Abstract

IMPORTANCE Acute low back pain (LBP) is highly prevalent, with a presumed favorable prognosis; however, once chronic, LBP becomes a disabling and expensive condition. Acute to chronic LBP transition rates vary widely owing to absence of standardized operational definitions, and it is unknown whether a standardized prognostic tool (ie, Subgroups for Targeted Treatment Back tool [SBT]) can estimate this transition or whether early non-guideline concordant treatment is associated with the transition to chronic LBP.

OBJECTIVE To assess the associations between the transition from acute to chronic LBP with SBT risk strata; demographic, clinical, and practice characteristics; and guideline nonconcordant processes of care.

DESIGN, SETTING, AND PARTICIPANTS This inception cohort study was conducted alongside a multisite, pragmatic cluster randomized trial. Adult patients with acute LBP stratified by SBT risk were enrolled in 77 primary care practices in 4 regions across the United States between May 2016 and June 2018 and followed up for 6 months, with final follow-up completed by March 2019. Data analysis was conducted from January to March 2020.

EXPOSURES SBT risk strata and early LBP guideline nonconcordant processes of care (eg, receipt of opioids, imaging, and subspecialty referral).

MAIN OUTCOMES AND MEASURES Transition from acute to chronic LBP at 6 months using the National Institutes of Health Task Force on Research Standards consensus definition of chronic LBP. Patient demographic characteristics, clinical factors, and LBP process of care were obtained via electronic medical records.

RESULTS Overall, 5233 patients with acute LBP (3029 [58%] women; 4353 [83%] White individuals; mean [SD] age 50.6 [16.9] years; 1788 [34%] low risk; 2152 [41%] medium risk; and 1293 [25%] high risk) were included. Overall transition rate to chronic LBP at six months was 32% (1666 patients). In a multivariable model, SBT risk stratum was positively associated with transition to chronic LBP (eg, high-risk vs low-risk groups: adjusted odds ratio [aOR], 2.45; 95% CI, 2.00-2.98; P < .001). Patient and clinical characteristics associated with transition to chronic LBP included obesity (aOR, 1.52; 95% CI, 1.28-1.80; P < .001); smoking (aOR, 1.56; 95% CI, 1.29-1.89; P < .001); severe and very severe baseline disability (aOR, 1.82; 95% CI, 1.48-2.24; P < .001 and aOR, 2.08; 95% CI, 1.60-2.68; P < .001, respectively) and diagnosed depression/anxiety (aOR, 1.66; 95% CI, 1.28-2.15; P < .001). After controlling for all other variables, patients exposed to 1, 2, or 3 nonconcordant processes of care within the first 21 days were 1.39 (95% CI, 1.21-2.32), 1.88 (95% CI, 1.53-2.32), and

Key Points

Question Is the transition from acute to chronic low back pain (LBP) associated with risk strata, defined by a standardized prognostic tool, and/or with early exposure to guideline nonconcordant care?

Findings In this cohort study of 5233 patients with acute LBP from 77 primary care practices, nearly half the patients were exposed to at least 1 guideline nonconcordant recommendation within the first 21 days after the index visit. Patients were significantly more likely to transition to chronic LBP as their risk on the prognostic tool increased and as they were exposed to more nonconcordant recommendations.

Meaning In this study, the transition rate to chronic LBP was substantial and increased correspondingly with risk strata and early exposure to guideline nonconcordant care.

Supplemental content

(continued)

Author affiliations and article information are listed at the end of this article.

Abstract (continued)

2.16 (95% CI, 1.10-4.25) times more likely to develop chronic LBP compared with those with no exposure (P < .001).

CONCLUSIONS AND RELEVANCE In this cohort study, the transition rate to chronic LBP was substantial and increased correspondingly with SBT stratum and early exposure to guideline nonconcordant care.

