## Abstract:

We review the current status of the use of focused electron beam induced deposition (FEBID) for the growth of magnetic nanostructures. This technique relies on the local dissociation of a precursor gas by means of an electron beam. The most promising results have been obtained using the  $\text{Co}_2(\text{CO})_8$  precursor, where the Co content in the grown nanodeposited material can be tailored up to more than 95%. Functional behaviour of these Co nanodeposits has been observed in applications such as arrays of magnetic dots for information storage and catalytic growth, magnetic tips for scanning probe microscopes, nano-Hall sensors for bead detection, nano-actuated magnetomechanical systems and

1  
2  
3 nanowires for domain-wall manipulation. The review also covers interesting results  
4  
5 observed in Fe-based and alloyed nanodeposits. Advantages and disadvantages of FEBID  
6  
7 for the growth of magnetic nanostructures are discussed in the article as well as possible  
8  
9 future directions in this field.

## 1. Introduction

### 1.1 Magnetic nanostructures

The field of nanomagnetism is nowadays one of the most active topics in condensed-matter and materials-science research, offering many opportunities (1). Successful applications of magnetic nanostructures have been found for instance in high-density information storage and magnetic sensing (2). One of the key events in this development was the discovery of giant magnetoresistance in magnetic nanostructures (3, 4), awarded with the Nobel prize in Physics in 2007 (5, 6), which opened the field of Spintronics. The magnetoresistance effect is applied for the sensitive detection of small stray fields produced by tiny magnetic information bits or magnetic beads and in non-volatile magnetic memories (7).

Another relevant application of magnetic nanostructures has been proposed, though not yet realized, based on the manipulation of domain walls in magnetic nanowires. Thus, the racetrack memory proposed by Parkin et al. (8) and the magnetic logic proposed by Allwood et al. (9) are promising applications based on the fast movement (in the scale of the nanosecond) of magnetic domain walls triggered by magnetic fields or current pulses. Intense research is developed at present aiming to produce domain-wall manipulation by spin-torque effects via injection of a spin-polarized current (10). Furthermore, this spin-torque mechanism can bring about the magnetization precession in certain conditions, producing the emission of radio-frequency waves with application as RF oscillators in telecommunication devices (11).

Another emergent field is that of magnetic biosensing, where magnetic nanoparticles tag biorecognition events and are detected by magnetic sensors such as giant or tunnel magnetoresistance sensors (12) or planar Hall sensors (13). From the detected signal, it is possible to obtain a quantitative determination of the concentration of a targeted analyte

1  
2  
3 (virus, hormone, enzyme, DNA strand, etc.) (14). Also in life-sciences applications, arrays  
4  
5 of highly-sensitive magnetic sensors are being developed for detection of the heart and brain  
6  
7 activity (15).  
8  
9

10 Most working devices in the field of magnetic nanostructures rely for their creation  
11 on a top-down approach. This implies the use of thin-film growth techniques and/or micro-  
12 and nano-lithography techniques (16, 17). The methods of choice should address crucial  
13 aspects such as resolution, roughness, shape, materials involved, cost, etc. For the growth of  
14 magnetic films by physical techniques, sputtering is usually preferred, even though thermal  
15 or electron-beam evaporation, molecular beam epitaxy and pulsed laser deposition are also  
16 frequently used (18). With respect to the lithography techniques used, optical lithography is  
17 normally preferred down to the micron scale and electron-beam lithography below the  
18 micron scale (17). Optical lithography relies on UV-sensitive light resists and is indeed able  
19 to reach resolution better than 22 nm in the state-of-the-art steppers used in the  
20 Semiconductor industry, but their huge cost impedes the use at the laboratory level. Electron  
21 beam lithography relies on electron-sensitive resists spun onto the sample and submitted to  
22 electron beam irradiation inside a Scanning Electron Microscope (SEM). Ion milling or lift-  
23 off processes permit to define nanostructures in the range of 100 nm and in some favourable  
24 cases down to 10 nm. However, some of the involved steps are critical and the final sample  
25 features can be far from ideal and affect the device functionality (19). In order to circumvent  
26 the use of resists and multiple-step lithography processes, direct patterning by focused-ion-  
27 beam is not rare, but this technique can strongly modify the magnetic properties of the  
28 materials, restricting its use (20). Nanoimprinting (and related techniques) has the potential  
29 to produce high throughput, thus being recommended for industrial applications, but the  
30 mold has to be grown with another lithography technique.

1  
2  
3 It is in this context that Focused Electron Beam Induced Deposition (FEBID) of  
4 magnetic materials is becoming a promising route for the direct growth of magnetic  
5 nanostructures in a single step. As will be developed along the next sections, this technique  
6 does not involve the use of resists, etching or lift-off processes, whereas maintaining the  
7 high lateral resolution down to the nanometric scale and being able to grow materials with  
8 appropriate magnetic properties.

## 20 1.2 FEBID technique

21 FEBID can be considered a beam-assisted Chemical Vapour Deposition (CVD) technique.  
22 But, in this case, the energy required to dissociate the precursor molecules is not thermally  
23 provided, as occurs in CVD, but by electron beam irradiation, whilst the substrate is  
24 generally maintained at room temperature. The precursor molecules are delivered onto the  
25 substrate surface by means of a nearby gas-injection system and the focused beam is  
26 scanned on the substrate, creating a deposit with the same shape of the beam scanning.

54 Figure 1 illustrates this process.

55 **Figure 1.** Sketch of Focused Electron Beam Induced Deposition (FEBID). This is an  
56 electron-assisted chemical growth technique giving rise to high-resolution patterning in a  
57 single step. The precursor molecules are locally dissociated by a Scanning Electron  
58 Microscope.  
59  
60

1  
2  
3 A few review articles (21-24) and books (25) on the FEBID technique are available  
4 and the reader is referred to such references for deeper understanding of this technique. An  
5  
6 important aspect to consider is that the energy of the bonds in the precursor molecules is in  
7  
8 the range of a few eV, implying that their dissociation is generally governed by the  
9  
10 secondary electrons produced in the substrate and the growing structure (26-28). This  
11  
12 phenomenon is important for the understanding of the achievable lateral resolution and the  
13  
14 appearance of a thin halo grown around the main deposit, as will be shown in the following  
15  
16 sections of this review.  
17  
18  
19  
20  
21

22 We note that, prior to the present review article, other publications have partially  
23  
24 addressed the specific topic of magnetic deposits with a relative broad perspective (29, 30).  
25  
26 However, such publications are not comprehensive review articles of the topic. Here, we  
27  
28 aim to include references to all published work so far on the topic of magnetic deposits by  
29  
30 FEBID technique.  
31  
32  
33  
34  
35

### 36 **1.3 Gas precursors for magnetic nanodeposits**

37  
38 The precursors used so far for magnetic nanodeposits by FEBID are collected in Table I  
39  
40 together with all the references that have reported their experimental use. The number of  
41  
42 these precursors is limited to a few but the number of references has strongly increased  
43  
44 during last years. It should be mentioned that practical issues limit the availability of  
45  
46 precursors for FEBID, as recently discussed by J. J. L. Mulders (31). For the sake of  
47  
48 completeness, we include in Table I references where these magnetic precursors were also  
49  
50 used for Focused Ion Beam Induced Deposition (FIBID), as well as for the growth of  
51  
52 magnetic alloys with two precursors simultaneously injected. In the case of cobalt,  
53  
54  $\text{Co}_2(\text{CO})_8$  is by far the precursor gas commonly used (29, 30, 32-93). The advantage of this  
55  
56 precursor is its low spontaneous dissociation temperature, around 100°C (94). This indicates  
57  
58  
59  
60

1  
2  
3 relative low bonding energies in this molecule, which is favorable for its dissociation by  
4  
5 electron irradiation in order to attain high metallic content. In fact, in 2002 the growth of Co  
6  
7 tips on AFM cantilevers by FEBID using that precursor was reported and magnetic imaging  
8  
9 of a hard disk was realized (34-36). The reported Co content reached 80% (34, 41), and that  
10  
11 large value was mainly ascribed to heating effects when using high beam current. Recent  
12  
13 studies enlarged the expectations of this precursor, as 95% Co content was reported when  
14  
15 the growth was performed under high electron beam current and using a field-emission  
16  
17 electron gun (42). Heating effects were definitely found to be important for the degree of  
18  
19 precursor dissociation (46, 57), although other effects are competing (45, 60) making  
20  
21 difficult to disentangle the role of all contributing effects. The good news is that using low  
22  
23 electron beam currents it is also possible to obtain deposits at room temperature with Co  
24  
25 content greater than 90% (60). Another cobalt-based precursor,  $\text{Co}(\text{CO})_3\text{NO}$ , has been  
26  
27 studied experimentally (34, 57, 95-100) but does not seem advantageous with respect to  
28  
29  $\text{Co}_2(\text{CO})_8$  regarding the achievable Co content.  
30  
31  
32  
33  
34  
35

36  
37 In the case of Fe-based nanodeposits, several carbonyl-based precursors have been  
38  
39 used such as  $\text{Fe}(\text{CO})_5$ ,  $\text{Fe}_3(\text{CO})_{12}$ ,  $\text{Fe}_2(\text{CO})_9$  and  $\text{Fe}(\text{C}_5\text{H}_5)_2$ . In 1987, Kunz and Mayer  
40  
41 reported the growth of 150 nm-wide iron wires by FEBID using the  $\text{Fe}(\text{CO})_5$  precursor (101,  
42  
43 102). The composition of the nanodeposits was not shown in that work. The spontaneous  
44  
45 thermal decomposition of  $\text{Fe}(\text{CO})_5$  on Si was found at 250 °C, and strong catalytic effects  
46  
47 were reported in that work. Only in 2004, Fe deposits by FEBID were again reported by  
48  
49 Shimojo et al., who described the formation of alpha-Fe and some carbides using the  
50  
51  $\text{Fe}(\text{CO})_5$  precursor and performing an annealing process (103). Since that moment, literature  
52  
53 on Fe-based nanostructures is more abundant and, for example, Zhang et al. reported the  
54  
55 growth of alpha-Fe nanocrystals on carbon grids (104). In 2005, Bruk et al. reported the use  
56  
57 of  $\text{Fe}_3(\text{CO})_{12}$  (105), whereas in 2006 Takeguchi et al. reported the use of  $\text{Fe}(\text{C}_5\text{H}_5)_2$  (106)  
58  
59  
60

1  
2  
3 and Lavrijsen et al. reported the use of  $\text{Fe}_2(\text{CO})_9$  in 2011 (107). Working under high-vacuum  
4 conditions, standard for SEM chambers, the Fe content using all the available Fe precursors  
5 seems limited to about 80% before annealing or purification processes (108) although the  
6 use of ultra-high-vacuum conditions has allowed Luckaszyk et al. to grow Fe  
7 nanostructures on Si substrates using the  $\text{Fe}(\text{CO})_5$  precursor with Fe content above 95%  
8 (109).  
9

10  
11  
12 Recently, a heteronuclear precursor,  $\text{HFeCo}_3(\text{CO})_{12}$ , has been used with total Fe  
13 plus Co content around 80% (110). For Ni deposition,  $\text{Ni}(\text{C}_5\text{H}_4\text{CH}_3)_2$  and  $\text{Ni}(\text{PF}_3)_4$  have  
14 been used for the growth of Ni-based deposits whereas  $\text{Ni}(\text{CO})_4$  has been discarded for its  
15 toxicity (111, 112).

