins [Yin and Nie, 1993; Zhou and Graham, 1996; Roger et al., 2010], and is separated from the Qiangtang terrane by the upper Triassic–lower Jurassic Jinsha suture [Yin and Harrison, 2000; Pullen et al., 2008]. The Qiangtang terrane is juxtaposed with the Lhasa block to the south along the uppermost Jurassic–lower Cretaceous Bangong–Nujiang suture [Dewey et al., 1988; Yin and Harrison, 2000; J. L. D. Kapp et al., 2005; L.-L. Wang et al., 2008; Zhang, 2010]. The Eocene Indus–Yarlung suture zone (IYSZ) in the south separates the Lhasa terrane from the Himalaya.

[18] The Pamir–Hindu Kush region west of the Tibetan Plateau has been subdivided into continental fragments equivalent to the Tibetan terranes, in addition to the Kohistan intraoceanic-arc and Kohistan–Ladakh batholith [Schwab et al., 2004; Cowgill, 2010]. The Kohistan arc is bounded in the north by the ~70 Ma old Shyok suture [Burtman and Molnar, 1993; Searle et al., 1997; Schwab et al., 2004]. In our reconstruction, we follow *Searle and Treloar* [2010] and restore late Cretaceous ophiolite emplacement over Greater India (and Arabia [Gnos et al., 1997]), followed by collision of Greater India with the Kohistan arc in the Eocene.

[19] We do not reconstruct the western margin of the collision zone in Afghanistan and Pakistan because there is a general absence of kinematic data. We note, however, that there is evidence for Cenozoic extrusion of the Afghan Block westward along the conjugate Helmand and Chaman strike-slip faults [Tapponnier et al., 1981], and E–W closure of the Sistan ocean between the Afghan Block and the Lut Block in eastern Iran, which perhaps continued until Oligocene–Miocene times [Rezaei-Kahkhaei et al., 2010] (Figure 2). Given the kinematics of the known major faults and the E–W compression in eastern Iran, restoring this region would probably indicate some westward lateral escape of the Afghan Block. The amount of westward motion, the timing, and the relationship between the Afghan Block and the blocks in Iran, however, remain subject for future work.

3.4.2. The Altyn Tagh Fault and Its Terminations

[20] The 1600 km long, lithosphere-scale [Wittlinger et al., 1998] sinistral Altyn Tagh fault (ATF) bounds the Tibetan Plateau in the north [Molnar and Tapponnier, 1975] (Figure 2). Displacement along the ATF is transferred into transpressional fold-and-thrust belts of the Western Kunlun Shan–Tianshuihe region in the west, and the Eastern Kunlun Shan–Qaidam–Qilian Shan–Nan Shan region in the east [Cowgill et al., 2003]. The central segment of the ATF is

predominantly strike-slip [Cowgill et al., 2003; Dupont–Nivet et al., 2004b]. Piercing point studies suggest displacements along the ATF ranging from 300 to 500 km [Ritts and Biffi, 2000; Cowgill et al., 2003; Gehrels et al., 2003; Yue et al., 2004, 2005; Ding et al., 2004].

[21] To the west, the ATF connects to the transpressional system of the western Kunlun Shan. The western Kunlun Shan overthrusts the Tarim basin to the north, is bounded in the west by the Kashgar–Yecheng transfer system, and is bounded in the south by the sinistral Karakax strike-slip fault. The Karakax fault coincides spatially with the Ayimaqin–Kunlun–Mutztagh suture [Matte et al., 1996; Mattern et al., 1996; Yang and Liu, 2002; Cowgill, 2010]. A balanced cross-section in the central-eastern part of the Western Kunlun Shan shows ~100 km of Cenozoic upper crustal shortening [Cowgill, 2001], consistent with >80 km of shortening estimated from isostatic equilibrium calculations [Lyon–Caen and Molnar, 1984]. South of the Karakax fault, the Tianshuihai range underwent post-late Cretaceous shortening along south-dipping thrusts [Yin and Harrison, 2000; Cowgill et al., 2003; Cao et al., 2009]. Cowgill et al. [2003] proposed that shortening in the Western Kunlun Shan decreases eastward, whereas in the Tianshuihai range, shortening increased eastward. Four hundred km of displacement along the N70°E striking ATF corresponds to ~150 km of N–S shortening, and ~350 km of eastward motion. The ~150 km of N–S shortening may have been partitioned in the Western Kunlun Shan and Tianshuihai range, but it should be considered a maximum because it assumes rigid block translation of Tibet along the ATF. The amount of ATF displacement may increase eastward, accommodated by late Miocene and younger E–W extension and strike-slip faulting within Tibet (see section 4.3). The Karakax Fault does not crosscut and displace the Karakoram fault. Its displacement must hence be accommodated east of the Karakoram fault by E–W compression to its north, or E–W extension to its south, and its displacement after the initiation of the Karakoram fault was probably within tens of kilometers. Prior to Karakoram fault activity, the Karakax fault may have continued along the Ayimaqin–Kunlun–Mutztagh suture in the northern Pamir, although this remains untested by field studies. Splaying off of the southwestern termination of the ATF is the NE–SW striking Longmu–Goza sinistral strike-slip system south of the Tianshuihai range. Post-10 Ma displacement of 25–32 km along the Longmu–Goza fault led to the formation of a restraining bend along the Karakoram Fault [Rateman et al., 2007].

[22] To the northeast, ATF displacement is accommodated in the Eastern Kunlun Shan–Qaidam–Qilian Shan–Nan Shan region. The Eastern Kunlun Shan transpressional system is separated from the Qilian Shan–Nan Shan fold-and-thrust belt to the north by the Qaidam Basin (Figures 1 and 2). These thrust systems absorbed at least some of the motion along the ATF in the northeast. Shortening estimates in this region vary. Yin et al. [2008a] suggested that shortening along the northern margin of the Qaidam Basin varies along-strike between 20 and 60%, and Yin et al. [2007] suggested that Cenozoic upper crustal shortening within the Qaidam basin decreases eastward from >48%, (~150 km), to <1%. Zhou et al. [2006], on the other hand, suggested only ~10% shortening for the Qaidam Basin. The Qilian Shan–Nan Shan belt is a thick-skinned fold-and-thrust belt

with an estimated 150 km of NE-SW shortening since the Miocene [Tapponnier *et al.*, 1990; Meyer *et al.*, 1998]. The main trend of the fold-and-thrust belts in this region is $\sim 70^\circ\text{W}$, along which a total of ~ 260 km of shortening would accommodate all ATF displacement. Several authors have suggested that as much as 320 km of displacement of the ATF penetrated farther into the North China block prior to middle Miocene time [Yue and Liou, 1999; Yue *et al.*, 2004; Darby *et al.*, 2005]. Because the exact location and distribution of shortening in the eastern Kunlun–Qaidam–Qilian Shan–Nan Shan region remains enigmatic, we assume for simplicity that all motion along the ATF was accommodated south of the northern Qilian Shan front, and apply bulk shortening, evenly distributed over the area from the Eastern Kunlun Shan to the Qilian Shan.

[23] Yue *et al.* [2001, 2005] suggested that 360 ± 40 km of ATF displacement occurred after 23 Ma. Cenozoic denudation of the Western [Sobel and Dumitru, 1997] and Eastern Kunlun Shan [Mock *et al.*, 1999; Jolivet *et al.*, 2001; Yin *et al.*, 2008b; Clark *et al.*, 2010] began since ~ 30 Ma, coinciding with increased subsidence in the Tarim Basin [Graham *et al.*, 1993; Yang and Liu, 2002] and the age of gouge developed along major thrusts within the range [Duvall *et al.*, 2011]. Correlating uplift and erosion in NE Tibet to activity of the ATF, Jolivet *et al.* [2001] associated rock uplift and erosion in NE Tibet to slip along the ATF to argue ATF activity may have begun as early as 40 ± 10 Ma, and Yin *et al.* [2008b] argued that ATF-related deformation around the Qaidam basin may even have started 65 Ma ago. However, early Cenozoic deformation in the eastern part of NE Tibet was associated with clockwise rotations and Dupont-Nivet *et al.* [2002] argued that Eocene vertical axis rotations in this region were caused by right-lateral transpression between Qaidam and the South China block. We assume that 400 km of displacement along the ATF, and the accommodating transpression in the northeastern and southwestern terminations, occurred at a constant rate since 30 Ma.

3.4.3. Karakoram Fault and Kashgar-Yecheng Transfer System

[24] The Karakoram fault and the Kashgar-Yecheng transfer system (KYTS) to the west of the Tarim basin are separated by the Kunlun terrane, which there trends NNW-SSE in the eastern Pamir [Cowgill, 2010]. The Karakoram fault and KYTS form a transform system that accommodates northwestward motion of the Pamir-Hindu Kush region with respect to both Tibet and the Tarim basin. The KYTS transferred convergence along the North Pamir Thrust to shortening in the Western Kunlun Shan [Cowgill, 2010]. The Karakoram fault has transferred shortening in the Rushan-Pshart fold-and-thrust belt to shortening in the Himalaya and along the IYSZ [e.g., Strecker *et al.*, 1995; Murphy *et al.*, 2000; Robinson, 2009]. Between the Rushan-Pshart fold-and-thrust belt and the Main Pamir Thrust the N-S trending Kongur Shan extensional detachment system has accommodated up to 34 km of E-W extension since ~ 7 –8 Ma, and the Karakoram Fault does not connect with the Main Pamir Thrust [Robinson *et al.*, 2004, 2007].

[25] The KYTS was noted by Burtman and Molnar [1993] and Sobel and Dumitru [1997] and described in detail by Cowgill [2010] as a ~ 50 km wide transpressional zone of anastomosing strike-slip faults with a total dextral displacement of ~ 270 –280 km. Age constraints for the onset of

activity of the Kashgar-Yecheng system are inferred to coincide with the 37–23 Ma onset of shortening in the Western Kunlun Shan [Sobel and Dumitru, 1997; Cowgill *et al.*, 2003]. We assume a 30 Ma onset age for the KYTS. Assuming a 37 or 23 Ma onset of deformation would decrease or increase the rate of shortening in the northern Pamir by 1–2 cm/yr, respectively.

[26] The age of, and displacement along the Karakoram Fault are strongly debated. One school of thought argues for a maximum displacement of the fault of 150 km [Searle, 1996; Phillips *et al.*, 2004; Schwab *et al.*, 2004; Searle and Phillips, 2007; Robinson, 2009], with slip initiating as recently as 14–12 Ma [Bhutani *et al.*, 2009; Streule *et al.*, 2009; Wang *et al.*, 2009]. Murphy *et al.* [2000] concluded that the Karakoram Fault propagated southward around 10 Ma, crosscutting the IYSZ and linking with the Gurla-Mandhata metamorphic complex (Figure 2). About 65 km of displacement accumulated after this linkage. In this scenario, the Karakoram fault has transferred shortening in the Rushan-Pshart to the Main Boundary Thrust of the southern Himalaya since the late Miocene [Murphy and Copeland, 2005].