## 2. Cobalt nanostructures by FEBID

### 2.1 Composition and microstructure

The main parameters determining the Co content in  $\text{Co}_2(\text{CO})_8$  will be discussed hereafter. The first reports, dating back to 2002, already stressed the influence of the electron beam current in the Co content (34). The use of high beam currents ( $\mu\text{A}$  range) permitted to reach Co contents up to 80%, but killing the lateral resolution due to the corresponding micrometric beam diameter (41). Substrate heating up to 58°C at 3  $\mu\text{A}$  beam current was put

1  
2  
3 forward to explain such dependence. The microstructure of the deposits was observed to be  
4  
5 composed of small (few nm) polycrystalline Co grains immersed in a carbonaceous matrix  
6  
7 (34, 41). Fernández-Pacheco et al. found that Co content up to 95% was feasible using a  
8  
9 field-emission electron gun, as shown in figure 2(a). At a low beam current of 0.1 nA, the  
10  
11 Co content was found to be 80% but rose to 95% when the beam current became greater  
12  
13 than 1 nA (42). Beam currents in the nA range impose limitations in lateral resolution.  
14  
15 Reaching resolutions below 100 nm is in general not possible with such current values.  
16  
17 However, by means of a heater, Córdoba et al. showed that it is possible to obtain high Co  
18  
19 content (above 90%) if the substrate is heated above 100 ° C even for beam currents as low  
20  
21 as 44 pA, as shown in figure 2(b) (46). Substrate heating was expected to favor precursor  
22  
23 dissociation, as later confirmed by Mulders et al. (57). This is in good agreement with the  
24  
25 expected low dissociation energy of bonds in the  $\text{Co}_2(\text{CO})_8$  molecule, which is thermally  
26  
27 decomposed around that temperature (46, 57, 94).

Despite the importance of thermal effects, there are other relevant growth parameters in FEBID impacting the final metal content of the deposits. For example, Bernau et al. found that residual hydrocarbon molecules in the chamber can contribute to the deposit composition but can be controlled by variations in the electron dwell time (45). As an example, figure 3 shows experiments in which the use of short dwell time gives rise to significant hydrocarbon decomposition compared to carbonyl decomposition, leading to only 20% Co content in the deposit. However, there is lack of enough hydrocarbon replenishment when the dwell time is long, which increases the Co content three times (45).

**Figure 3.** Atomic percentage of Co, C and O versus dwell time  $t_d$  (25 keV, 1 nA, 10 ms refresh time) in Co-C deposits grown in the presence of two adsorbates  $[\text{Co}_2(\text{CO})_8]$  and hydrocarbon. Reprinted from L. Bernau et al., *Angewandte Chemie*, 49, 8880–8884, Copyright (2010), with permission from WILEY. Ivo.Utke@empa.ch

Additionally, Serrano-Ramón et al. have shown that, besides the dwell time, the precursor flux is a tuning parameter of the metal content (60). As shown in figure 4, there is an optimum precursor flux that maximizes the Co content. The explanation is that at low precursor gas flux (precursor-limited regime) there is a significant amount of chamber

residual molecules that are decomposed compared to the number of Co molecules. Some atoms of such residual molecules become incorporated in the deposit. At high precursor flux, the amount of Co molecules outcomes the residual ones, and the probability of having more Co in the deposit increases. However, in this electron-limited regime, some bonds of the Co molecule cannot be dissociated, leading to C and O atoms in the deposit with origin in the  $\text{Co}_2(\text{CO})_8$  molecule itself. Thus, an optimum value of the precursor flux, at the crossover between the precursor-limited and electron-limited regimes is found. In that situation, even for low beam currents such as 21 pA (allowing lateral resolution of 30 nm) Co content greater than 90% is found (60). Similarly, Wachter et al. have reported the advantage of Co growth at the crossover between the precursor-limited and electron-limited regimes (82). Summarizing, thermal effects are not necessary to achieve high Co content as thought in the first studies, which makes possible to obtain simultaneously high Co content and lateral resolution.

**Figure 4.** Atomic percentage of Co, C and O as a function of the  $\text{Co}_2(\text{CO})_8$  precursor flux in nanodeposits grown at 3 kV and 21 pA. An SEM image of the typical cobalt squares grown

1  
2  
3 is shown in the inset. The relative change of precursor flux is here defined by the  
4  
5 expression: Precursor flux (%) =  $100 \times (P_{\text{process}} - P_{\text{base}}) / P_{\text{base}}$ . Reprinted with permission from

10  
11  
12  
13  
14  
15 In case that as-grown deposits present low Co content, it is possible to apply a post-  
16  
17 growth purification process to enhance the metal content. Begun et al. have investigated  
18  
19 several treatments to find that the most effective one is the combination of 300°C, H<sub>2</sub>  
20  
21 exposure and electron irradiation, which produces virtually-pure Co deposits from the  
22  
23 surface down to a depth of 20 nm (84).  
24  
25

26  
27 Regarding the microstructure of the Co deposits, detailed Transmission Electron  
28  
29 Microscopy (TEM) studies on low-Co-content and high-Co-content deposits have shown  
30  
31 their polycrystalline nature (50). The difference between both types of deposits is that low-  
32  
33 Co-content ones present isolated 2-3 nm Co grains immersed in a carbonaceous matrix,  
34  
35 whereas high-Co-content ones present a compact metal structure with 5-7 nm Co grains.  
36  
37 Electron diffraction indicates that the crystallographic structure of such grains is a mixture  
38  
39 of hexagonal-close-packed (hcp) and face-centered-cubic (fcc) ones (50). Gazzadi and  
40  
41 Frabboni have recently shown that the application of large electrical current through Co  
42  
43 nanowires produces structural changes, modifying the relative amount of hcp and fcc grains  
44  
45 (86).  
46  
47  
48  
49

50  
51 As mentioned before, Co(CO)<sub>3</sub>NO precursor molecule has also been studied as an  
52  
53 alternative to Co<sub>2</sub>(CO)<sub>8</sub> for Co deposition. Lau et al. found that high-current deposition from  
54  
55 this precursor results in autocatalytic growth due to temperature rise (34). Gazzadi et al. (95,  
56  
57 96) as well as Mulders et al. (57) found that this precursor produces deposits with around  
58  
59 50% Co content. Gazzadi et al. performed annealing procedures up to 400°C finding that  
60

1  
2  
3 despite the Co relative percentage does not vary significantly, there is a change of the Co  
4  
5 crystalline structure and grain size (86, 95).  
6  
7

8 Additionally, growth of Co nanostructures exploiting autocatalytic effects has been  
9  
10 observed on specific surfaces using  $\text{Co}_2(\text{CO})_8$  (62, 63) and  $\text{Co}(\text{CO})_3\text{NO}$  (99).  
11  
12

## 13 14 15 **2.2 Magnetic and electrical properties**

16  
17 The magnetic and electrical functionality of Co nanostructures grown by FEBID will depend  
18  
19 to a great extent on their composition and microstructure. In the previous section, we have  
20  
21 noted that these can vary significantly amongst different growth conditions. As a summary,  
22  
23 the set of results with  $\text{Co}_2(\text{CO})_8$  as precursor indicates that deposits with high Co content (>  
24  
25 90%) show metallic and ferromagnetic behavior, whereas deposits with low Co content (<  
26  
27 80%) show semiconducting and paramagnetic/super-paramagnetic behavior. Regarding  
28  
29 electrical properties, Lau et al. found electrical resistivity values equal to  $159 \mu\Omega\text{cm}$  in those  
30  
31 deposits with highest Co content (of  $\approx 80\%$ ), which is 25 times greater than pure Co (34).  
32  
33 Fernández-Pacheco et al. found significantly lower resistivity values, of  $40 \mu\Omega\text{cm}$  at 300K,  
34  
35 and  $27 \mu\Omega\text{cm}$  at 2 K, in deposits with 95% Co (42). Figure 5 shows some of these results,  
36  
37 including the temperature dependence of resistivity for this type of high-Co-content deposits  
38  
39 (figure 5(a)) and the Hall effect (figure 5(b)), where two contributions, the anomalous Hall  
40  
41 effect (proportional to the magnetization) and the ordinary Hall effect (linear with the  
42  
43 magnetic field and depending on the number of carriers) are observed. Similar results have  
44  
45 been observed in purified Co deposits, with metal content approaching 100% and resistivity  
46  
47 value of  $15 \mu\Omega\text{cm}$  at low temperature (84). On the other hand, Co content below 80% in  
48  
49 general gives rise to semiconducting behavior (42) and absence of clear separation of the  
50  
51 ordinary and anomalous Hall effects (48).  
52  
53  
54  
55  
56  
57  
58  
59  
60

**Figure 5.** (a) Resistivity-vs-temperature measurement for the wire shown in the inset, grown by FEBID, showing metallic behaviour. (b) Hall effect for this wire, measured at 300 K and 2 K. The indicated saturation field makes possible to obtain the saturation magnetization of the material. *Reproduced with permission from "Magnetotransport properties of high-quality cobalt nanowires grown by focused-electron-beam-induced deposition", by A. Fernández-Pacheco, et al, Journal of Physics D: Applied Physics 42, 055005 (2009). IOP Publishing Ltd.*

Regarding the magnetic switching behavior of Co structures by FEBID, deposits with metal content above 90% display conventional ferromagnetic behavior. Given that these deposits are polycrystalline with a small (5-7 nm) grain size, the magnetocrystalline anisotropy is averaged to zero and shape anisotropy governs the magnetization reversal. This was demonstrated by Fernández-Pacheco et al. on Co wires with the same length and thickness but varying width by means of Magneto-optical Kerr Effect (MOKE) measurements. As shown in Figure 6, the coercive field becomes larger as the width decreases due to the increasing shape anisotropy (44). As a consequence, the coercive field is easily tunable through modification of the dimensions of the Co nanostructures, as later also observed by Nikulina et al. (64).

**Figure 6.** (a-d) MOKE hysteresis loops for Cobalt FEBID rectangles of different aspect ratios: AR = 1 (a), 2 (b), 12 (c), 26 (d). (e) Coercivity of the rectangles as a function of its width, for two thicknesses, showing a  $1/\text{width}$  dependence. *Reproduced with permission from "Magnetization reversal in individual cobalt micro- and nanowires grown by focused-electron-beam-induced-deposition", by A Fernández-Pacheco et al, Nanotechnology 20 (47), 475704 (2009). IOP Publishing Ltd.*

The same type of high-content Co nanowires gives very good contrast in Magnetic Force Microscopy (MFM) measurements (54, 55), which allows the microscopic investigation of the magnetic state of these Co nanostructures. As Figure 7 shows, the magnetic remanent state in these Co wires depends on the aspect ratio for fixed length, as expected when shape anisotropy dominates. For narrow wires (width smaller than 400 nm), a mono-domain magnetic state occurs whereas magnetic domain walls are noticed in wider nanostructures (55).

**Figure 7.** (a) Topography and (b) MFM image of an array of Co wires with varying width. 2  
3 Electron holography and Lorentz microscopy inside a TEM have been carried out in  
4 order to investigate the magnetic state of Co nanowires grown by FEBID on Si<sub>3</sub>N<sub>4</sub>  
5 membranes (70, 71). The observed magnetic states are in good agreement with the  
6 performed micro-magnetic simulations in standard polycrystalline Co nanowires (71).  
7  
8  
9

10  
11  
12 On the other hand, low-Co-content deposits display super-paramagnetic behavior, in  
13 good agreement with their microstructure, formed by small isolated grains within a non-  
14 magnetic carbonaceous matrix, which, incidentally, is useful for the fabrication of Hall  
15 sensors with large sensitivity as shown by Gabureac et al. (48).  
16  
17  
18  
19  
20

21  
22 The work by Gazzadi et al. indicates that Co deposits grown with the Co(CO)<sub>3</sub>NO  
23 precursor are very resistive (6000 μΩcm), but an annealing procedure at 400 °C gives rise to  
24 Co nanowires with low resistivity at room temperature, 60 μΩcm, and metallic behavior as a  
25 function of temperature (96).

### 33 34 **2.3 High-resolution and densely-packed cobalt nanostructures**

35  
36 As introduced in section 2.1, it was soon understood that although the use of high beam  
37 current (μA range) could produce Co deposits with high metal content, the lateral resolution  
38 was in that case compromised (34) due to the increasing electron beam size with increasing  
39 beam current. This effect adds to the production of secondary electrons beyond the impact  
40 point, due to the interaction of the primary electron beam with the growing deposit as well  
41 as with the substrate, which further limits the lateral resolution (26, 145). The first approach  
42 to improve the lateral resolution is consequently the growth under low electron beam  
43 currents, in the pA range, with beam diameters of only a few nm. As discussed in 2.1, for  
44 the Co<sub>2</sub>(CO)<sub>8</sub> precursor, there are appropriate combinations of precursor flux and dwell time  
45 that permit the growth of Co nanostructures with high Co content (≈90%) and lateral  
46 resolution. In Figure 8, the best lateral resolution obtained by Serrano-Ramón et al. (≈30  
47

54 A very good lateral resolution has been reached even on non-conventional substrates  
55 such as flexible and transparent polycarbonate ones (87). As can be noticed in Figure 9, sub-  
56  
57  
58  
59  
60  
100 nm Co nanowires, with high Co content and metallic behavior, have been grown on this

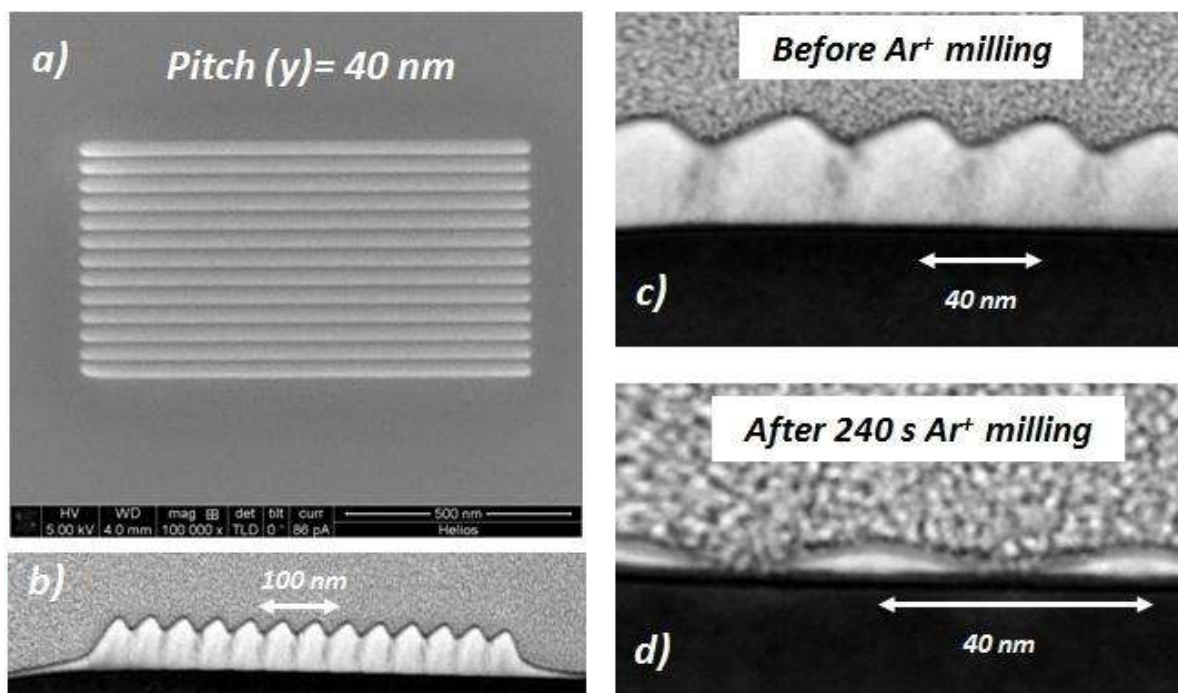

non-conductive substrate, opening new avenues for applications of this material in flexible electronics or magnetic sensing (87).

**Figure 9.** (a, b) Scanning electron micrographs of Co nanowires grown by FEBID on flexible and transparent polycarbonate substrates. An important issue in the area of nano-magnetism is the feasibility to integrate many nanostructures in a small space. This is for example the case for magnetic memories and logic applications. On the one hand, the FEBID technique is known to have a potential lateral resolution of a few nanometers in isolated structures (146). On the other hand, there

1  
2  
3 are practical limitations to attain such resolution in densely-packed structures, mainly  
4 dictated by the proximity effect present in FEBID. A small halo around the main deposit  
5 exists in FEBID deposits due to precursor dissociation by secondary electrons reaching far  
6 distances beyond the primary impact point (26). The thickness of this halo (in the range of  
7 10% of the thickness of the main deposit) rapidly falls with distance, and is in general not a  
8 problem for the functionality of isolated deposits. In the case of Co nanostructures, it has  
9 been shown that such halo structure in the vicinity of the main deposit at most modifies the  
10 magnetic coercive field (44). However, in densely-packed structures, a deposit grows in  
11 between the main structures that can be considerably thick, in the range of 50% of the  
12 thickness of the main deposit, as shown in Figure 10 (76). The route followed by De Teresa  
13 and Córdoba to fabricate arrays of densely-packed Co nanowires has been to grow in first  
14 place thickness-modulated deposits by fine control of the beam pitch (76). The pitch was as  
15 small as 30 nm. Figure 10 illustrates the case of 40 nm pitch. One can notice in that figure a  
16 crest-valley periodic structure in agreement with such small beam pitch value. A subsequent  
17 soft Ar<sup>+</sup> plasma post-processing decreases the deposit thickness quite homogeneously along  
18 the full deposit, which finally leads to a set of isolated Co nanowires separated by distance  
19 corresponding to the pitch value. With that approach it has been possible to fabricate  
20 isolated nanowires every 40 nm.

It is worth mentioning that Co nanowires have been grown by FEBID using a helium ion microscope (74). Although the lowest electrical resistivity reported in those nanowires (64  $\mu\Omega\text{cm}$ ) is higher than in some Co FEBID nanowires (see section 2.2), the lateral resolution of isolated nanowires is very good, down to 10 nm.

#### 2.4 Ion irradiation effects

Nikulina et al. have found that a significant amount of material is deposited in between Co pillar structures (caused by halo effects), which totally modifies the magnetic coupling between them as well as their magnetization reversal mechanism (68). These authors have

used a 1kV Xe<sup>+</sup> beam post-processing to get rid of such unwanted halo deposit, which minimizes the magnetic coupling amongst the pillars, separated around 200 nm as displayed in Figure 11.

**Figure 11.** Out-of-plane MOKE hysteresis loops and schematic sketches of possible magnetization reversal states for 2-dimensional arrays of FEBID cobalt nanopillars: as-deposited structures, having the pillars connected with the cobalt halo (a), (b) and Xe ion exposed with a dose of 120 mC/cm<sup>2</sup> (c), (d). The inset in (c) shows the optical image of the sample, and the dotted square defines the region of interest used for measuring the MOKE loops. Reprinted with permission from E. Nikulina, O. Idigoras, J. M. Porro, P. Vavassori, A. Chuvilin and A. Berger “Origin and control of magnetic exchange coupling in between focused electron beam deposited cobalt nanostructures”, *Appl. Phys. Lett.* **103**, 123112 (2013). Copyright 2013, AIP Publishing LLC.