[27] A second school of thought argues that slip on the Karakoram Fault initiated at or before 25 Ma, with much higher total displacements, mainly based on alternative correlations of terranes and sutures from Tibet to the Pamir-Hindu Kush (see overview by Cowgill [2010]). Slip estimates provided by this school have systematically decreased from initially as high as 1000 km [Peltzer and Tapponnier, 1988], to 600 km [Lacassin *et al.*, 2004], >280 to 400 km [Valli *et al.*, 2007, 2008], ~ 300 km [Rolland *et al.*, 2009], and most recently to ~ 200 km [Leloup *et al.*, 2011]. Besides the timing of fault initiation, another difference is the interpretation that the Karakoram fault does not link with the Gurla-Mandhata core complex [Lacassin *et al.*, 2004]. Instead, it was suggested to transfer slip to dextral strike-slip faults along the Bangong-Nujiang suture zone (i.e., Karakoram-Jiali fault zone [Armijo *et al.*, 1989]) and IYSZ [e.g., Replumaz and Tapponnier, 2003]. We discuss the geometric and kinematic consequences of both views later.

3.4.4. Pamir-Hindu Kush

[28] The Pamir-Hindu Kush region, from the Pakistan Himalaya in the south to the Main Pamir Thrust in the north, is a northward convex orogenic belt. A Benioff zone is imaged beneath the Main Pamir Thrust to ~ 250 km depth [Hamburger *et al.*, 1992; Burtman and Molnar, 1993; Pavlis and Das, 2000], consistent with seismic tomographic images showing >300 km of nearly vertical subducted lithosphere [Nikolaev *et al.*, 1985; Van der Voo *et al.*, 1999a; Negrodo *et al.*, 2007; Zhao *et al.*, 2010]. Cowgill [2010] interpreted the northern part of the Pamir salient as a half-orocline, with only the western part of the region having undergone counterclockwise vertical-axis rotations and thrusting [Thomas *et al.*, 1994]; the eastern part was bounded by the KYTS.

[29] Paleomagnetic data from the western Himalayas and the Hindu Kush support northward convex oroclinal bending, with locally varying counterclockwise rotations of up to 100° in the western limb, and up to 20° clockwise rotation in the eastern limb since the Eocene [Klootwijk *et al.*, 1985, 1986, 1994; Zaman and Torii, 1999; Schill *et al.*, 2001]. We reconstruct a northward decrease of clockwise rotation of

the eastern limb of the Pamir-Hindu Kush orocline, with full accommodation by rotation in the south, and full accommodation by strike-slip motion in the north.

[30] Shortening estimates in the Pamir-Hindu Kush region between the Main Pamir Thrust and the IYSZ are scarce. *Burtman and Molnar* [1993] provided a crude estimate of 300 km of Cenozoic shortening. Contractual deformation, metamorphism, and magmatism started in the Central and Southern Pamir zones in late Cretaceous-Paleocene time [*Searle et al.*, 2010]. We reconstruct the Pamir-Hindu Kush based on kinematic constraints from the bounding faults, the Tadjik Depression, paleomagnetic constraints, and the notion that the total amount of Cenozoic shortening in the Pamir must exceed the shortening in Tibet to form the northward convex orocline.

3.4.5. N-S Shortening in Tibet

[31] The Lhasa, Qiangtang and Songpan-Ganzi terranes of the Tibetan Plateau were significantly shortened through folding and thrusting during the Cretaceous and Paleogene. The bulk of shortening of the Qiangtang and Lhasa terranes predates ~50 Ma: the Qiangtang terrane underwent ~50% shortening (~300 km) between 140 and 100 Ma during the Lhasa-Qiangtang collision [*P. Kapp et al.*, 2005, 2007a; *DeCelles et al.*, 2007]. Subsequently, the Lhasa terrane underwent ~50% (~250 km) shortening between 100 and 50 Ma [*Murphy et al.*, 1997; *Ding and Lai*, 2003; *Kapp et al.*, 2003, 2007a, 2007b; *Guynn et al.*, 2006; *Volkmer et al.*, 2007]. These largely Cretaceous thrust systems straddle the Bangong-Nujiang suture, and have not been displaced more than ~15 km by younger strike-slip faults along the Central Tibet Conjugate Fault Zone (CTCFZ, Figure 2) [*Taylor et al.*, 2003; *P. Kapp et al.*, 2005; *Ratschbacher et al.*, 2011]. The Bangong-Nujiang suture plays a fundamental role in the model of major extrusion of Indochina away from central Tibet [*Replumaz and Tapponnier*, 2003; *Royden et al.*, 2008]. The extrusion model follows the suggestion of, e.g., *Armijo et al.* [1989] that >700 km of sinistral displacement accumulated between the Qiangtang and Lhasa terranes during the Oligocene and early Miocene. Field evidence from the Bangong-Nujiang suture in western and central Tibet, however, shows a laterally continuous E-W belt of Cretaceous thrust faults and associated basins that underwent only minimal reactivation by thrusting at 30–20 Ma [*P. Kapp et al.*, 2003, 2005]. Thus, field observations from the plateau interior preclude the major strike-slip faulting that is postulated in the extrusion scenario.

[32] Percentages of Paleogene shortening in Tibet decrease from north to south, and we subdivide the Tibetan Plateau into three belts accordingly. The northern belt includes the Paleogene Fenghuo Shan–Nanqian fold-thrust belt, which is bounded in the north by the Anyimaquen–Kunlun suture and includes the Jinsha suture zone [*Coward et al.*, 1988]. The Fenghuo Shan fold-and-thrust belt underwent at least 80 km of Paleogene shortening (43%) [*Coward et al.*, 1988; *Zhang and Zheng*, 1994] and is unconformably overlain by only gently folded Miocene sediments [*Leeder et al.*, 1988; *Smith and Xu*, 1988; *Liu et al.*, 2001; *C. Wang et al.*, 2008; *Wu et al.*, 2008]. Apatite fission track analyses show rapid 30–22 Ma cooling in the Fenghuo Shan [*C. Wang et al.*, 2008] and the Fenghuo Shan is intruded by 31 ± 1 Ma undeformed syenite [*Harris et al.*, 1988]. *Spurlin et al.* [2005] documented >110 km (>43%) of shortening in

the Yushu-Nangqian region along strike to the east of the Fenghuo Shan, mainly between ~50 Ma and 37 Ma [*Horton et al.*, 2002]. The Tanggula Shan underwent major N-S shortening recorded by folded lower Paleogene sediments that are unconformably overlain by only weakly deformed Oligocene sediments and lavas [*Wang et al.*, 2002; *C. Wang et al.*, 2008; *Lippert et al.*, 2011]. We assume that the consistent intense Paleogene shortening documented from the Yushu-Nangqian and Fenghuo Shan regions is representative for the entire Songpan-Ganzi belt, and apply ~50%, or ~200 km N-S shortening between 50 and 30 Ma.

[33] Estimates of Cenozoic shortening by thrusting in the southern Qiangtang terrane (between 50 and 30 Ma) and along the Bangong-Nujiang suture zone (between 30 and 20 Ma) are ~25% (~120 km) in total [*P. Kapp et al.*, 2003, 2005, 2007a; *Lippert et al.*, 2011]. Shortening of the Lhasa terrane after deposition of the widespread 69–47 Ma Linzizong volcanics [*He et al.*, 2007; *Lee et al.*, 2009] was minimal, was localized along relatively small thrusts and did not exceed ~15% (~40 km) between 50 Ma and 20 Ma [*He et al.*, 2007; *Kapp et al.*, 2007b].

[34] Contractual deformation shortened the Indus-Yarlung suture zone in Cenozoic time. The top-to-the-south Gangdese thrust [*Harrison et al.*, 1992; *Yin et al.*, 1994, 1999a] placed Gangdese arc and forearc rocks over suture-zone and Tethyan Himalayan rocks to the south between 30 and 24 Ma and accommodated a minimum of ~40–50 km shortening [*Yin et al.*, 1994, 1999a; *Murphy and Yin*, 2003]. In middle Miocene time, the IYSZ was further shortened along the top-to-the-north Great Counter thrust system, backthrusting suture zone and Tethyan Himalayan rocks over the Gangdese arc and forearc by at least 16 km [*Yin et al.*, 1999a; *Murphy et al.*, 2009].

[35] Some paleomagnetic data from the Lhasa and Qiangtang terrane are available [*Chen et al.*, 1993; *Cogné et al.*, 1999; *Liu et al.*, 2003; *Dupont-Nivet et al.*, 2010a; *Liebke et al.*, 2010; *Lippert*, 2010; *Lippert et al.*, 2011]. Given the spatial resolution of the currently available data, and the variable clockwise and counterclockwise rotations reported, the most conservative interpretation is that rotations are controlled by local structures, without a wholesale rotation of the Tibetan Plateau [*Lippert*, 2010]. Consistently clockwise rotations were reported from the Qiangtang terrane in eastern Tibet [*Dupont-Nivet et al.*, 2002, 2004a]. The magnitudes of post-Cretaceous clockwise rotation increase eastward to ~50° in eastern Tibet [*Otofujii et al.*, 1990; *Huang et al.*, 1992; *Huang and Opdyke*, 1993; *Sato et al.*, 1999; *Yoshioka et al.*, 2003], and 90° clockwise in the Three Rivers region [*Sato et al.*, 2001] (Figure 1). The Sichuan basin underwent no rotation [*Huang and Opdyke*, 1992]. The amount of rotation in eastern Tibet is roughly proportional to a change in the trend of the Qiangtang terrane from E-W to NNW-SSE. This has been interpreted as a result of Cretaceous to Cenozoic dextral shearing of the Qiangtang terrane along the western boundary of the South China Block as a result of shortening of the Tibetan Plateau [*England and Molnar*, 1990; *Dupont-Nivet et al.*, 2002, 2004a].

3.4.6. E-W Extension in Tibet and E-W Shortening in the Longmen Shan

[36] The central and southern Tibetan Plateau, and in places the Himalaya, began extending E-W via the forma-

tion of N-S trending (half-)grabens in the middle to late Miocene [Armijo *et al.*, 1986; Burchfiel *et al.*, 1991; Coleman and Hodges, 1995; Yin *et al.*, 1999b; Murphy *et al.*, 2002; Garzzone *et al.*, 2003; Taylor *et al.*, 2003; Jessup and Cottle, 2010; Leloup *et al.*, 2010; Saylor *et al.*, 2010]. Estimates for the onset of E-W extension, based on stratigraphic analyses of associated basins and low-temperature thermochronology of uplifted footwall rocks, cluster around ~14–8 Ma [Burchfiel *et al.*, 1991; Coleman and Hodges, 1995; Harrison *et al.*, 1995; Blisniuk *et al.*, 2001; Garzzone *et al.*, 2003; J. L. D. Kapp *et al.*, 2005]. The distributed nature of the N-S trending grabens leads to an eastward increasing rate of eastward motion of the Tibetan Plateau with respect to the Tarim block. This eastward increase is clearly observed in GPS measurements [Shen *et al.*, 2001; He and Chery, 2008]. Much of the cumulative slip is accommodated in the north along the sinistral Kunlun fault, with a displacement of 100 ± 20 km in its central segment since 10 ± 2 Ma [Van der Woerd *et al.*, 2000, 2002; Fu *et al.*, 2005; Fu and Awata, 2007; Kirby *et al.*, 2007]. Toward the east, slip along the Kunlun fault gradually decreases with sinistral slip probably being transferred northward into the eastern Kunlun Shan [Kirby *et al.*, 2007; Duvall and Clark, 2010].