Serrano-Ramón et al. have performed 30 kV Ga<sup>+</sup> irradiation on 2D Co nanowires, finding some important consequences (72, 73). Up to irradiation doses of 3x10<sup>16</sup> ions/cm<sup>2</sup>, the coercive field for magnetization reversal increases due to two main effects (72). The first effect is a decrease in the magnetic volume of the parasitic halo around the nanowire, which

1  
2  
3 leads to the disappearance of nucleation centers of domains. The second effect is the  
4  
5 formation of a 20 nm outer shell with Co crystals about twice the size of those forming the  
6  
7 core of the nanowire, causing a net increase of the local magnetocrystalline anisotropy. By  
8  
9 studying the behavior of both, nucleation and propagation fields of domain walls, it is  
10  
11 concluded that this type of global irradiation improves the overall magnetic behavior of the  
12  
13 nanowires significantly after irradiation doses in the range of  $1 \times 10^{16}$  ions/cm<sup>2</sup>. As expected,  
14  
15 high irradiation doses ( $> 4 \times 10^{16}$  ions/cm<sup>2</sup>) deteriorate the nanowires structurally and  
16  
17 magnetically (72).

## 24 **2.5 Three-dimensional Co nanostructures**

25  
26 One of the distinct features of FEBID is its capability to grow 3D structures. So far, most of  
27  
28 the work has been focused on the growth of out-of-plane Co nanowires (30, 34, 36, 66, 68,  
29  
30 81, 88, 90). The angle formed by the nanowire with the substrate can be controlled through  
31  
32 the tilting angle of the substrate with respect to the electron beam direction (66). Co  
33  
34 nanowires with shape of nano-spirals can be fabricated by scanning the beam in circular  
35  
36 form (30, 66). Some images of 3D Co nanowires grown by FEBID are displayed in Figure  
37  
38 12. The magnetization reversal mechanism of such 3D nanowires has been characterized by  
39  
40 means of MOKE measurements (66). Also, recent electron tomography-holography  
41  
42 measurements of a 3D Co nanowire grown on a special sample holder have allowed the  
43  
44 study of the spatially-resolved 3D magnetic state of the nanowire (90). Suspended 3D Co  
45  
46 nanowires have been investigated by Vavassori et al. for application in remote  
47  
48 magnetomechanical nanoactuation (92).

Fernández-Pacheco et al, Three dimensional magnetic nanowires grown by focused electron-beam induced deposition. Sci. Rep. 3, 1492 (2013). NPG.*

FEBID is more adequate than other lithography techniques for cantilever functionalization given the difficulty of using photo- or electron-beam- resists on cantilevers. This was already realized on the pioneer work by Utke et al. to fabricate Co nanowires at the apex of cantilevers for Magnetic Force Microscopy (MFM) (36). More recently, magnetic Co deposits have been grown on soft cantilevers suitable for Ferromagnetic Resonance Force Microscopy (FMRFM) experiments (61, 79). In particular, the spherical geometry is the most suitable for that application given that it minimizes the magnetic hysteresis of the tip. In Figure 13, we show examples of nano-spheres grown by

1  
2  
3 Sangiao, Casado and De Teresa in Zaragoza. The diameter of such nano-spheres ranges  
4  
5 from 100 nm to 500 nm and their magnetic moment has been characterized by Mofakhmi  
6  
7 and De Loubens in CEA-Saclay to find that nano-spheres with diameter above 150 nm  
8  
9 display magnetization values close to that of bulk Co,  $1370 \text{ emu/cm}^3$  (unpublished).

### 3. Fe nanostructures by FEBID

#### 3.1 Composition and microstructure

The group of Furuya et al. investigated Fe deposits grown by FEBID using the  $\text{Fe}(\text{CO})_5$  precursor along the period 2004 to 2007. They found that as-grown deposits consisted of a Fe:C nanocomposite with amorphous crystal structure which transformed into crystalline  $\alpha$ -

1  
2  
3 Fe and Fe-carbides phases after annealing processes at 600°C, (103), (117), (118). Also,  
4  
5 using mixtures of H<sub>2</sub>O and Fe(CO)<sub>5</sub> precursors, these authors achieved the growth of  
6  
7 crystalline Fe<sub>3</sub>O<sub>4</sub> at room temperature (122). Additionally, by using mixtures of Fe(C<sub>5</sub>H<sub>5</sub>)<sub>2</sub>  
8  
9 and Fe(CO)<sub>5</sub> precursors, the Fe content was controlled in the range 70%-30% (123).  
10  
11 Furthermore, electron-beam-post-irradiation of Fe structures grown by FEBID was found to  
12  
13 produce the formation of α-Fe nanocrystals (104). In certain growth conditions (high  
14  
15 precursor flux and long irradiation times), it was possible to observe the formation of α-Fe  
16  
17 nanocrystals at room temperature (124). The same effect of Fe-nanocrystal formation was  
18  
19 later observed by Rodríguez et al. using the Fe<sub>2</sub>(CO)<sub>9</sub> precursor under growth conditions of  
20  
21 high precursor flux and large beam current (144). Lavrijsen et al. used a mixture of H<sub>2</sub>O and  
22  
23 Fe<sub>2</sub>(CO)<sub>9</sub> precursors to produce amorphous Fe deposits at room temperature, with varying  
24  
25 Fe content in the range 50-80% (107). The growth of 3D nanopillars using the Fe(CO)<sub>5</sub>  
26  
27 precursor was found to be quite complex by Hochleitner et al. due to strong thermal effects  
28  
29 (130). The nanopillars and the planar Fe deposits that show an amorphous or nanocrystalline  
30  
31 structure, also present a 3-to-5-nm oxidized layer at the surface (134), (143), (144), (138).  
32  
33 The best reported Fe content (80-85%) in FEBID deposits grown in high-vacuum conditions  
34  
35 at room temperature without annealing have been obtained by Gavagnin et al. using the  
36  
37 Fe(CO)<sub>5</sub> precursor (134) and by Rodríguez et al. using the Fe<sub>2</sub>(CO)<sub>9</sub> precursor (144).

### 49 **3.2 Magnetic and electrical properties**

50  
51 Using the Fe<sub>3</sub>(CO)<sub>12</sub> precursor, Bruk et al. found that Fe deposits showed electrical  
52  
53 resistivity values in the range 10<sup>4</sup>-10<sup>9</sup> μΩcm (105). Lavrijsen et al. used a mixture of H<sub>2</sub>O  
54  
55 and Fe<sub>2</sub>(CO)<sub>9</sub> precursors, giving rise to deposits with resistivity values in the range 10<sup>2</sup>-10<sup>7</sup>  
56  
57 μΩcm (107) (142), to be compared with the value for pure Fe, of 10 μΩcm. A clear  
58  
59 correlation is observed between the Fe content and the resistivity, as shown in Figure 14.  
60

Measurements of resistivity as a function of temperature indicate that the residual resistivity value ( $\rho_{300K}/\rho_{2K}$ ) approaches 1 for deposits with 70% Fe whereas it decreases to 0.05 for deposits with 56% Fe, a signature of semiconducting behavior (142). A giant value of the anomalous Hall effect was found in these samples, ascribed to the large contribution of skew scattering (142).

**Figure 14.** Room-temperature resistivity versus Fe content for Fe wires. The line is a guide to the eye. Reprinted with permission from R Lavrijsen et al 2011 *Nanotechnology* 22 025302. Copyright (2011), IOP. DOI: 10.1088/0957-4484/22/2/025302; deteresa@unizar.es.

In the following, we will describe the magnetic properties of Fe-based nanostructures grown by FEBID. Takeguchi et al. reported in as-grown and annealed nanorods the use of electron holography to infer magnetic induction values of 0.61 T and 0.45 T respectively (117). These are significant values, corresponding unequivocally to ferromagnetic response, but far from the bulk value of  $\alpha$ -Fe, equal to 2.2 T. In samples fabricated from mixtures of

1  
2  
3 Fe(C<sub>5</sub>H<sub>5</sub>)<sub>2</sub> and Fe(CO)<sub>5</sub> precursors, where the Fe content was controlled in the range 70%-  
4  
5  
6 30%, electron holography measurements gave magnetic induction values from 0.8 T down  
7  
8 to 0.2 T (123). Lavrijsen et al. performed Kerr effect and magnetoresistance measurements  
9  
10 demonstrating the ferromagnetic character of the Fe deposits grown with the mixture of H<sub>2</sub>O  
11  
12 and Fe<sub>2</sub>(CO)<sub>9</sub> precursors (107) (142). From Hall-effect measurements on those samples, the  
13  
14 authors estimated saturation magnetization values scaling with the deposit Fe content. Thus,  
15  
16 the sample with 70% of Fe showed roughly 70% of Fe bulk saturation magnetization (107)  
17  
18 (142). Using the Fe<sub>2</sub>(CO)<sub>9</sub> precursor, Franken et al. grew Fe pillars by FEBID on top of  
19  
20 perpendicular magnetic domain-wall conduits which were able to pin moving domain walls  
21  
22 through the stray field created by the pillar (143).  
23  
24  
25  
26