[37] The east directed Longmen Shan thrust system bounding the western margin of the Sichuan basin in eastern Tibet was predominantly active during the Mesozoic [Wang *et al.*, 1989; Mattauer, 1992; Chen and Wilson, 1996; Li *et al.*, 2003; Wilson *et al.*, 2006; Zheng *et al.*, 2006; Roger *et al.*, 2008, 2010; Robert *et al.*, 2010]. It was reactivated during the late Miocene (11–8 Ma) recorded by $^{40}\text{Ar}/^{39}\text{Ar}$ and (U-Th)/He cooling ages in its hanging wall [Kirby *et al.*, 2002; Godard *et al.*, 2009], and renewed subsidence in the Sichuan Basin [Wang *et al.*, 1989; Zheng *et al.*, 2006]. The fault system remains active today [Burchfiel *et al.*, 2008]. Approximately ~20–25 km of E-W Neogene shortening has been documented in the Longmen Shan thrust system [Wallis *et al.*, 2003; Burchfiel *et al.*, 2008; Hubbard and Shaw, 2009]. The South China block moved ~80 km SE-ward with respect to Siberia [Replumaz and Tapponnier, 2003]. E-W compression in the Longmen Shan demonstrates that eastern Tibetan crust moved eastward at a higher rate than South China. The Sichuan basin behaved as a rigid indenter in late Neogene time [Clark and Royden, 2000], with Tibetan crust moving around the northern edge of the Sichuan Basin along dextral strike-slip faults in the Qinling Shan since 9–4 Ma [Enkelmann *et al.*, 2006]. SE-directed motion of fragments of Tibet and the South China Block occurred between the sinistral Xianshuihe fault, and the dextral Jiali fault southwest of the Sichuan basin (Figure 2). 60–80 km of post-8–10 Ma displacement has been documented for the Xianshuihe fault [Allen *et al.*, 1991; Wang and Burchfiel, 2000], and some additional displacement between 13 and 10 Ma may have occurred [Roger *et al.*, 1995]. The Xianshuihe fault terminates in the south against the Red River Fault [Schoenbohm *et al.*, 2006b]. The amount of displacement along the Jiali fault is unknown.

[38] We estimate ~100 km of post 14–12 Ma extension from Tibet. This value is determined from the ~20 km E-W shortening in the Longmen Shan combined with the ~80 km SE ward motion of the south China block with respect to North China (Table 1, Figure 3).

3.5. Mainland SE Asia

3.5.1. SE Asian Terranes and Their Connection to Tibet

[39] The Qiangtang and Lhasa terranes correlate with pre-Cenozoic continental terranes in SE Asia (i.e., ‘Sundaland’) through the narrow region between the Eastern Himalayan syntaxis and South China—known as the Three Rivers region (Figures 1 and 2). The simplest and most common subdivision of Sundaland distinguishes among the Indochina, Sibumasu and West Burma/west Sumatra blocks, and the Andaman forearc and Burmese ophiolites (Figure 2).

[40] Given the apparent structural continuity of the Qiangtang and Sibumasu blocks [Pubellier, 2008] and the similar ages of the Jinsha and Sibumasu-Indochina sutures, it seems likely that Sibumasu and Qiangtang are part of the same microcontinent, that collided with Indochina/South China and the Songpan-Ganzi terrane, respectively, in the late Triassic [Mattauer, 1992; Kapp *et al.*, 2000; Ferrari *et al.*, 2008; Cai and Zhang, 2009].

[41] Sibumasu is presently bounded in the west by the West Burma Block, along the Miocene, dextral Sagaing fault [Curry *et al.*, 1979] (Figure 2). In Myanmar, the western margin of the Sibumasu terrane was intruded by a Jurassic to lower Cretaceous arc (~170–120 Ma) [Barley *et al.*, 2003; Searle *et al.*, 2007], with younger (120–50 Ma) granitoids found to the west of the Sagaing Fault [Barley *et al.*, 2003]. To the northwest of the Sagaing fault, serpentinite exposures contain zircon populations in jadeite that span an age range of 165–120 Ma [Shi *et al.*, 2009]. These rocks are interpreted to have formed in an oceanic subduction channel that extended beneath the Jurassic-early Cretaceous arc in Sibumasu. The age range of this subduction-collision history is time-equivalent to that of the Bangong-Nujiang suture and therefore the West Burma Block may be correlative with the Lhasa block [Searle *et al.*, 2007; Zhou *et al.*, 2008].

3.5.2. Mainland Sundaland and the Red River, Three Pagodas and Mae Ping Faults

[42] Sundaland is bounded in the north by the >1000 km long Red River Fault (RRF) [e.g., Peltzer and Tapponnier, 1988]. In the last ~8 Myr, the RRF accumulated 40 km of dextral displacement [Replumaz *et al.*, 2001; Schoenbohm *et al.*, 2006a]. Earlier in the Cenozoic motion along the RRF was sinistral. This sinistral motion forms the basis for models of major SE-ward extrusion of Sundaland from between the Himalayas and the Qiangtang block [Peltzer and Tapponnier, 1988; Armijo *et al.*, 1989; Leloup *et al.*, 1995, 2001; Replumaz and Tapponnier, 2003; Royden *et al.*, 2008]. Major controversy exists regarding the amount of sinistral displacement along the RRF. An initial estimate of 330 ± 60 km [Lacassin *et al.*, 1993] was revised to 700 ± 200 km by the same group [Leloup *et al.*, 1995]. Chung *et al.* [1997] proposed 600 km of displacement. Searle [2006], however, argued that the basins, sutures and volcanic belts used as piercing points cannot be demonstrated to be lateral equivalents and that the amount of displacement remains elusive. Fyhn *et al.* [2009] analyzed the offshore eastern continuation of the RRF in the East Vietnam fault zone (Figure 2); they concluded that sinistral displacement of the RRF is only ~250 km. Hall *et al.* [2008] made a detailed plate restoration of SE Asia and concluded a similarly modest amount of

displacement along the RRF. In the discussion section we address the implications of both estimates (250 versus 750 km or more).

[43] The age of slip along the RRF is also controversial. Its displacement was originally suggested to be kinematically linked to the opening of the South China Sea between 32 and 16 Ma [Briais *et al.*, 1993], corresponding to ~30 and 17 Ma using the timescale of *Cande and Kent* [1995]. Recently, *Searle* [2010] suggested a maximum age range of 32–22 Ma, based on deformed and crosscutting granites in the Red River shear zone. *Wang et al.* [2000] presented cooling ages from rocks in the Ailao Shan to suggest a shorter, 27–22 Ma slip history. *Fyhn et al.* [2009] challenged the connection of the RRF to the South China Sea spreading center based on analyses of seismic lines offshore western Vietnam. They concluded that the RRF is directly connected to the East Vietnam Fault Zone, and that the bulk of the displacement predated the middle Oligocene, with perhaps several tens of kilometers after that. In the reconstruction by *Hall et al.* [2008], a large part of the South China Sea opened in response to southward subduction of a proto-South China Sea. This interpretation is based on a clear record of subduction from Borneo until the early Miocene. For a detailed reconstruction of southern Sundaland, we refer to *Hall* [2002] and *Hall et al.* [2008]: We assume that all sinistral displacement along the RRF occurred between 30 and 20 Ma.

[44] Southern mainland Sundaland is crosscut by the Mae Ping fault (a.k.a. the Wang Chao fault) and the Three Pagodas fault. The latter may be kinematically linked with the Tho Chu fault zone in the Bay of Thailand [Fyhn *et al.*, 2010a]. *Tapponnier et al.* [1986] estimated 160 km of displacement for both the Three Pagodas and Mae Ping faults, of which *Smith et al.* [2007] suggested 10–30 km occurred in the Oligocene, and the rest in the Eocene. *Lacassin et al.* [1993] suggested that Mae Ping displacement was at least 35–45 km. The analyses of *Fyhn et al.* [2010a, 2010b] of the basins offshore southern Thailand and Vietnam support sinistral shear, and suggest a displacement of ~50–100 km for the Mae Ping fault and up to 100 km of displacement along the Three Pagodas. *Tjia and Liew* [1996] suggested a 70 km dextral inversion of the Three Pagodas fault, but *Fyhn et al.* [2010a] concluded that this phase was of minor importance. Offshore stratigraphic and seismic data restrict sinistral motion along the Three Pagodas and Mae Ping fault zones to the late Eocene and Oligocene [Morley, 2007; Fyhn *et al.*, 2010a, 2010b]. We reconstruct 100 km of displacement along the Mae Ping and Three Pagodas faults between ~40 and 23 Ma (Table 1 and Figure 3).

3.5.3. West Burma Block, Sagaing Fault and Shan Scarp

[45] To the west, Sundaland is separated from the West Burma Block by a dextral strike-slip zone, which includes the Oligocene to early Miocene Shan Scarp shear zone and the late Miocene to Recent Sagaing Fault. The Sagaing Fault connects to the north with the Main Boundary Thrust of the Himalaya [G. Wang *et al.*, 2008; Maurin and Rangin, 2009; Yin *et al.*, 2010]. To the south, it connects with the ~N-S extensional spreading center of the Andaman Sea, which accommodated separation of the West Burma Block from the West Sumatra Block [Curry *et al.*, 1979, 1982;

Jarrard, 1986; McCaffrey, 1992] (Figure 2). Extension in the Andaman Sea began around 11 Ma, and led to seafloor spreading since 4–5 Ma [Kamesh Raju *et al.*, 2004; Khan and Chakraborty, 2005; Chakraborty and Khan, 2009]. The total Miocene displacement of the Sagaing Fault was estimated at ~460 km based on a restoration of the Andaman Sea [Curry *et al.*, 1979, 1982; Mitchell, 1981]. *Bertrand and Rangin* [2003] concluded that a total displacement since 4 Ma is 100–150 km. This latter estimate assumes no extension in the Andaman Sea prior to seafloor spreading. Approximately 450 km of displacement is consistent with the amount of India-Asia convergence since ~10 Ma and supports the interpretation that the West Burma Block has moved with India since this time. Spreading in the Andaman Sea transfers slip along the Sagaing Fault to the slower slipping dextral Mentawai and Sumatra faults that partition the strike-slip component of oblique subduction below Sumatra. Displacement along these faults is determined by 50–70 km of Pliocene extension in the Sunda Strait [Diament *et al.*, 1992; Malod *et al.*, 1995; Malod and Kemal, 1996; Schlüter *et al.*, 2002]. This 50–70 km should be added to the 450 km of Andaman Sea extension to arrive at a displacement of the Sagaing fault of 510–530 km since ~11 Ma.