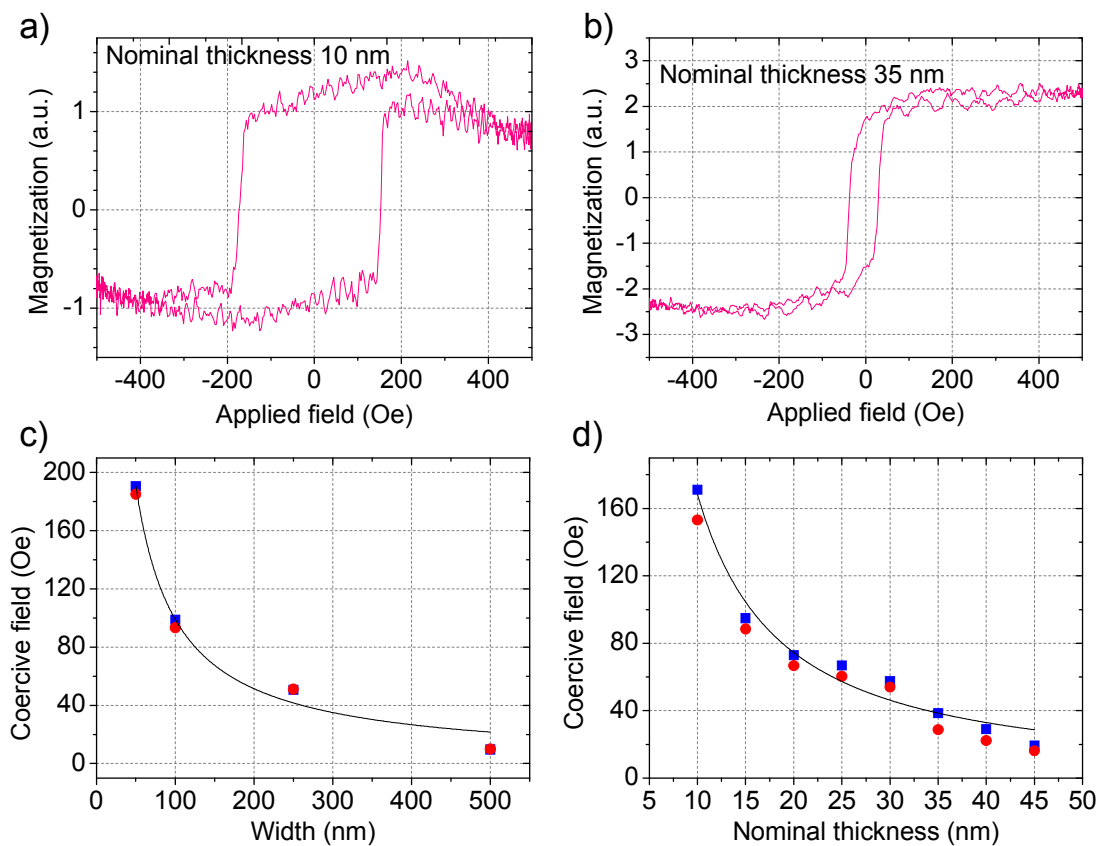

27 Gavagnin et al. fabricated small nano-magnets using the Fe(CO)<sub>5</sub> precursor for  
28  
29 application in nano-magnet logic, which were characterized by means of MFM  
30  
31 measurements. They found that for fixed length and width, the coercive field was different  
32  
33 for three different thicknesses. The same authors investigated by MFM the remanent  
34  
35 magnetic state of Fe deposits with different geometrical forms (136). As shown in Figure  
36  
37 15, good correspondence is found with the expected magnetic state when shape anisotropy is  
38  
39 the main anisotropy source in such nanomagnets.

Bertagnolli “Magnetic force microscopy study of shape engineered FEBID iron nanostructures”, *Phys. Status Solidi A*, 211, 368-374 (2014). Copyright 2014 WILEY-VCH Verlag GmbH & Co. KGaA, Weinheim.

Rodríguez et al. have fabricated Fe nanowires (Fe content above 80%) using the  $\text{Fe}_2(\text{CO})_9$  precursor (144). These nanowires present lengths of 4.5  $\mu\text{m}$  and varying thickness (10 to 45 nm) and width (50 to 500 nm). A summary of the MOKE results in these samples is shown in Figure 16, where it can be noticed that the coercive field decreases with increasing width and thickness. Thus, the coercive field can be easily tuned by adjusting the dimensions of the nanowire. Micromagnetic simulations indicate that such dependence can be explained by magnetization reversal taking place via non-coherent magnetization rotation. The characteristic bell-shape of the deposits and the surface oxidation are also

found to be relevant parameters in the exact value of the coercive field for each nanowire (144).

**Figure 16.** MOKE hysteresis loop of an Fe nanowire with 10 nm thickness (a) and 35 nm thickness (b). Dependence of the coercive field with width at fixed thickness of 25 nm (c) and with thickness at fixed width of 250 nm (d). *Reproduced with permission from Rodriguez LA, Deen L, Cordoba R, Magen C, Snoeck E, Koopmans B, et al. ### 3.3 Fe deposits in ultra-high-vacuum conditions

The group of H. Marbach et al. has investigated Fe deposition in UHV conditions using the  $\text{Fe}(\text{CO})_5$  precursor. In 2008, Lukasczyk et al. reported the growth of Fe nanostructures with

1  
2  
3 95% of Fe content, which was attributed to the ultra-clean conditions of the chamber and the  
4  
5 Si substrate surface (109). By working on perfectly-clean and less-clean Rh (110) surfaces,  
6  
7 Lukasczyk et al. have revealed the importance of the surface to produce catalytic-driven  
8  
9 precursor decomposition (131). The catalytic growth-rate enhancement under certain growth  
10  
11 conditions using the  $\text{Fe}(\text{CO})_5$  precursor had already been observed by Kunz and Meyer  
12  
13 (101). Walz et al. have found that electron irradiation of  $\text{SiO}_2$  surfaces prior to gas dosing  
14  
15 produces active SiO sites that decompose the  $\text{Fe}(\text{CO})_5$  molecules without the need of  
16  
17 electron-beam direct dissociation (147). After nucleation of the first Fe clusters, nanocrystal  
18  
19 formation proceeds via auto-catalytic decomposition of the  $\text{Fe}(\text{CO})_5$  precursor. This  
20  
21 procedure has been coined *Electron Beam Induced Surface Activation* (EBISA) and the  
22  
23 topic has been recently reviewed by H. Marbach (148). As displayed in Figure 17, Fe micro-  
24  
25 wires prepared by EBISA show electrical resistivity of  $88 \mu\Omega\text{cm}$  at room temperature (132),  
26  
27 still far from the bulk Fe value ( $10 \mu\Omega\text{cm}$ ) but lower than the value of  $186 \mu\Omega\text{cm}$  displayed  
28  
29 by micro-wires with 70% Fe content grown in high-vacuum conditions and studied by  
30  
31 Córdoba et al. (142). From Hall resistivity measurements in the same EBISA samples,  
32  
33 Porrati et al. (132) estimated a saturation magnetization of 1.47 T, which is similar to the  
34  
35 value found by Córdoba et al. (142). The tendency of Fe deposits to surface oxidation can be  
36  
37 avoided by the growth of a protective capping layer, as carried out by Schimer et al. with a  
38  
39 second titanium-oxide deposit (133). Fe deposits grown by EBISA have permitted  
40  
41 fundamental studies related to the proximity effect (149) (150). In fact, using  $\text{TiO}_2$   
42  
43 substrates and the EBISA technique, Vollnhals et al. have fabricated Fe nanowires of width  
44  
45 about 20 nm (151).

#### 4. Ni and alloyed nanostructures

##### 4.1 Ni nanostructures

Perentes et al. investigated the growth of Ni nanostructures using the  $\text{Ni}(\text{PF}_3)_4$  and  $\text{Ni}(\text{C}_5\text{H}_4\text{CH}_3)_2$  precursors (111). The maximum Ni content obtained was 40% and 10% respectively. The minimum electrical resistivity achieved was respectively  $10^3 \mu\Omega\text{cm}$  and  $10^6 \mu\Omega\text{cm}$ , much larger than that of pure Ni,  $6.9 \mu\Omega\text{cm}$ . These authors also tried simultaneous injection of molecular flows of oxygen and hydrogen with the Ni precursors, without improvement of the Ni content (111). More recently, Córdoba et al. have extended

1  
2  
3 the research on Ni deposits using  $\text{Ni}(\text{C}_5\text{H}_4\text{CH}_3)_2$  (112). The as-grown deposits display a  
4  
5 maximum Ni content of 18% by FEBID and 22% by FIBID. A post-treatment process has  
6  
7 been performed at room temperature, consisting of electron beam irradiation under oxygen  
8  
9 flux, which gives rise to carbon removal and the appearance of the cubic NiO species in  
10  
11 polycrystalline form (with 5 nm grain size). The as-grown FEBID Ni deposits show an  
12  
13 electrical resistivity value at room temperature of  $\approx 10^7 \mu\Omega\text{cm}$ , whereas the FIBID one of  
14  
15  $\approx 10^5 \mu\Omega\text{cm}$ . Both deposits display semiconducting behavior as a function of temperature.  
16  
17  
18 The post-processed Ni deposits, with NiO stoichiometry, have very large resistivity values,  
19  
20  $\approx 10^9 \mu\Omega\text{cm}$ . Such NiO deposits exhibit potential resistive-switching and exchange-bias  
21  
22 phenomena (112). It is also worth mentioning that,  $\text{Ni}(\text{CO})_4$  has never been used for FEBID  
23  
24 due to the high toxicity of the Ni radical (31) .  
25

29  
30  
31

## 32 **4.2 Co and Fe alloys**

33  
34 The main route to achieve the growth of Co and Fe alloys by FEBID has consisted of the  
35  
36 simultaneous use of two precursors during growth plus subsequent annealing procedures.  
37  
38 Following this route, Che et al. synthesized  $L1_0$  Fe-Pt alloy nanorods at 600 °C that showed  
39  
40 high magnetic induction values ( $\approx 1.5$  T) as measured by electron holography (121). The  
41  
42 same group used later a modified sequence of deposition and annealing procedures to  
43  
44 achieve various Fe-Pt alloys (125). Porrati et al. obtained  $L1_0$  Co-Pt alloys by using two  
45  
46 simultaneous precursors plus a room-temperature post-electron-irradiation process (65).  
47  
48 Interestingly, Dobrovolskiy et al. have carried out controlled post-processing with mesoscale  
49  
50 lateral resolution, which permits to tune the coercive field locally (85) . The same group has  
51  
52 also fabricated Co-Si alloys by simultaneously injecting two precursors which relative flux  
53  
54 can be controlled, producing alloys with tunable Co/Si content and corresponding  
55  
56 modulation in the electrical resistivity (69). Shawrav et al. have grown in a similar way Fe-  
57  
58  
59  
60

1  
2  
3 Au nanoalloys (139). In general, this route is able to produce nano-crystalline alloys at room  
4 temperature but with a substantial amount of residual species, typically carbon.  
5  
6

7  
8 Another strategy followed by Tanaka et al. was to synthesize iron silicide arrays of  
9 nano-rods or nano-triangles by using  $\text{Fe}(\text{CO})_5$  precursor, Si(111) substrates, high substrate  
10 temperature and electron deposition in a TEM (152). Nano-rods as long as 100 nm and 10  
11 nm in width were grown in this way (153). When the same authors used Si(110) substrates,  
12 beta- $\text{FeSi}_2$  islands were formed instead (126).  
13  
14  
15  
16  
17  
18