[46] To the east of the Sagaing fault, a N-S trending, high-grade metamorphic belt of several tens of kilometers wide is exposed in the Shan Scarp [Socquet and Pubellier, 2005]. The Shan Scarp is a steeply dipping, NNW striking dextral strike-slip shear zone [Bertrand and Rangin, 2003]. To the north, it branches into the E-W trending Mogok belt, which exposes N and S-dipping foliations with NNW trending lineations and bivergent shear-sense indicators [Bertrand and Rangin, 2003; Searle *et al.*, 2007]. Cooling ages of metamorphic rocks range from ~30 Ma in the south to ~18 Ma in the north of the Shan Scarp, and ~15 Ma in the Mogok belt [Bertrand *et al.*, 2001]. The Mogok belt continues northward to the Gaoligong shear-zone along the Bangong-Nujiang suture, southeast of the Himalayan syntaxis [G. Wang *et al.*, 2008]. Similar to the Shan Scarp, the Gaoligong is a dextral strike-slip shear zone that yielded cooling ages of ~28 Ma [Wang *et al.*, 2006]. It experienced a younger, late Miocene to Recent brittle transtensional episode [G. Wang *et al.*, 2008]. There is no estimate for the total amount of dextral strike-slip accommodated along the Shan Scarp, but the metamorphic record is interpreted to reflect significant dextral motion between the West Burma Block and Sibumasu since the late Eocene or early Oligocene. This is consistent with the presence of late Eocene to Miocene transtensional basins in central Myanmar, located between the Sagaing fault in the east and the Indo-Burma wedge to the west. These basins have been inverted by dextral transpression since ~10 Ma [Maurin and Rangin, 2009].

[47] The Indo-Burman wedge is a 1200 km long, west-verging fold-and-thrust belt [Brunnschweiler, 1966; Gansser, 1980; Johnson and Alam, 1991]. It consists of Cretaceous to Oligocene turbidite sequences in the inner wedge that underlie ophiolites, and Paleozoic and older metasediments [Acharya and Mitra, 1986], and Miocene to Quaternary sediments of the Bengal fan in the outer wedge [Maurin and Rangin, 2009] (Figures 1 and 2). At least 11 km of shortening have accumulated in the outer wedge since 2 Ma [Maurin and

Rangin, 2009]. The inner wedge, which is bounded by ~N-S trending dextral strike-slip faults and thrusts, is intensely deformed due to E-W shortening. The total amount of E-W shortening in the inner wedge is unknown, however, in part because it includes a strong dextral transpressional component [Maurin and Rangin, 2009]. At present, ~30% of the dextral shear between India and Sundaland is partitioned along the strike-slip zones in the inner Indo-Burma wedge [Vigny et al., 2003; Maurin and Rangin, 2009].

3.5.4. Three Rivers Region and Gaoligong Fault

[48] Late Miocene and younger deformation northwest of Sundaland accommodated the southward transfer of material from the Tibetan Plateau through the Three Rivers region between the eastern Himalayan syntaxis and the South China Block. GPS measurements [Allmendinger et al., 2007; Sol et al., 2007] show that along the eastern margin of the Tibetan Plateau, SSE-directed motion is partitioned into N-S sinistral strike-slip along the Xianshuihe Fault and a minor component of E-W shortening. To the south, GPS velocity vectors curve around the eastern Himalayan syntaxis and become W-directed with respect to Eurasia. These velocities follow the main structural trend, e.g., along the Gaoligong fault which curves from N-S in the north to E-W into the Mogok belt to the south [G. Wang et al., 2008]. The region of westward-directed GPS velocity vectors south of the Himalayan syntaxis is characterized by N-S trending active normal faults that originated in the late Miocene (~8.5 Ma), and were especially active in the Pliocene [G. Wang et al., 2008]. These GPS velocity patterns suggest that most southward east Tibetan motion today, and probably at least since the Pliocene, is transferred to the Indo-Burma wedge.

3.5.5. Paleomagnetism of Sundaland

[49] Many paleomagnetic studies have been conducted in Sundaland to constrain vertical axis rotations and paleolatitudinal changes associated with the motion along the RRF. These studies, all based on Mesozoic to Eocene red beds from Thailand, Vietnam, the Three Rivers region in southern China, and Myanmar, generally conclude that mainland Sundaland had a significant southward motion component with respect to South China, with attendant Cenozoic clockwise rotation. The amount of clockwise rotation varies strongly from 0° in southern Vietnam [Chi and Dorobek, 2004] to 70°, or even larger rotations in the Shan Thai deformed belt south of the RRF [Yang et al., 1995; Aihara et al., 2007; Sato et al., 2007; Tanaka et al., 2008]. Most authors argue for ~10–20° regional clockwise rotation of mainland Sundaland and strong rotations associated with distributed, dextral strike-slip deformation in the Shan Thai region close to the RRF [Huang and Opdyke, 1993; Charusiri et al., 2006; Aihara et al., 2007; Takemoto et al., 2009]. Southern Sundaland, on the other hand, is characterized by counterclockwise rotations of ~20–40° (Thai-Malaya peninsula and Borneo) since late Cretaceous time [Richter et al., 1999; Yamashita et al., 2011], and 50° on Borneo in the Neogene [Fuller et al., 1999]. It remains uncertain whether these data indicate regional block rotations or local deformation associated with sinistral strike-slip tectonism [e.g., Hall et al., 2008; Fyhn et al., 2010a].

[50] Many paleomagnetic studies have argued for major Cenozoic southeastward displacement of Sundaland along the RRF. This conclusion is based on the findings of steeper

inclinations in rocks from mainland Sundaland than predicted by the Eurasian APWP. Estimates typically have errors of 5–10° and report southward latitudinal displacements of 7–14° [Yang and Besse, 1993; Yang et al., 1995, 2001; Sato et al., 1999, 2001, 2007; Chi and Dorobek, 2004; Takemoto et al., 2005]. We discuss the tectonic implications of these reports in section 4.

4. Interpretation: Retrodeforming Intra-Asian Shortening and Extrusion

4.1. Reconstruction of Greater Asia

[51] Reconciling the kinematic constraints of intra-Asian deformation (Table 1 and Figure 3) leads to the evolution of Greater Asian deformation as shown in Figures 4a–4f. Figure 5 illustrates the amount of intra-Asian shortening and Sundaland extrusion since 50 Ma. Figure 6 illustrates the portion of India-Asia convergence that is accommodated in the overriding plate (i.e., Greater Asia) for three modern longitudes corresponding to the western, central and eastern regions of the collision zone. In this section, we summarize the main findings of this reconstruction. In following sections, we discuss subregions in more detail. Our intra-Asian shortening reconstruction uses the low end-member estimates for displacements of the Karakoram fault and RRF, rather than larger estimates that would lead to 700 km or more of SE-ward extrusion of Sundaland [Lee and Lawver, 1995; Replumaz and Tapponnier, 2003; Royden et al., 2008] (Figure 7). We discuss the differences between our reconstruction and models that predict major extrusion in section 4.6.

[52] We estimate a total of ~600 km of post-50 Ma shortening at the longitude of eastern Tibet (~95.5°E) (Figure 6). This deformation is partitioned between ~450 km of N-S Paleogene shortening in the Tibetan Plateau, and up to ~150 km of N-S shortening associated with slip along the ATF, which is accommodated in NE Tibet. At the longitude of central Tibet (~82°E), ~450 km of Tibetan shortening, a ~150 km N-S shortening component associated with the ATF, and ~150 km of shortening in the Tien Shan and Mongolia result in ~750 km of shortening since 50 Ma. In the western segment (~72°E), south of the Pamir Hindu-Kush region, the total amount of intra-Asian shortening is ~1050 km since 50 Ma. This estimate is based on ~350 km N-S shortening associated with ~400 km of cumulative right-lateral displacement along the N30°W trending Karakoram fault and KYTS relative to Tibet (which underwent ~450 km of shortening since 50 Ma), and ~250 km of shortening north of the Main Pamir Thrust.

[53] Additional post-collisional N-S shortening in southern Tibet can be inferred from the observation that Cretaceous to Eocene Gangdese arc-related granites are exposed immediately north of the IYSZ [e.g., Chiu et al., 2009]. The Xigaze forearc that must have developed above the Neotethyan subduction zone and south of the magmatic arc has thus been entirely consumed by shortening (e.g., underthrusting or subduction erosion). Our restoration of the Gangdese and Great Counter thrusts assumes a pre-Oligocene size of the Xigaze forearc of ~100 km. Forearc basins are typically 166 ± 60 km wide [Gill, 1981]; shallow dipping slabs may increase this width to >400 km [Gutscher et al.,

2000]. We emphasize that our restored forearc width is an underestimate and more shortening probably accumulated directly after collision with the Tethyan Himalaya around 50 Ma. Because the India-Asia convergence rate around 50 Ma was more than 150 km/Myr [van Hinsbergen *et al.*, 2011], and the uncertainty in collision age is on the order of several million years, we consider the forearc to disappear upon collision and do not specifically include it in our total shortening budget.

[54] Finally, we note that the total amount of shortening in the eastern segment is subject to the largest uncertainty. The 600 km estimated assumes that shortening measured in central Tibet is also valid in the east, where no estimates are available. This may be incorrect, however, no detailed field observations are available to support or refute this assumption. Indeed, the total amount of India-Asia con-

vergence since ~50 Ma is largest in the east (~3200 km [van Hinsbergen *et al.*, 2011]) whereas the total amount of intra-Asian shortening is lowest; this appears counterintuitive. In addition, seismic tomographic images suggest that the main Tethyan subduction zone curves southward more gradually in eastern Tibet than shown in our reconstruction [Van der Voo *et al.*, 1999a, Hafkenscheid *et al.*, 2006; Replumaz *et al.*, 2010]. The reentrant east of the collision zone prior to 50 Ma (Figure 4) may therefore be incorrect, and the amount of shortening in eastern Tibet may be underestimated in our reconstruction. Future structural geological work in this region, as well as vertical axis rotation analysis of the Lhasa terrane, is required to improve the reconstruction in this area.

[55] Our estimates for intra-Asian shortening are somewhat larger than previous estimates of ~600 km [Dewey *et al.*, 1988; Yin and Harrison, 2000; Johnson, 2002; Guillot *et al.*, 2003]. The main difference arises from the inclusion of the Tien Shan in our reconstruction. Direct comparison of paleomagnetic data from southern Tibet with those from Mongolia and Siberia indicate 1100 ± 500 km of Cenozoic intra-Asian convergence [Dupont-Nivet *et al.*, 2010a, 2010b; Lippert *et al.*, 2011], which is consistent with our reconstruction.

4.2. Deformation North of Tibet and the Pamir

[56] The amount of shortening of the Tien Shan directly east of the Talas-Ferghana fault is estimated at 200 km [Avouac and Tapponnier, 1993; Yin *et al.*, 1998]. Assuming that the 60 km of dextral displacement along the Talas-Ferghana fault is constant along the fault [Burtman *et al.*, 1996], this requires 260 km of total shortening in Eurasian lithosphere to the west of the Talas-Ferghana fault. This is similar to the estimate of 240 km of Bourgeois *et al.* [1997], which is based on the rotation and shortening patterns in the Tadjik Depression. Assuming 110 km of shortening in the Chatkal range [Thomas *et al.*, 1993], a 60 km offset along the Talas-Ferghana fault allows 50 km of shortening to the north of the offset marker of Burtman *et al.* [1996] in the

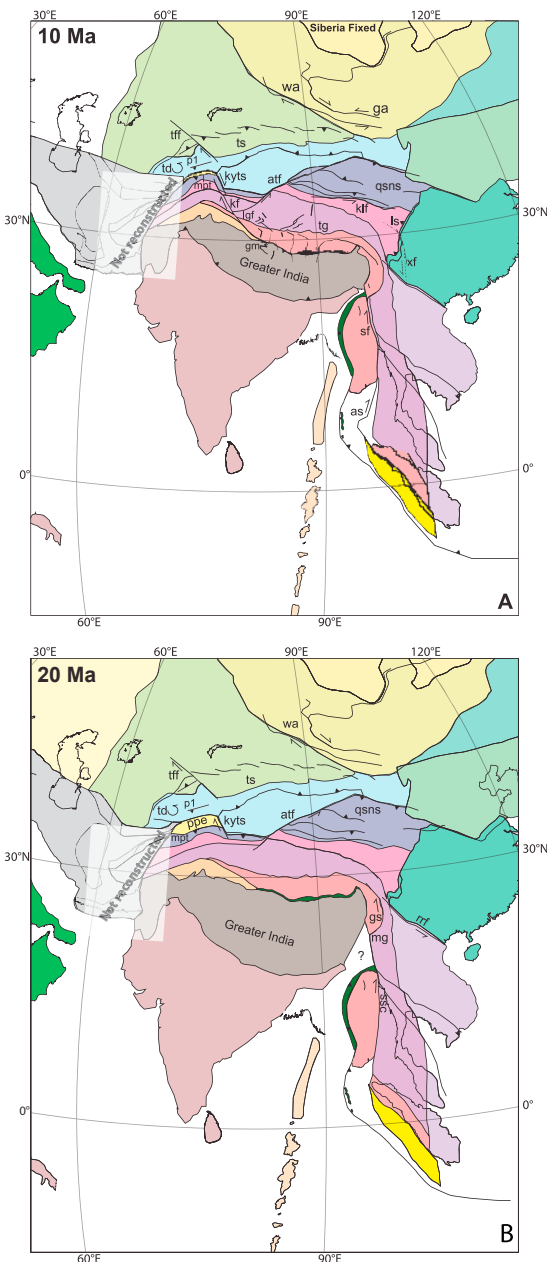

Figure 4

Figure 4. Reconstruction of configurations of pre-Cenozoic terranes in Asia in a 3D Globe projection and a Siberia-fixed reference frame at (a) 10, (b) 20, (c) 30, (d) 40, (e) 50, and (f) 60 Ma. Structures that are active at the restored time slice are indicated. Abbreviations are 3pf, Three Pagodas fault; as, Andaman Sea; atf, Altyn Tagh fault; evfz, East Vietnam fault zone; ga, Gobi Altai; gm, Gurla Mandhata metamorphic complex; gs, Gaoligong shear zone; kf, Karakoram fault; kl, Kohistan-Ladakh intraoceanic arc; klf, Kunlun fault; Longmu-Goza fault; kyts, Kashgar-Yesheng transfer system; Lh, Lhasa shortening; ls, Longmen Shan; mbt, Main Boundary Thrust; mg, Mogok metamorphic belt; mpf, Mae Ping fault; mpt, Main Pamir Thrust; p1, Peter the First range; ppe, Proto-Pamir embayment; qsns, Qilian Shan-Nan Shan; Qt, Qiangtang shortening; rrf, Red River fault; sf, Sagaing fault; Sg, Songpan-Ganzi shortening; ssc, Shan Scarp; td, Tadjik Depression; tff, Talas-Ferghana fault; tg, Tibetan grabens; ts, Tien Shan; wa, Western Altai; xf, Xianshuihe fault; xfa, Xigaze forearc.

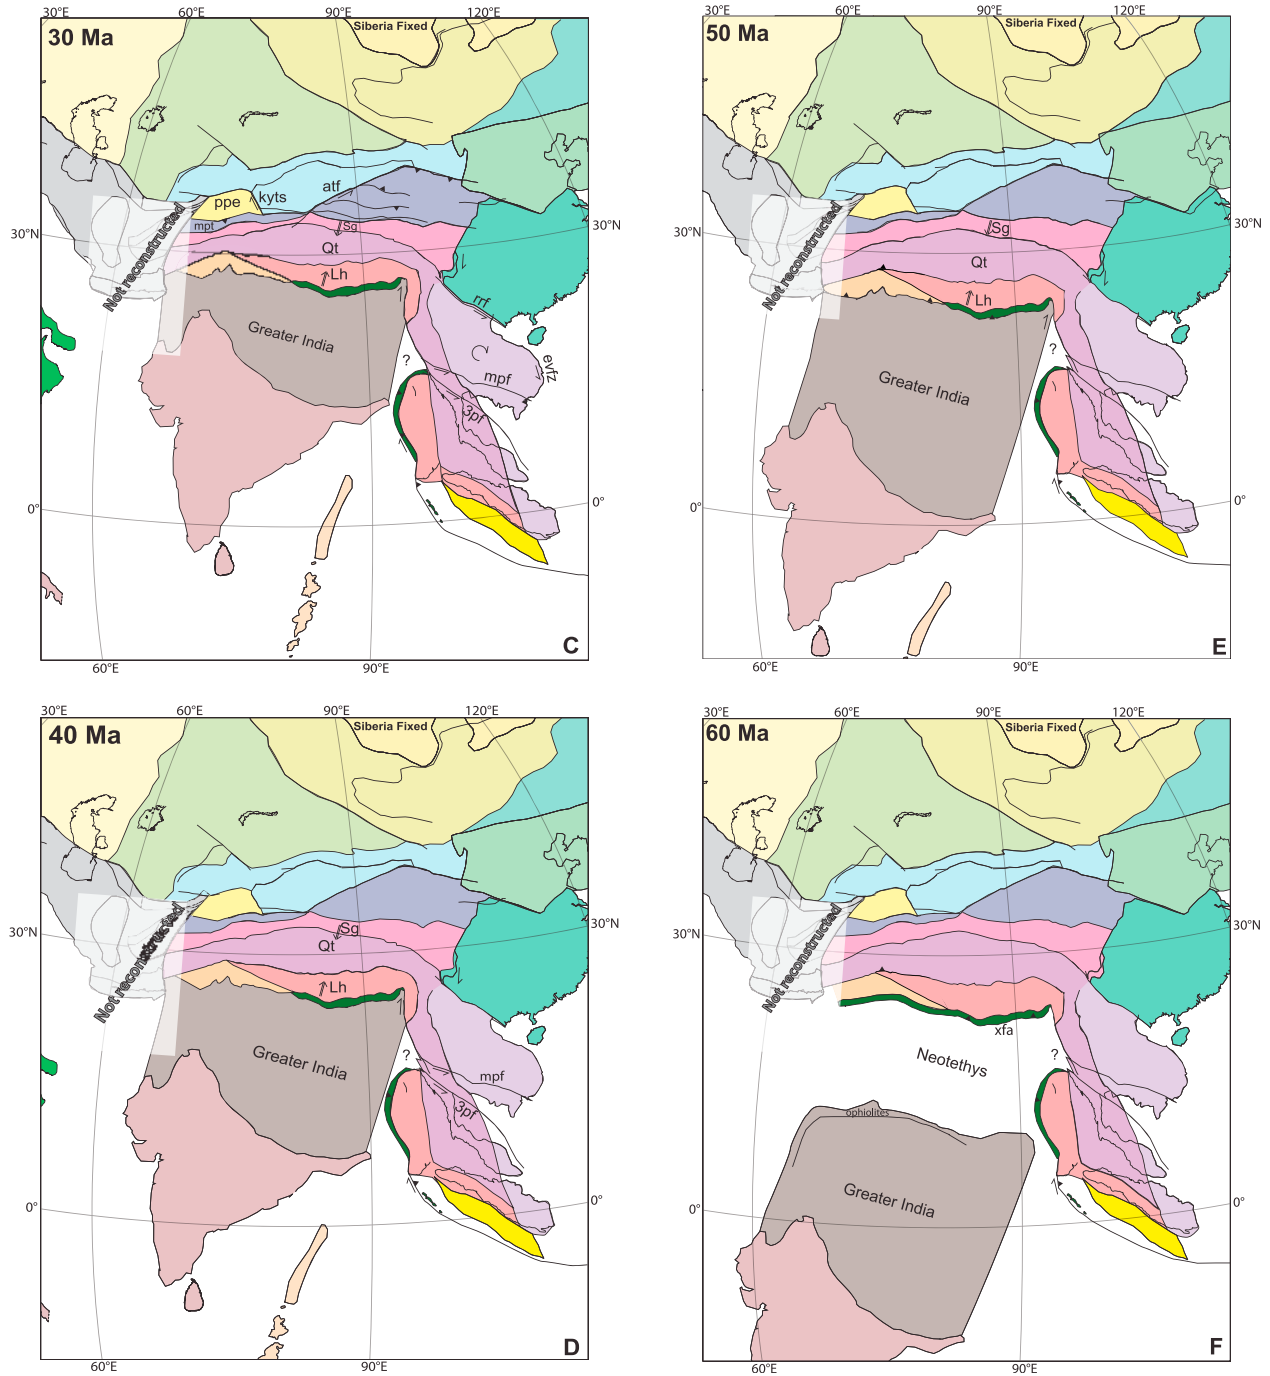

Figure 4. (continued)

central Tien Shan. This implies that the remaining 150 km of shortening in the eastern Tien Shan accumulated in the southern half of the belt. This prediction is consistent with the interpretation that deformation began earlier in the south than in the north [Hendrix *et al.*, 1994; Yin *et al.*, 1998; Yang and Liu, 2002; Bullen *et al.*, 2003; Sobel *et al.*, 2006; Heermance *et al.*, 2007; Charreau *et al.*, 2009; Sun and Zhang, 2009; Li

et al., 2011]. Moreover, shortening to the south of the Chatkal range should have been 150 km as well, in order to maintain the dextral offset along the Talas-Ferghana fault.