19  
20 On the other hand, Pérez-Roldán et al. have grown nano-pillars by FEBID using  
21 simultaneously  $\text{Co}_2(\text{CO})_8$  and  $\text{Si}(\text{OC}_2\text{H}_5)_4$  precursors, finding that the growth of Co occurs  
22 at the outer part of the pillar (88). This forms a kind of Co magnetic tubule filled with non-  
23 magnetic silicon oxide. The ferromagnetic properties are thus exclusively localized at the  
24 outer part of the structure as revealed by electron holography. Compositionally-  
25 inhomogeneous deposits at the nanoscale had been previously observed in FIBID deposits  
26 using two precursors,  $\text{W}(\text{CO})_6$  and  $\text{C}_{10}\text{H}_8$  (154). Precursor competition with relevant  
27 kinetical processes upon certain growth conditions is the underlying reason for that  
28 intriguing behavior, which could be of general occurrence in co-deposition.  
29  
30  
31  
32  
33  
34  
35  
36  
37  
38  
39  
40

41 Recently, Porrati et al. have used a single bimetallic precursor,  $\text{HFeCo}_3(\text{CO})_{12}$ , to  
42 directly grow an alloy (110). The composition of the deposits is roughly Co:Fe:C:O=  
43 60%:20%:10%:10%. The lowest room-temperature resistivity found is  $43 \mu\Omega\text{cm}$  and the  
44 maximum magnetic induction is estimated to be  $\approx 1.6$  T. TEM measurements indicate that  
45 the deposits consist of a bcc Co-Fe phase mixed with a  $\text{FeCo}_2\text{O}_4$  spinel oxide phase with  
46 nanograins about 5 nm.  
47  
48  
49  
50  
51  
52  
53  
54

55 It is pertinent to mention that some magnetic alloys grown by FIBID have been  
56 reported. Thus, Xu et al. grew FePt and CoPt micro-particles using two precursors  
57 simultaneously and performing an annealing process at  $600^\circ\text{C}$  to crystallize the particles  
58  
59  
60

1  
2  
3 (113). Pogoryelov and Suzuki used three precursors simultaneously to grow FeCoPt ternary-  
4 alloy micro-particles which showed different magnetic properties before and after annealing  
5  
6 at 600°C (141) .  
7  
8  
9

## 10 11 12 **5. Applications of magnetic nanostructures by FEBID**

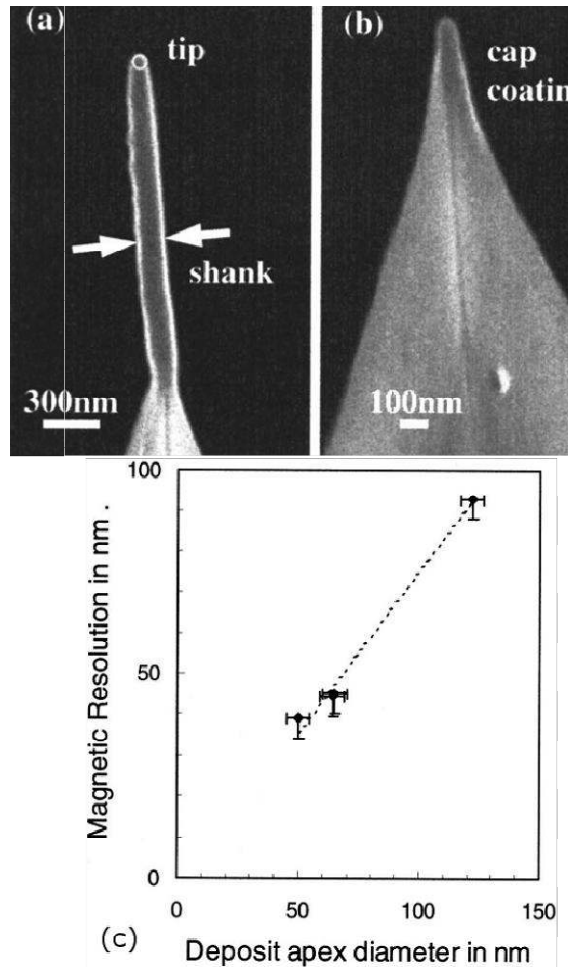

13  
14  
15  
16  
17 In the following subsections, the most important applications reported so far for magnetic  
18 nanostructures grown by FEBID will be described.  
19  
20  
21

### 22 23 24 **5.1 Magnetic dots for magnetic storage and catalytic growth**

25  
26 Dots grown by FEBID can have very small dimensions, in the nanometer range, as already  
27 demonstrated using Pt precursor (155). However, the requirements of current magnetic-  
28 recording technology are very stringent (2, 156). For example, the magnetic anisotropy of  
29 the recording units should be large enough to retain the information for long periods of time.  
30  
31 The present limitations in the chemistry of precursors and the difficulties in tailoring the  
32 crystal structure make quite improbable the use of magnetic dots grown by FEBID for this  
33 application. Nevertheless, the potential of beam-induced deposition for growing magnetic  
34 dots with small periodicity has been demonstrated (32) (33) (37) (38) (116) (120) and an  
35 interesting application of this type of structures in catalysis has been demonstrated by Ervin  
36 and Nichols (100). These authors used Co deposits grown with different doses to catalyze  
37 the growth of carbon nanotubes (CNTs). They found that at low doses no growth of CNTs  
38 occurred, whereas at intermediate and high doses single-wall and multi-wall CNTs were  
39 grown respectively. These differences were ascribed to the Co nanoparticle size variation

## 5.2 Growth of MFM and FMRFM tips

For applications in high-resolution Atomic Force Microscopy, carbon-based tips grown by FEBID have been proposed (157). The high aspect ratio of the apex achievable in such tips made them to be coined *supertips*. For the study of magnetic samples, MFM tips are usually fabricated by evaporating a magnetic layer on an AFM cantilever (158). This implies that the magnetic interaction between tip and sample is somehow delocalized, which can lead to a loss of sensitivity and lateral resolution. Utke et al. challenged the growth of Co *supertips* for MFM studies (35) (36). As shown in Figure 18, the advantage of FEBID is the precise growth of the magnetic tip at the apex of a cantilever with controlled tip dimensions. Such tips were used to image the magnetic bits of a hard disk, reaching magnetic imaging resolution of 40 nm (36). Subsequent work by Belova et al. has improved the resolution of Co magnetic tips down to 10 nm (61). On the other hand, Gavagnin et al. have grown Fe tips using FEBID for MFM where the importance of the tilt angle of the magnetic tip with respect to the scanned sample has been revealed (138).

**Figure 18.** Scanning electron micrographs of typical FEB deposits. A high-aspect-ratio magnetic tip on top of a pyramidal Si tip is shown in (a). Deposition parameters are 133 pA at 25 kV during 2 min. The tip apex diameter is 72 nm, the shank diameter 160 nm, and the tip length is 1.7mm. Magnetic cap coatings (b) are deposited at 100 pA, 25 kV, and 5 s resulting in 50 nm of apex diameter. (c) MFM resolution of several FEB deposits measured under ambient conditions with the lift-retrace tapping mode. The magnetic resolution corresponds to the smallest resolved magnetic transition. The resolution error is assumed as one half of the difference of the smallest resolved transition and the adjacent nonresolved transition. The dashed interpolated line has a slope of 0.8. *Reprinted with permission from [I. Utke et al., Applied Physics Letters 80, 4792 (2002)]. Copyright [2002], AIP Publishing LLC.*

Another interesting application of magnetic deposits by FEBID in the field of scanning microscopies has been recently unveiled. As introduced in section 2.5, FMRFM experiments are based on magnetic resonance force microscopy, where the magnetic resonance of a magnetic sample is sensitively detected through the magnetic force exerted on a cantilever equipped with a small magnetic tip (159). A soft cantilever is commonly used with a magnetic nanosphere glued at the apex (160). The spatial resolution of the technique is directly linked to the size of the nanosphere. Gluing a sub-micron particle to the apex of a cantilever tip is a painstaking work that can be substituted by directly growing it by FEBID. Using FEBID Co nanoparticles, very successful FMRFM experiments have been performed so far (161) (162) (163) (164) (165) (166) .