4.3. Miocene E-W Extension in Tibet and Activity of the Karakoram and Altyn Tagh Faults

[57] GPS measurements and active seismicity demonstrate that the sinistral ATF and the dextral Karakoram

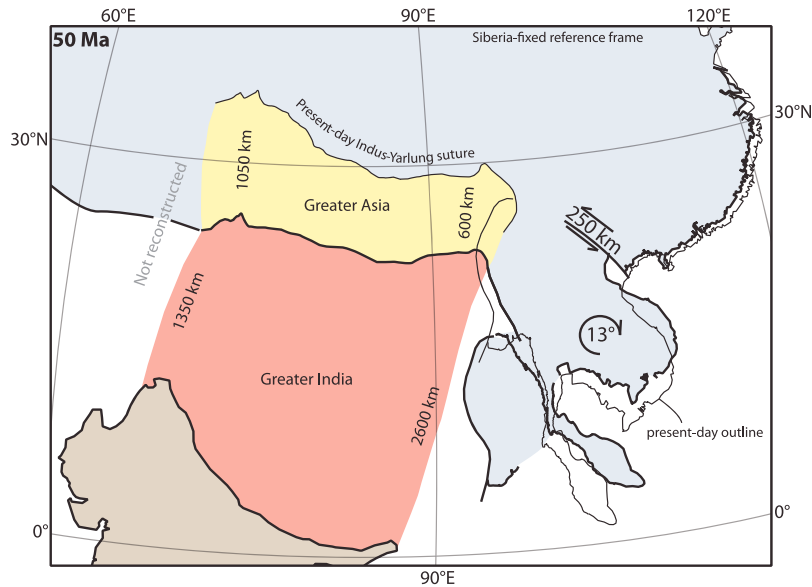

Figure 5. Cartoon illustrating the reconstructed size of Greater Asia, i.e., the total amount of intra-Asian shortening north of India, defined by the position of the IYSZ today and the reconstructed position 50 Ma ago. In this paper we assume that the Tethyan Himalaya collided with Asia at 50 Ma. This collision age has no bearing on the amount of intra-Asian shortening. Map is in a Siberia-stable reference frame in a 3D Globe projection; the position of India with respect to stable Asia is based on the plate circuit of *van Hinsbergen et al.* [2011].

fault are active today, and geological studies suggest that they have been simultaneously active since at least the late Miocene [e.g., *Zhang et al.*, 2004; *He and Chery*, 2008]. Approximately 100 km of distributed E-W extension has accumulated in the Tibetan Plateau since ~13 Ma (Table 1 and Figure 3). This extension is kinematically compatible with eastward increasing sinistral motion along of the ATF after 13 Ma. East of the central segment of the ATF, however, E-W extension in Tibet appears to be entirely accommodated by slip along the left-lateral Kunlun Fault [e.g., *Van der Woerd et al.*, 2000; *Jolivet et al.*, 2001]. *He and Chery* [2008] showed that across central Tibet (84–95°E), from the ATF to the Himalayan arc, E-W extension rates are 8–10 mm/yr. At these rates, it would take 10–12.5 Ma to accumulate the ~100 km of total E-W extension estimated in Tibet. This is consistent with the initiation age of N-trending grabens in Tibet.

[58] The region north of the Kunlun fault, however, has undergone, and is still characterized by sinistral transpression. It is not possible to kinematically link this transpression directly to E-W extension in Tibet. Rather, the N-S shortening component south of the ATF appears to increase eastward since the late Miocene. Therefore, we restore a minor (~3°) counterclockwise rotation of Tibet relative to Tarim around a pole located at the Karakoram fault–Karakax junction. This rotation produces E-W extension in central Tibet, and dextral transpression in NE Tibet.

[59] In this scenario, the Tibetan Plateau is a crustal block that has rotated counterclockwise with respect to Tarim around a pole of rotation near the western Kunlun Shan–Karakoram junction and has deformed internally. This kinematic pattern has characterized deformation in Tibet

since the late Miocene. Over the same time interval, the Tarim basin has rotated by similar magnitude but in an opposite direction with respect to Siberia. Thus, the net rotation of Tibet with respect to Siberia is negligible. A counterclockwise rotation of Tibet with respect to Tarim would produce transpression along the ATF, but transpressional deformation along its central segment is minor. East-west extension to the south of the central ATF segment transfers this transpressional component eastward into NE Tibet, whereas the E-W component of motion south of NE Tibet is absorbed by the Kunlun Fault (Figure 8). In our reconstruction, the left-lateral motion of the ATF and the observation that western Tibet is not significantly displaced with respect to Tarim is a direct consequence of the opposing rotations of Tarim and Tibet, with respect to Siberia.

[60] The ATF has been continuously active since at least the latest Oligocene [*Yue et al.*, 2001, 2004; *Yang and Liu*, 2002; *Zhuang et al.*, 2011]. The ATF can only be active simultaneously with the Karakoram fault if Tibet is E-W extending or otherwise, it should crosscut and offset the Karakoram fault. The onset of E-W extension in Tibet at 14–12 Ma [*Burchfiel et al.*, 1991; *Coleman and Hodges*, 1995; *Harrison et al.*, 1995; *Blisniuk et al.*, 2001; *Garzzone et al.*, 2003] is contemporaneous with the onset of slip along the Karakoram fault of 14–12 Ma suggested by [*Bhutani et al.*, 2009; *Streule et al.*, 2009; *Wang et al.*, 2009; *Searle et al.*, 2010]. The much older ages of ~25 Ma, suggested by *Lacassin et al.* [2004], *Valli et al.* [2007, 2008], *Rolland et al.* [2009], and *Leloup et al.* [2011] are based on the interpretation that ~23 Ma granites found along the Karakoram fault are synkinematic and the result of shear

Figure 6. Graphs illustrating the size of Greater India as a function of collision age, using the restoration of intra-Asian shortening as reconstructed in this paper. Our preferred size assumes a 50 Ma collision age, but alternative scenarios with ages of 35, 40 and 60 Ma are also indicated. Even the youngest proposed collision age still requires a size of Greater India that is up to 3 times larger than the amount of shortening recorded in the Himalaya. This suggests that a large portion of Greater India subducted entirely without accretion, that a substantial amount of Greater Indian upper crust is duplexed beneath Tibet, or both.

heating along the Karakoram fault. This mechanism for granite batholith emplacement is disputed, however, by, e.g., *Searle and Phillips* [2007]. We note that a 23 Ma onset of the Karakoram fault would require that either the ATF was not active between ~ 25 and ~ 13 Ma, or that the Karakoram Fault was associated with an NE-SW extensional component, or that the Karakoram Fault was offset by the Karakax fault. All of these options are challenged by geological evidence. We therefore apply a 13 Ma age for onset of the Karakoram fault in our reconstruction, and reconstruct up to ~ 100 km of displacement along the central ATF since this time, with the remaining 300 km between 30 and 13 Ma.

4.4. Tibetan Shortening and the Amount of Karakoram Fault Offset

[61] The Karakoram fault transfers shortening in the Rushan-Pshart fold-and-thrust belt at its northwestern termination [*Robinson et al.*, 2004], to shortening absorbed in the Lesser Himalaya and around the IYSZ at its southeastern termination. Approximately 65 km of displacement of the Karakoram fault is transferred into the Gurla-Mandhata core complex, and from there it is probably transferred to the Main Boundary Thrust [*Murphy and Copeland*, 2005]. The Great Counter Thrust is the only recognized structure that could have absorbed the remainder of Karakoram fault displacement (Figure 8).

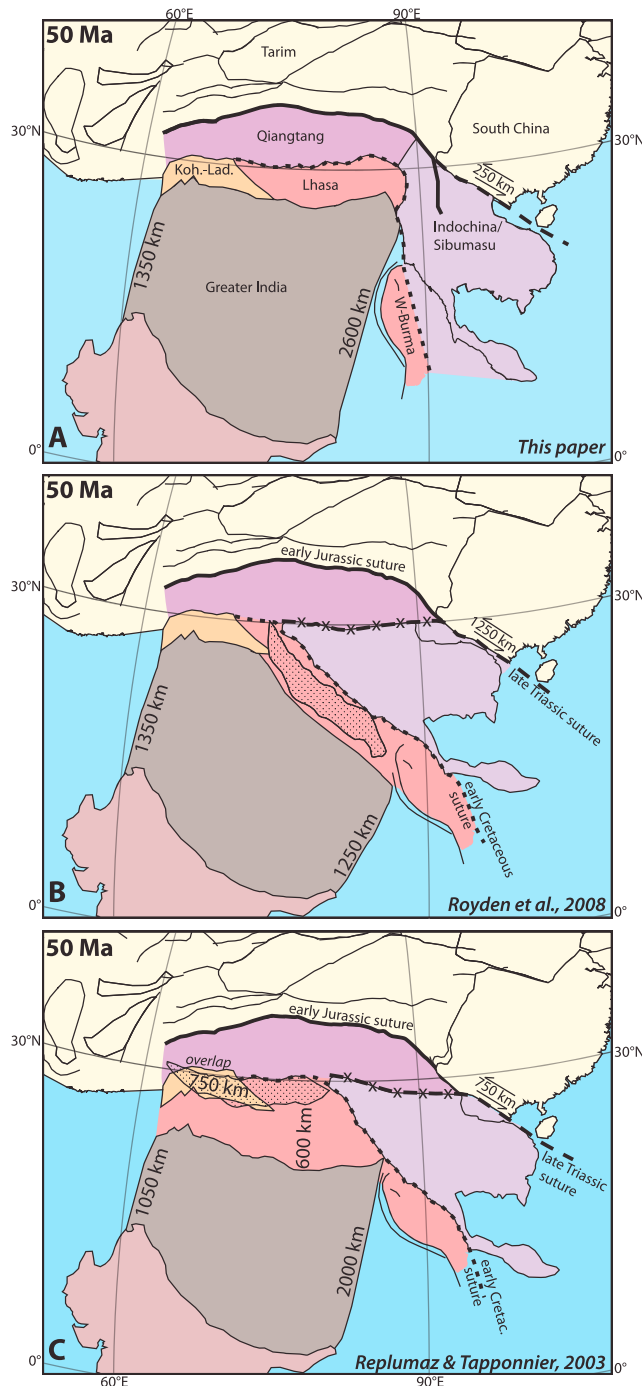

Figure 7. Reconstructions of Greater Asia (a) following this paper; (b) using the reconstruction of Asia in this paper but including ~ 1250 km of Indochina extrusion from between the Lhasa and Qiangtang terranes similar to those of Royden *et al.* [2008] and (c) same as Figure 7b but including ~ 750 km of Indochina extrusion similar to that of Replumaz and Tapponnier [2003].

[62] Approximately 16 km of shortening between 18 and 11 Ma have been documented along the Great Counter Thrust [Yin *et al.*, 1999a; Murphy and Yin, 2003; Murphy *et al.*, 2009]. The low total displacement end-member sce-

nario for Karakoram fault, with offsets of up to 150 km, requires ~ 70 km of N-S shortening along the Great Counter thrust system. Although we reconstructed this amount of shortening, we note that this displacement is nearly five times as much as documented. Searle and Phillips [2007] suggested that the displacement along the Karakoram fault may even be much smaller than 150 km, which would resolve this discrepancy. Thus, we thus interpret the amount of displacement along the Karakoram Fault and the associated amount of shortening in the Rushan-Pshart fold-and-thrust belt and the Great Counter Thrust in our reconstruction as a maximum estimate. There is no geological evidence for the hundreds kilometers of Neogene shortening in southern Tibet required by much higher estimates of 300–600 km of Karakoram Fault displacement of Lacassin *et al.* [2004], Valli *et al.* [2007, 2008] and Rolland *et al.* [2009].

4.5. Restoring Southward Subduction Along the Main Pamir Thrust

[63] The total amount of N-S convergence accommodated along the Main Pamir Thrust is estimated from the dextral displacement along the KYTS (~ 270 km) and the ~ 100 km of Cenozoic shortening of the Western Kunlun Shan [Cowgill, 2001]. The amount of convergence accommodated along the Main Pamir Thrust is thus ~ 370 km. This estimate is consistent with the 300–350 km of subduction below the Pamir estimated from seismic tomographic images [e.g., Negredo *et al.*, 2007] and the Benioff zone below the Pamir to ~ 300 km depth [e.g., Pegler and Das, 1998; Pavlis and Das, 2000].

4.6. The Extrusion of Indochina: Small Versus Large Displacement Along the RRF

[64] The estimates for the amount of ~ 30 – 20 Ma (or slightly younger) sinistral displacement along the RRF vary from ~ 250 km [Hall *et al.*, 2008; Fyhn *et al.*, 2009] to 700 ± 200 km [Leloup *et al.*, 1995]. Royden *et al.* [2008] inferred this displacement to be as large as ~ 1250 km. In this section, we first attempt to reconcile the minimum amount of RRF displacement with the geology of Tibet. We will then test whether large displacements are consistent with regional kinematic constraints. To accommodate the minimum displacement, we reconstruct an ~ 200 – 250 km \sim E-W shortening component of the Qiangtang and Lhasa terranes in the Yunnan region between the eastern Himalayan syntaxis and the South China block, while the RRF is active as sinistral shear zone. Because N-S shortening was simultaneously active in Tibet. This style of deformation is consistent with the narrow, N-S trending geometry of the Lhasa and Qiangtang terranes, the consistently large clockwise rotations in this region, and the Oligocene dextral strike-slip component in the Gaoligong shear zone (Figure 9 and Table 1).

[65] Restoring Sundaland 250 km to the NW in Oligocene-Miocene time generates overlap between the West Burma Block (see section 4.7) and (Greater) India. This overlap can be avoided by reconstructing a clockwise vertical axis rotation of mainland Sundaland. The minimum angle over which we have to rotate mainland Sundaland (around a pole on the RRF, see below) to avoid a west Burma–India overlap is 13° clockwise. This rotation is consistent with paleomagnetic estimates of 10 – 20° of clockwise rotation [Huang and Opdyke, 1993; Charusiri *et al.*, 2006; Aihara *et al.*, 2007;

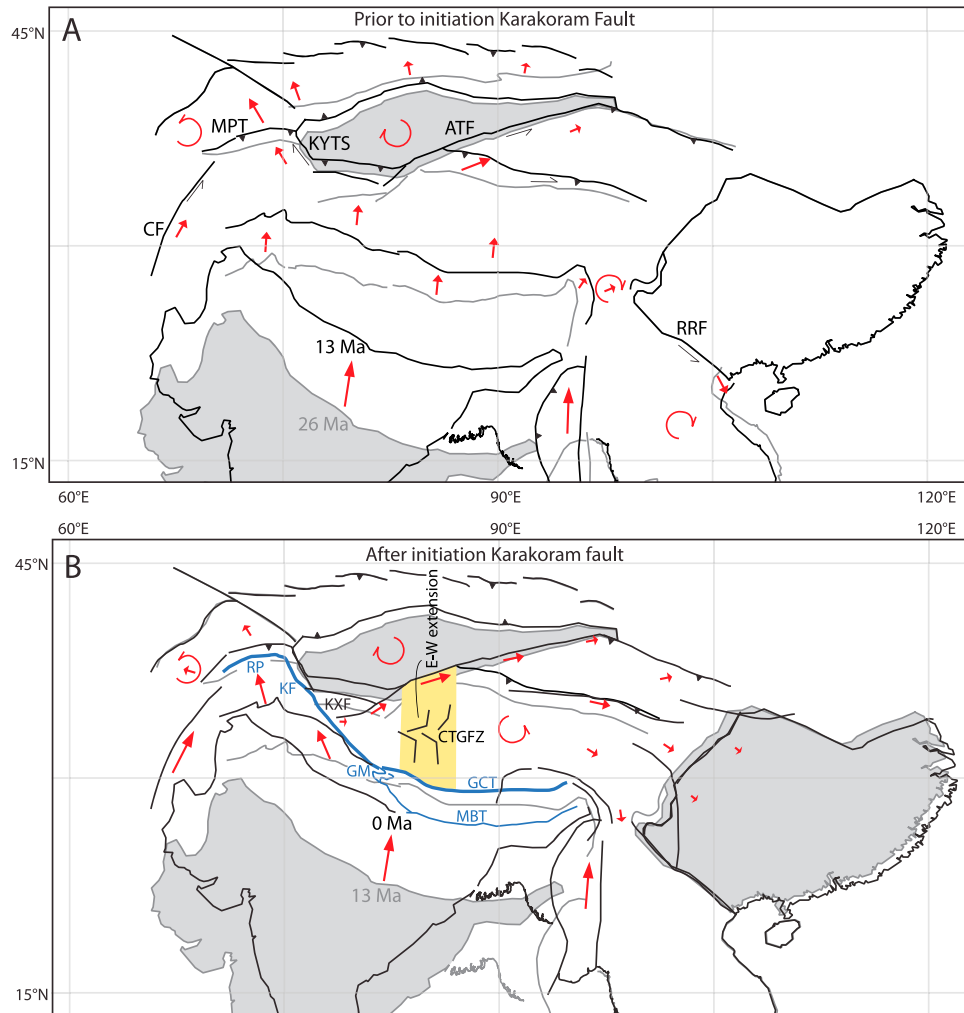

Figure 8. Kinematic evolution of the Tibetan Plateau. (a) Prior to the existence of the Karakoram Fault (26–13 Ma), the Tarim basin acted as a rigid indenter with motion to the NNW in the Pamir and ENE in the NE Tibet. We postulate a dextral fault, or distributed shear zone, along the southern edge of NE Tibet to accommodate the eastward motion component with respect to central Tibet. (b) The Karakoram Fault (13–0 Ma) and its terminations are indicated in blue. To the NW, dextral slip of the Karakoram Fault is accommodated in the Rushan Pshart region, whereas in the SE it is transferred first to the Great Counter Thrust (until ~10 Ma) and then the Main Boundary Thrust via the Gurla Mandhata core complex [Murphy *et al.*, 2000; Murphy and Copeland, 2005]. The Karakoram Fault prevents motion of western Tibet with respect to Tarim: the Karakax Fault is sealed by the Karakoram Fault. Coeval motion of the Altyn Tagh Fault can only occur through a counterclockwise rotation of Tibet about a pole at the Karakoram Fault, in combination with E-W extension in the segment south of the central Altyn Tagh Fault.

Takemoto *et al.*, 2009]. The rotation pole is estimated based on the distribution of transpression and transtension along the RRF. Several authors have argued for a transtensional component in the central and southeastern part of the RRF [Leloup *et al.*, 1995, 2001; Harrison *et al.*, 1996]. We restore a N-S extensional component for the SE part of the RRF of up to 50 km, superimposed on the 250 km of translation, and a maximum ~150 km ~N-S shortening component in the northwest. Transpression is partitioned over the Shan Thai deformed belt south of the RRF, consistent with the large, and locally varying clockwise rotations measured there [e.g., Yang *et al.*, 1995; Aihara *et al.*, 2007; Sato *et al.*, 2007;

Tanaka *et al.*, 2008]. We conclude that a displacement of 250 km along the RRF gives predictions for eastern Tibetan tectonics that are consistent with the available constraints.

[66] The larger displacements of ~750 [Replumaz and Tapponnier, 2003] or ~1250 km [Royden *et al.*, 2008] (Figure 7) predict several regional geometries and configurations that appear inconsistent with geological observations.

[67] 1. Both scenarios assume a NW-SE striking strike-slip fault across the Three Rivers region that connects the RRF with the hypothetical Karakoram-Jiali strike-slip fault. Left-lateral displacement on this hypothetical fault must

equal to the amount of extrusion (750 km or more). Such a fault remains to be documented.

[68] 2. The Karakoram-Jiali strike-slip fault would run along the Bangong-Nujiang suture. This region is well-studied and is characterized by a Cretaceous fold-thrust belt that underwent only minor thrust reactivation in the critical time interval of 30–20 Ma [Kapp *et al.*, 2007a]. These observations are clearly at odds with the prediction of major Oligocene strike-slip. Post-20 Ma strike-slip faults in this region has displacements of less than 20 km [Taylor *et al.*, 2003].

[69] 3. The model of Replumaz and Tapponnier [2003] restores the Lhasa block ~700 km westward, which would require 700 km of E-W extension. This extension would need to accumulate either along the Karakoram Fault or in the Pamir-Hindu Kush depending on the assumed onset age of the Karakoram Fault. There is no evidence for substantial E-W extension in Tibet or the Pamir prior to 13 Ma.

[70] 4. Sundaland is much wider than the Lhasa terrane. Thus, the extrusion scenario predicts that the Lhasa terrane accumulated ~600 km Oligocene-early Miocene N-S shortening by [Replumaz and Tapponnier, 2003]. Thick piles of flat lying to gently dipping upper Cretaceous to Eocene volcanics units throughout the Lhasa terrane [P. Kapp *et al.*, 2005, 2007a; Ding *et al.*, 2007; Lee *et al.*, 2009; Pullen *et al.*, 2011; Zhu *et al.*, 2011], as well as balanced cross sections from the region [Kapp *et al.*, 2007b], preclude this shortening history. Royden *et al.* [2008] predict ~40° counterclockwise rotation of the Lhasa block. Paleomagnetic evidence from the southern Lhasa block, however, suggests minimal vertical axis rotation of this region since the Cretaceous [Tan *et al.*, 2010; Dupont-Nivet *et al.*, 2010a].

[71] 5. Royden *et al.* [2008] suggest diachronous eastward motion of the Indochina block, resulting in a “collision” between Lhasa and Qiangtang during the Cenozoic extrusion. Folding and thrusting across the Bangong-Nujiang suture, however is largely pre-Cenozoic in age [P. Kapp *et al.*, 2005].

[72] 6. All extrusion models restore the Indochina block south of the Qiangtang terrane [Lee and Lawver, 1995; Replumaz and Tapponnier, 2003; Royden *et al.*, 2008]. The Indochina-South China suture, however, is of middle-late Triassic age [Ferrari *et al.*, 2008; Cai and Zhang, 2009] and predates the upper Triassic-lower Jurassic Jinsha suture north of the Qiangtang block [Yin and Harrison, 2000]. The Indochina-South China suture certainly is not equivalent to the lower Cretaceous Bangong-Nujiang suture [Dewey *et al.*, 1988; Yin and Harrison, 2000; Kapp *et al.*, 2007a]. Thus, a palinspastic position of Indochina south of the Qiangtang block (Figure 7) is inconsistent with the suture ages.

[73] We thus conclude that a position of the Indochina block as far west as central Tibet, as required by 750 km or more of displacement of the RRF, is inconsistent with geological observations. We note, however, that we have probably underestimated the amount of shortening in eastern Tibet and therefore cannot exclude that the amount of extrusion was (slightly) higher than the 250 km postulated by Hall *et al.* [2008]. Additional structural geological data from eastern Tibet, as well as vertical axis rotation patterns of the eastern Lhasa terrane, could help resolve the kinematic evolution of this part of the collision zone.

4.7. Paleomagnetic Constraints on SE Asian Motion?

[74] On first glance, the paleomagnetic interpretations of southward motion of Indochina of 7–14° seem to support major displacement along the RRF [Yang and Besse, 1993; Yang *et al.*, 1995, 2001; Sato *et al.*, 1999, 2001, 2007; Chi and Dorobek, 2004; Takemoto *et al.*, 2005]. Upon closer inspection, however, these data sets are mutually inconsistent and suggest an amount of southward translation that cannot be reconciled with known geological constraints.