### 5.3 Nano-Hall sensors for bead detection

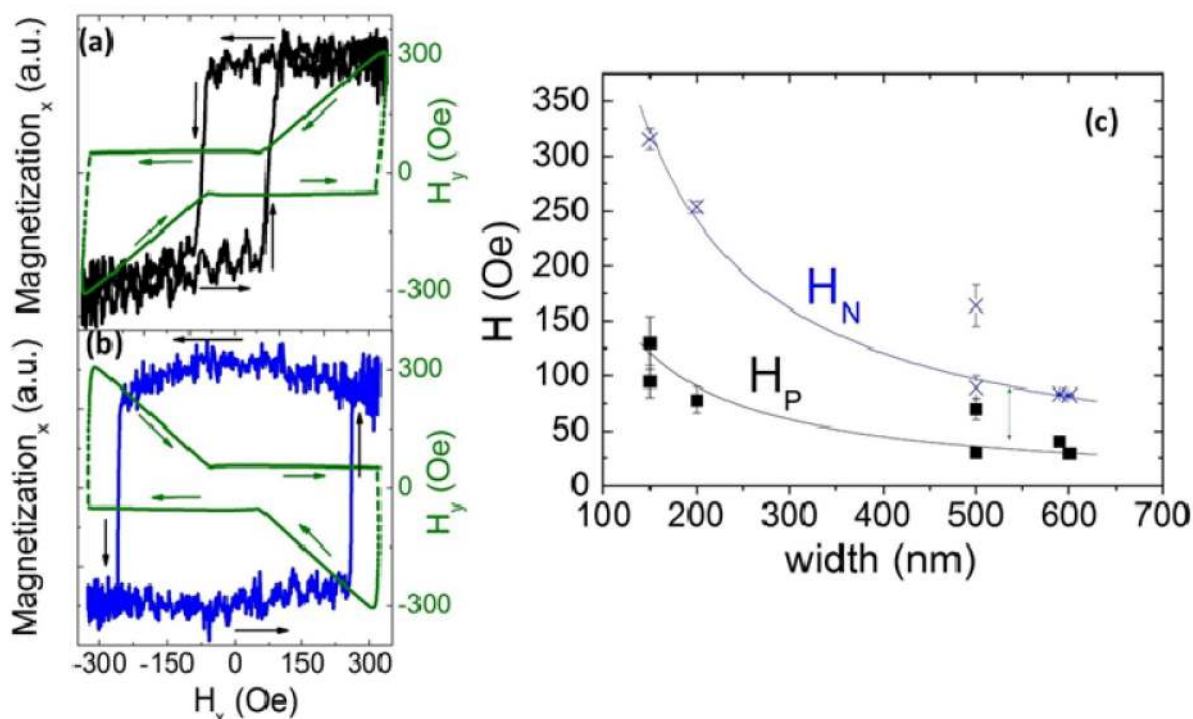

In a Hall sensor, the voltage output changes as a function of magnetic field due to the Hall effect, which generates a transverse voltage perpendicular to the passing current. The voltage output is governed by the properties of the material and the existing external magnetic field. In general, the Hall sensor is based on either a semiconductor material with a linear response as a function of the external magnetic field due to the ordinary Hall effect or a magnetic material with an additional contribution due to the anomalous Hall effect (167). Hall sensors with high spatial resolution are interesting in diverse applications: in biosensing for the detection of biological moieties conjugated to magnetic nanoparticles (13), in scanning Hall microscopy (168), in nano-magnetometry (169), in magnetic logic applications (170), etc. Boero et al. reported that sub-micrometric Co Hall sensors can be grown by FEBID with good sensitivity (40). Further work demonstrated the great potential of such Co Hall sensors, with minimum magnetic flux detectable in the range of  $10^{-6} \times \Phi_0$ , where  $\Phi_0$  is the quantum of flux (48) (60). This value is very competitive compared to other

1  
2  
3 nanoscale Hall sensors and was achieved by carefully tuning the composition and  
4 dimensions of the Co-based FEBID deposit. An experiment with controlled approximation  
5 of a magnetic bead to the Co-based Hall sensor was performed by Gabureac et al. (67). By  
6 performing the experiment in a SEM chamber, the Hall sensor output is monitored at the  
7 same time that the bead is controllably approached to the device. On the other hand,  
8 Córdoba et al. have fabricated Hall structures based on Fe deposits grown by FEBID (142).  
9 These authors have found a giant anomalous Hall effect in these structures due to their high  
10 resistivity, which gives rise to large skew-scattering phenomena.  
11  
12

#### 25 **5.4 Nanowires in 2D and 3D for domain-wall manipulation**

26 The concept of domain-wall conduit was introduced in 2002 by Cowburn et al. to illustrate  
27 the unperturbed propagation of magnetic domain walls inside a magnetic material (171).  
28 Such behavior implies that the magnetic field required to displace a domain wall within the  
29 nanowire (the propagation field) is lower than the magnetic field required to create new  
30 domain walls (the nucleation field). This effect can be applied for applications in magnetic  
31 logic (9) as well as in racetrack memories (8). Fernández-Pacheco et al. demonstrated that  
32 2D Co nanowires grown by FEBID sustain unperturbed propagation of domain walls (43).  
33 Figure 19 illustrates such behavior. L-shaped nanowires were grown in order to measure the  
34 nucleation and propagation fields of domain walls in this material. The results indicated that,  
35 in the range of nanowire dimensions studied, the propagation field is lower than the  
36 nucleation field. The most appropriate dimensions for optimized domain-wall conduit  
37 behavior were later determined by Rodríguez et al. using Lorentz microscopy (71). These  
38 authors concluded that such dimensions were related to the crossover between the formation  
39 of transverse and vortex domain walls.

Domain wall conduit behavior in cobalt nanowires grown by focused electron beam induced deposition. Applied Physics Letters. 2009;94(19):192509. Copyright 2009 AIP Publishing LLC.*

Additionally, Serrano-Ramón et al. found that an improvement in the domain-wall-conduit behavior of 2D Co nanowires grown by FEBID was achievable by high-voltage global  $\text{Ga}^+$  irradiation (72), as mentioned in section 2.4. This was linked to the structural and micro-structural changes produced by the highly-energetic irradiation. Moreover, local  $\text{Ga}^+$  irradiation was found to pin domain walls efficiently at well-localized areas, as directly observed by means of scanning transmission x-ray microscopy (73).

1  
2  
3 The domain-wall-conduit behavior has not been proved in FEBID Fe nanowires so  
4 far. Micromagnetic simulations performed by Rodríguez et al. in 2D nanowires indicate that  
5 the magnetization reversal is quite complex and not via simple transverse or vortex wall  
6 nucleation and propagation (144). The domain-wall-conduit behavior in 3D magnetic  
7 nanowires grown by FEBID is still an open question too, although Fernández-Pacheco et al.  
8 suggested that it could be the case in 3D Co nanowires (66).

17 Another application has been demonstrated by Franken et al., who have used Fe  
18 nanopillars grown by FEBID on top of perpendicular domain-wall conduits to pin domain  
19 walls in a controllable way (143). The positive or negative stray field produced by the Fe  
20 nanopillars on the magnetic domain-wall conduit is used to stop or let pass the  
21 corresponding domain wall under the pillar.

### 32 **5.5 Spintronics and nanomagnetism**

33 Spintronics relies on the spin degree of freedom of the electron to build electronic devices  
34 (172) (173). Spintronics is currently at the basis of many types of memories and sensing  
35 schemes (5) (7) (8) (174). One of the most successful devices is a magnetic tunnel junction,  
36 consisting of two magnetic layers separated by an insulating layer. The current proceeds via  
37 spin-polarized tunneling and gives rise to large magnetoresistance ratios beyond 500% at  
38 room temperature (175). This has been achieved through complex engineering of the  
39 thickness, composition and crystallographic structure of all the layers forming the  
40 magnetoresistive stack. Constanzi et al. have challenged the growth of magnetic tunnel  
41 junctions using Co electrodes and SiO<sub>2</sub> barrier, all grown by FEBID (75). Unfortunately, the  
42 obtained 0.5% magnetoresistive ratio, comparable to the anisotropic magnetoresistance  
43 value of Co, 0.8% (42), is three orders of magnitude below the state of the art, and has little  
44 chances of applicability without further development. One of the potential issues in the

2  
3 grown device is the quality and nature of the barrier, which is known to play a central role in  
4 magnetic tunnel junctions (176). It is worth mentioning that Sangiao et al. have measured a  
5 high spin polarization (40%) for Co grown by FEBID in Andreev reflection measurements  
6 (59). This value is close to that measured for Co grown by sputtering (177). This means that,  
7 in principle, Co grown by FEBID can be used efficiently in spintronic devices as an active  
8 element. It is also worth mentioning the work by Fernández-Pacheco et al. regarding the  
9 fabrication of Co nanoconstrictions grown by FEBID in a single step (93). The good  
10 correlation between the magnetoresistive behavior of such nanoconstrictions and their  
11 magnetic state probed by scanning transmission x-ray microscopy is indicative of the good  
12 functionality of this material down to the nanoscale (93).

60  
Other routes have been followed by the group of M. Huth to apply FEBID materials  
in the field of Spintronics and Nanomagnetism. Pohlit et al. have grown artificial square spin  
ice structures based on Co nanowires grown by FEBID (89) (91). Artificial spin ice  
structures, characterized by geometrical frustration, are being studied for their exotic  
physical behavior and are potential candidates for memory devices (178). The results by  
Pohlit et al. point towards magnetization reversal statistically following different paths most  
likely driven by thermal perturbations (89). The differences between the magnetic behavior  
of isolated Co nanoislands grown by FEBID and the cluster formed by several interacting  
Co nanoislands have been highlighted by the same authors (91). On the other hand, Porrati  
et al. have fabricated Co nanopillars embedded in a Pt-C nano-granular matrix to achieve  
magnetoresistive effects (81). All the constituents of the device have been grown by  
FEBID. The value of the magnetoresistive effect measured at 4 K is low, below 6%.  
Besides, Lara et al. have fabricated circular Co disks by FEBID, designing holes by FIB in  
order to investigate their magnetization reversal through metastable states with half  
antivortices (80). The device is shown in Figure 20. The pinning landscape provided by the

holes guide the magnetization reversal. The authors argue that the finding is relevant for the development of multi-hole spintronic and magnetic memory devices.

**Figure 20.** The top left panel shows an optical image of the high frequency probe and the gold contacts to which it is attached. The other three panels show SEM images of the Co dots deposited by FEBID between the gold contacts. Three cases are shown: without nanoholes, with two nanoholes, and with three nanoholes. *Reprinted with permission from A. Lara et al., Applied Physics Letters 105, 182402 (2014). Copyright [2014], AIP Publishing LLC.*

The recent use of 3D Co nanowires for magnetomechanical actuation is another promising route of work. The authors foresee applications in fields such as nano-biomechanics, nano-optics and nano-transport (93).

### 5.5 Nano-magnetic logic

Highly-integrated nanomagnets with dipolar coupling have been proposed for application in logic computing, the field being coined nanomagnet logic (179). Different logic gates have

1  
2  
3 been demonstrated using materials such as Permalloy or Co/Pt films grown by sputtering  
4  
5 (180). Gavagnin et al. have used 2D Fe nanomagnets grown by FEBID to build  
6  
7 demonstrative logic gates (134). As an example of this, a NAND/NOR logic gate is shown  
8  
9 in Figure 21. The same group later showed the capability of FEBID to fabricate 3D logic  
10  
11 gates using again Fe deposits (138).

## 5.5 Combination of magnetic deposits with superconductors

The group in Zaragoza demonstrated for the first time functional devices combining magnetic nanostructures grown by FEBID and superconducting nanostructures grown by FIBID (59) (58). The device, shown in Figure 22, consists of a nanocontact between the magnetic Co FEBID deposit and the superconductive W FIBID deposit. Such nanocontacts have allowed the extraction of important material parameters such as the spin polarization of the magnetic material and the superconducting gap (59). The value of the superconducting gap extracted from these experiments is in agreement with direct scanning tunneling microscopy experiments, which stresses the capability of preparing clean nanocontacts by FEBID/FIBID techniques with a single (or very few) conduction channel (181). Subsequent experiments in nanocontacts with worse definition or cleanliness gave rise to multi-channel transport (83). In fact, the experiments are difficult and, for example, the growth order is critical. If the FIBID superconducting deposit is grown after the magnetic one, the use of ions can degrade the magnetic properties of the nanocontact (182).