[75] First, all these paleomagnetic data sets were obtained from red beds, which are known to be biased by compaction-induced swallowing of paleomagnetic inclinations, leading to underestimates of paleolatitude [e.g., King, 1955; Tan and Kodama, 2002; Tauxe, 2005; Tauxe *et al.*, 2008]. None of the studies from Sundaland have been evaluated for inclination shallowing. Typical flattening factors of 0.6 would increase the southward translation suggested by the data sets to 10–20°, or 1100–2200 km. This is much more than the 450 km (~4°) of southward motion associated with the largest RRF displacement estimate of 900 km [Leloup *et al.*, 1995]. Even if we assume no inclination flattening, the 770–1500 km of paleomagnetically inferred southward motion would place Indochina at the latitude of the Tarim basin. This is clearly inconsistent with the geological evidence.

[76] Second, there are inconsistencies among the data sets. Takemoto *et al.* [2005] reported results from the Son Da region to the south of the RRF, which indicate no southward motion with respect to South China, and suggested that extrusion was accommodated along a fault to the south of the RRF. Liu and Morinaga [1999] also concluded that the RRF did not accommodate extrusion because their data suggest southward translations of 8–14° of blocks to the north of the RRF. Tanaka *et al.* [2008] argued for southward translation of Indochina along the RRF, but prior to 32 Ma, i.e., prior to the demonstrated existence of this fault. Instead of southward motion Richter and Fuller [1996] reported ~5° northward motion of the Shan plateau in Myanmar, east of the Sagaing Fault. The reasons for these inconsistencies remain elusive, but at this stage we do not take these data into account.

4.8. Restoration of the West Burma Block and the Three Pagodas and Mae Ping Faults

[77] We reconstructed a 13° clockwise rotation of Sundaland between 30 and 20 Ma. This avoids an overlap between Greater India and the West Burma Block in that time period. A reconstruction of the West Burma Block with respect to India and Sundaland that follows the available constraints and avoids overlaps, however, requires additional corrections.

[78] The available constraints (Table 1 and Figure 3) include (1) 530 km of displacement along the Sagaing Fault since 11 Ma; (2) right-lateral motion along the Shan Scarp and Mogok Belt in the Oligocene to Early Miocene; (3) 100 km of displacement on both the Three Pagodas and Mae Ping faults between ~40 and 23 Ma and (4) at least 300 km of eastward subduction of India below the West Burma Block [Van der Voo *et al.*, 1999a; Li *et al.*, 2008].

[79] There are two geometrical arguments why northward displacement of the West Burma Block was not restricted to

Figure 9. Snapshots from the reconstruction at 30 and 20 Ma, showing how extrusion of Indochina from eastern Tibet has been reconciled. Approximately 250 km of extrusion [Hall *et al.*, 2008; Fyhn *et al.*, 2009] can be accommodated by dextral transpression between Tibet and Indochina. There is no evidence for Oligocene-early Miocene faults connecting the NW termination of the RRF with faults in Tibet, or significant offset between the Lhasa and Qiangtang terranes in SE Tibet. More displacement along the RRF would place Indochina south of the Bangong-Nujiang suture, or would require ~500 km of shortening in the central and western Lhasa terrane. Neither of these scenarios are consistent with the known geology of the region (see text for discussion), and we conclude that displacements along the RRF cannot be substantially larger than suggested by Hall *et al.* [2008] and Fyhn *et al.* [2009] are at odds with geological constraints of Tibet. See text for further discussion. See Figure 2 for legend.

530 km of post-11 Ma displacement (Table 1 and Figure 3). First, leaving the West Burma Block in its 11 Ma position leads to overlap between the West Burma Block and the Shillong Plateau prior to 11 Ma. The Shillong Plateau has an unmetamorphosed Mesozoic and younger cover, and there is no evidence that this plateau was disconnected from the Indian continent prior to its late Miocene and younger deformation [Clark and Bilham, 2008]. Therefore, the West Burma Block cannot have a position that overlaps with the pathway of the Shillong Plateau with respect to Sundaland. Second, the 11 Ma position of the West Burma Block brings its central part due west of the western terminations of the Mae Ping and Three Pagodas faults. Each of these faults has 100–160 km of left-lateral displacement between 40 and 23 Ma (Table 1). There is no evidence for equivalents of the Three Pagodas or Mae Ping faults crosscutting the West Burma Block, which must therefore have been south of the Three Pagodas Fault until at least ~23 Ma ago. Morley [2004] suggested that the Shan Scarp is connected to the Three Pagodas fault. This configuration, however, requires a major Miocene displacement along the Three Pagodas fault to avoid overlap between the Shillong Plateau and the West Burma Block. The pre-23 Ma age and only 100–160 km displacement of the Three Pagodas fault (Table 1 and Figure 3) seem to preclude this scenario.

[80] Bringing the northern edge of the West Burma Block south of the northwestern termination of the Three Pagodas Fault requires a northward motion of the West Burma Block that equates to India's northward motion since 23 Ma (~600 km). This age coincides with the end of activity of the Three Pagodas Fault [Fyhn *et al.*, 2010a], and prevents overlap between the West Burma Block and the Shillong Plateau pathway. Partitioning of oblique India-Indochina motion through strike-slip along the Shan Scarp

and subsequently to the Sagaing fault generates 350 km of eastward subduction of India below the West Burma Block. This prediction is consistent with seismic tomographic interpretations [Van der Voo *et al.*, 1999a; Li *et al.*, 2008].

[81] In summary, to fulfill all constraints on the motion of west Burma with respect to India and Sundaland, we reconstruct a large (~650 km) displacement along the Shan Scarp between 23 and 11 Ma, and assume continuity of the Shan Scarp offshore to NW Sumatra. Prior to 23 Ma, we couple the West Burma Block with southern Sibumasu, and restore a minimum sinistral displacement of 100 km from 40 to 23 Ma for both the Mae Ping and Three Pagodas faults (Table 1).

5. Discussion: The Size of Greater India as a Function of Collision Age

[82] Our restoration of intra-Asian shortening has direct implications for the amount of Indian plate lithosphere that subducted after the initial Tethyan Himalaya-Lhasa collision. Different proposals exist for the age of this collision, varying from ~65 Ma [e.g., Cai *et al.*, 2011] to ~35 Ma [Aitchison *et al.*, 2007, 2011]. Most authors prefer an age between 55 and 50 Ma [e.g., Zhu *et al.*, 2005; Green *et al.*, 2008; Najman *et al.*, 2010; Wang *et al.*, 2011]. The arguments for the collision age have been recently reviewed by van Hinsbergen *et al.* [2011], and we follow their preference for a ~50 Ma collision age in the reconstructions shown in Figures 4, 5, and 7. We note, however, that our restoration is independent from the collision age and can be used to determine the size of Greater India as a function of collision age, as shown for three reference sections in Figures 2 and 6. The curves in Figure 6 show the amount of India-Asia convergence measured along great circles in 5 Ma intervals,

using the plate circuit of *van Hinsbergen et al.* [2011] and the intra-Asian shortening through time reconstructed in this paper. Uncertainties in the convergence estimates are on the order of 100–200 km. For illustration, we have indicated the minimum and maximum proposed collision ages, as well as our preferred collision age.

[83] A ~50 Ma collision requires that the size of Greater India was 1350, 2060 and 2600 km wide for our three reference points from west to east, respectively, at the time of initial collision (Figure 6). This size of Greater India is much larger than reconstructed fits with the western Australian margin in early Cretaceous and older time [*Ali and Aitchison, 2005*]. It is consistent, however, with paleogeographic reconstructions based on independent, high-quality paleomagnetic poles from ~70 and ~60 Ma old sediments from the Tethyan Himalaya [*Patzelt et al., 1996*] corrected for inclination swallowing due to sedimentation and compaction [*Dupont-Nivet et al., 2010b*]. These Tethyan Himalayan poles show $17 \pm 4^\circ$ of paleolatitudinal separation (i.e., 1900 \pm 450 km) between the Tethyan Himalaya and India [*Dupont-Nivet et al., 2010b*].

[84] A collision younger than 50 Ma would decrease the required size of Greater India. A 35 Ma collision age would, however, still require that Greater India was ~1200 km and ~1600 km wide in the central and eastern part of the collision zone. An older collision age of ~65 Ma would increase the size of Greater India to as much as 4000 km (Figure 6).

[85] The Himalaya consist of rocks that were scraped off of Indian plate continental crust during post-50 Ma subduction and underthrusting. Eight balanced cross-sections across the Himalaya, i.e., the geological record of Greater India [*Hodges, 2000*], at longitudes from the western to eastern Himalayan syntaxes [see *DeCelles et al., 2002; Long et al., 2011*, and references therein] show that the currently ~275 km wide Himalaya was shortened by ~450 to ~650 km. One cross section from western Nepal [*Robinson et al., 2006*] shows as much as 900 km of shortening. The amount of shortening in the Himalaya is thus much less than the early Eocene size of Greater India determined paleomagnetically [*Patzelt et al., 1996*], as well as suggested by our reconstruction of Greater Asia. It therefore seems likely that the amount of shortening in the Himalaya significantly underestimates the amount of subduction of the Indian Plate since collision. This may in part be the result of erosion in the Himalaya, or structural burial and duplexing of Greater Indian upper crust below Tibet [*Hacker et al., 2005; Nábělek et al., 2009*]. In addition, or alternatively, one may speculate that a large portion of Greater India consisted of thinned continental, or even oceanic crust [*Dupont-Nivet et al., 2010a*]. Additional studies in the Himalaya are needed to test this inference, which would require substantial revision to our understanding of where and how Cenozoic convergence was accommodated between India and Asia.

6. Conclusions

[86] We review recent kinematic constraints from the Tibetan Plateau, the Pamir-Hindu Kush region, the Tien Shan, Mongolia, southern Siberia, Sundaland, and the West Burma Block to provide an updated estimate of the amount of India-Asia convergence that was accommodated by shortening and extrusion in the overriding plate since 50 Ma.

Reconciling all independent kinematic constraints shows that at the longitude of the western Himalayan syntaxis (~72°E), ~1050 km of intra-Asian shortening occurred. At longitude of the western Tibetan Plateau (~82°E), ~750 km of N-S shortening occurred since 50 Ma, decreasing to ~600 km in eastern Tibet (~95°E), with the largest uncertainty in the eastern Tibetan segment.

[87] Approximately 250 km of SE-ward extrusion of Sundaland along the Red River Fault, as predicted by palinspastic reconstructions of SE Asia, can be straightforwardly reconciled with dextral transpression in SE Tibet. Our estimates for Cenozoic intra-Asian shortening and extrusion are lower than in previous reconstructions of the collision zone, which predicted as much as 2000 km of intra-Asian shortening and 750–1250 km or more Sundaland extrusion. We conclude that such large values are inconsistent with geological evidence from Tibet. It remains possible that the amount of extrusion exceeded 250 km, but probably not by much. Future kinematic work in eastern Tibet is required to assess this possibility.

[88] Combining our intra-Asian shortening reconstruction with the Indo-Atlantic plate circuit allows us to estimate the size of Greater India as a function of the Tethyan Himalaya-Lhasa collision age. Estimates for this age vary from ~65 to ~35 Ma. Even for the youngest collision age, the required size of Greater India is up to 3 times larger than the amount of shortening recorded in the Himalaya. This suggests that a significant portion of Greater India subducted without accretion of its upper crust, or with its upper crust duplexed below the Tibetan Plateau.