**Figure 22.** (a) Artificially coloured scanning electron micrograph of a Co-W nanocontact created for current-in-plane Andreev Reflection measurements. (b) Temperature dependence of the normalized differential conductance of a Co-W nanocontact as a function of the applied voltage. Solid lines are fits to the extended BTK model. *Reprinted from Solid State Communications vol. 151, S. Sangiao et al., Ferromagnet-superconductor nanocontacts grown by focused electron/ion beam techniques for current-in-plane Andreev Reflection measurements, 37-41, Copyright (2011), with permission from Elsevier.*

In another application followed by the group of M. Huth, arrays of Co stripes have been grown by FEBID on superconductive Nb films to create uniaxial pinning potentials for

1  
2  
3 the movement of the vortex lattice (115) (47). Transport measurements in the  
4  
5 superconductor confirm the expectation of an anisotropic behavior induced by the uniaxial  
6  
7 pinning (47) as well as steps ascribed to matching effects between the Co line periodicity  
8  
9 and the vortex lattice periodicity (51).  
10  
11  
12

## 13 14 15 **6. Summary and outlook**

16  
17 In the previous sections, the state-of-the-art usage of FEBID for the growth of magnetic  
18  
19 nanostructures has been described. As a brief summary, since 2009 there is a revived interest  
20  
21 in the growth of magnetic nanostructures by FEBID. In the following, our view on the  
22  
23 expected evolution of the topic will be given. We focus on the main aspects involved in the  
24  
25 topic, first on the growth, later on the applications themselves:  
26  
27

28  
29       Regarding the growth, these are our views:  
30

31  
32       -*New precursors for magnetic deposits:* As shown in Table 1, the available  
33  
34 precursors for growth of magnetic materials by FEBID are scarce. Recently, Porrati et al.  
35  
36 introduced a heteronuclear precursor containing Fe and Co atoms (110). The total amount of  
37  
38 metal content (Fe+Co) in the grown deposits was 80%. New developments in precursor  
39  
40 chemistry for the growth of alloyed magnetic materials are expected. In particular, the  
41  
42 incorporation of rare-earth atoms in such precursors could be advantageous in certain  
43  
44 applications in magnetism. In general, one of the limitations in the use of FEBID compared  
45  
46 to other growth techniques such as sputtering is the lack of fine control in the final  
47  
48 composition of the grown material.  
49  
50

51  
52       -*New strategies for purification of deposits:* Although a high metal content (above  
53  
54 80%) can be currently achieved in magnetic deposits grown at room temperature using Co-  
55  
56 based and Fe-based carbonyl precursors, in some applications metal values close to 100%  
57  
58 may be necessary. This is why purification methods such as those recently developed for  
59  
60

1  
2  
3 magnetic materials are desired (84). In fact, such strategies should be easy to implement for  
4  
5 broad dissemination.  
6

7  
8 *-Growth of alloys by co-deposition:* As described in section 4, very little work has  
9  
10 been performed towards the growth of alloys by co-deposition. In some cases, the  
11  
12 achievement of the searched crystallographic phase calls for high-temperature annealing  
13  
14 processes. New magnetic alloys are expected to be grown by FEBID in the coming years to  
15  
16 enlarge its applicability.  
17

18  
19 *-Multi-layer deposition:* For some magnetic devices like magnetic tunnel junctions, a  
20  
21 stack of several materials should be grown. FEBID is well-suited for sequential deposition  
22  
23 of materials and one can expect new strategies in this direction. The combination of  
24  
25 magnetic materials with other functional materials (superconductive, optically-active,  
26  
27 insulating, etc.) seems attractive to explore beyond the few existing examples discussed in  
28  
29 section 5.  
30  
31

32  
33 *-Combination of FEBID with other growth or lithography techniques:* FEBID  
34  
35 technique has been combined with Atomic Layer Deposition (ALD) for the growth of pure  
36  
37 Pt nanostructures (183) (184) (185). Finding compatible FEBID-ALD processes for the  
38  
39 growth of pure magnetic nanostructures would be an exciting new route. FEBID has been  
40  
41 combined with FEBIE (Focused Electron Beam Induced Etching) to create  $\text{CoF}_3$  material  
42  
43 (77), which is known to be an antiferromagnetic material. This could potentially give rise to  
44  
45  $\text{Co}/\text{CoF}_3$  exchange-biased bilayers, with application in magnetic sensing.  
46  
47

48  
49 *-Use of FIBID:* The composition and lateral resolution of Co deposits obtained by  
50  
51 Wu et al. using the Helium Ion Microscope (HIM) are very promising (74). Although, in  
52  
53 general, the use of ions on magnetic materials degrades their properties, in this case, the  
54  
55 exhibited properties are of high quality. Further work using the HIM (or other ion sources)  
56  
57 for the growth of magnetic materials would be fantastic.  
58  
59  
60

1  
2  
3        -*Use of multi-electron-beam deposition*: Another limitation of FEBID, the low  
4 growth rate, could be overcome by the use of multi-electron-beam deposition (186).  
5  
6 Although such technology is still under development, its application for the fast growth of  
7 magnetic arrays would be welcome.

8  
9  
10        -*FEBID on liquid environment*: Some work exists on the use of liquid-phase  
11 electron-beam-induced deposition for Pt, Cu and Ag (187) (188). In this case, the precursor  
12 is adsorbed on the substrate in liquid phase and a focused electron beam from an  
13 environmental SEM allows precursor decomposition into pure nanostructures. This strategy  
14 has not been used for the growth of magnetic materials yet.

15  
16  
17        -*Catalytic growth*: As described in section 5.1, the growth of CNTs on Co dots  
18 grown by FEBID has been achieved, underlining the potential of the technique for catalytic  
19 growth (100). On the other hand, various experiments have been developed regarding  
20 catalytic effects in FEBID itself (131). Further investigations in those directions can be  
21 envisaged, with importance in the fields of surface science and self-assembly.

22  
23  
24        -*Use of non-standard substrates*: One of the advantages of FEBID is the freedom in  
25 the choice of substrate. The work by Peinado et al. has demonstrated that FEBID can be  
26 achieved on unconventional substrates such as flexible and transparent polycarbonate ones  
27 (87). Given that some applications such as stretchable magnetoelectronics are very  
28 promising (186), further work regarding the growth of magnetic nanostructures on  
29 unconventional substrates is expected.

30  
31  
32        Regarding applications, these are our views:

33  
34  
35        -*Magnetic storage*: The present magnetic storage density, beyond 1Tbit/inch<sup>2</sup>, and  
36 the stringent requirements of the hard disk components make difficult the change towards  
37 new magnetic storage strategies (189). However, the use of concepts for 3D magnetic  
38 storage is in vogue given the potentially-high storage density achievable (8, 190). As FEBID  
39  
40  
41  
42  
43  
44  
45  
46  
47  
48  
49  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 is well-suited for 3D growth, the development of 3D magnetic nanowires by FEBID (66)  
4  
5 could be interesting in contexts like the racetrack memory (8). Given that 2D Co nanowires  
6  
7 grown by FEBID display domain-wall conduit (43), 3D Co nanowires could also exhibit  
8  
9 such a property.  
10  
11

12        -*Domain-wall and logic*: The use of magnetic domain walls for 2D logic concepts  
13 was introduced a few years ago using Permalloy nanostructures (9). Magnetic materials  
14  
15 grown by FEBID, displaying domain-wall conduit (43), are appropriate for this application.  
16  
17 On the other hand, Permalloy and Co/Pt nanomagnets have been also used for the  
18  
19 development of nanomagnet logic concepts (180). 2D and 3D logic gates grown by FEBID  
20  
21 have been demonstrated (134) (138), but the present throughput is too low for cost-effective  
22  
23 device production. One should also consider that, despite domain-wall and nanomagnet  
24  
25 logic concepts are beautiful, the great improvements achieved in Si-based logic makes  
26  
27 improbable the use of magnetic domain walls in next-generation logic devices.  
28  
29  
30  
31  
32

33        -*Scanning Probe Microscopy (SPM) tips*: The difficulties to functionalize SPM tips  
34 with standard growth and lithography techniques make FEBID a competitive technique in  
35  
36 this application. Although some proof-of-concept examples have been shown for MFM, as  
37  
38 described in section 5.2, real applications are almost inexistent. However, we foresee strong  
39  
40 potential for topics such as quantitative MFM or high-resolution MFM. The results achieved  
41  
42 so far in FMRFM using Co deposits grown by Belova et al. indicate that FEBID is indeed  
43  
44 very useful in this application (163).  
45  
46  
47  
48  
49

50        -*Magnetic prototyping*: FEBID produces nanopatterned magnets with high resolution  
51 and shapes, and on non-standard substrates, which can be very difficult or impossible to  
52  
53 obtain with other growth and lithography techniques. This is very useful for magnetic  
54  
55 prototyping so that new magnetic states can be investigated with advanced local magnetic  
56  
57 characterization techniques (90).  
58  
59  
60

1  
2  
3        -*Vortex lattice pinning*: Physical phenomena in superconductors is very rich and with  
4 important technological implications. One of the holy grails in this field is the improvement  
5 of the critical current by means of hampering the motion of the vortex lattice in type-II  
6 superconductors. The use of magnetic nanostructures grown by FEBID for vortex pinning is  
7 a clean and effective process that permits the study of important effects related to vortex  
8 physics (51). Further studies in this direction will improve the understanding of the  
9 phenomena for adequate design of the vortex-pinning landscape in high- $T_C$  superconductors  
10 used in real applications.  
11  
12

13        -*Remote magnetomechanical actuation*: Nano-actuators normally use electrical  
14 contacts to convert electrical stimuli into mechanical motion. However, remote operation of  
15 nano-actuators by magnetic fields, avoiding the need of electrical contacts, has been recently  
16 demonstrated (93). The nano-actuators have been fabricated using Co nanowires grown by  
17 FEBID. This will surely inspire new devices based on this strategy.  
18  
19

20        Summarizing, the FEBID technique finds various applications in the fields of  
21 nanomagnetism and spintronics, mainly on some specific situations where this technique has  
22 competitive advantages with respect to the use of standard thin-film growth plus  
23 nanolithography. We foresee that FEBID will become better known in the coming years and  
24 will be used on the same foot as other growth and lithography techniques.