JAMA Network Open. 2021;4(2):e2037371. doi:10.1001/jamanetworkopen.2020.37371

Introduction

Low back pain (LBP) is the leading cause of disability in the United States, annually accounting for 4.3 million years lived with disability, nearly twice the burden of any other health condition.¹ Overall, 13% of adults have chronic LBP, with one-third experiencing moderate- to high-impact chronic pain.^{2,3} In the United States, treatment for LBP and related spine disorders now represents the most expensive medical problem, with most costs accrued in ambulatory care settings, including primary care.^{4,5} Chronic LBP contributes most to long-term disability, morbidity, health care, and societal costs, while, acute LBP is given less attention because patients are generally considered to have a favorable prognosis.^{6,7}

Recent evidence has questioned the prevailing belief that acute LBP resolves within 3 months.^{8,9} A systematic review indicated that 2% to 48% (median, 26%) of patients with acute LBP in primary care settings transition to chronic LBP.¹⁰ Wide variability can be attributed to heterogeneous populations and varying operational definitions of acute and chronic LBP. Among a cohort of 605 primary care patients with acute LBP, 9% to 35% were found to have chronic LBP at 6 months depending on chronic LBP operational definitions.⁸ Lacking a standardized definition, research investigating determinants and interventions associated with the transition from acute to chronic LBP is hampered, a main factor that led to convening a National Institute of Health (NIH) Task Force Pain Consortium to develop a standardized definition and research standards for chronic LBP.¹¹

The NIH Task Force also recommended further study of prognostic instruments, such as the Subgroups for Targeted Treatment (STarT) Back tool (SBT).¹¹ The SBT is a 9-item instrument designed to identify patients with LBP at risk of persistent functional limitations but has not been investigated to assess the transition to chronic LBP. It is also used to guide treatment decisions, whereby minimal care is provided for low-risk patients and more intensive treatment is recommended as risk increases.^{12,13} The SBT is reliable and valid for predicting poor functional outcomes; however, the SBT has not been investigated as a prognostic tool for the acute to chronic LBP transition.¹⁴

Clinical guidelines consistently recommend reassurance (eg, most episodes of acute LBP resolve quickly and have a very low likelihood of serious underlying pathology) and advice to maintain activity as tolerated.¹⁵⁻¹⁷ Recently, nonpharmacologic interventions, such as heat, massage, acupuncture, or spinal manipulation, are recommended as first-line treatment options, while initial use of diagnostic imaging, specialty consultation, and prescription of opioid medications in the absence of red flags (eg, fever, fracture, malignant neoplasms) are not recommended.¹⁷ Nonconcordant care can lead to direct and indirect harm, given that it has been linked with medicalization and unnecessary health care utilization.¹⁸⁻²⁰ Accumulating evidence indicates that guideline-concordant care has not been successfully implemented in primary care; however, the association of nonconcordant care with the transition to chronic LBP remains unclear.^{21,22}

To obtain estimates of the transition from acute to chronic LBP, assess the SBT prognostic capabilities, and identify pragmatic factors associated with poor outcomes, we conducted a large multisite inception cohort study. We prospectively enrolled patients with acute LBP who were seen in primary care, administered the SBT at baseline, and assessed for chronic LBP at 6 months using the NIH Task Force definition. The objectives for this study were to assess the association between risk

of acute to chronic LBP transition with (1) baseline SBT risk strata; (2) patient demographic and clinical characteristics and practice characteristics; and (3) guideline nonconcordant processes of care.

Methods

Study Design and Setting

A detailed study protocol has been published,²³ and reporting of this manuscript follows the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) reporting guideline for cohort studies. Briefly, we conducted an inception cohort study alongside the multisite, pragmatic (ie, tested in real-world settings), cluster randomized Targeted Interventions to Prevent Chronic Low Back Pain in High-Risk Patients (TARGET) clinical trial (NCT02647658). Patients presenting to primary care clinics with acute LBP were stratified by risk (ie, low, medium, and high) for developing chronic LBP using the SBT.²⁴ High-risk patients were enrolled in the RCT and cohort studies. Medium-risk and low-risk patients were only enrolled in the cohort study. All patients were enrolled between May 2016 and June 2018 in 77 primary care practices in 4 US health systems (Pittsburgh, Pennsylvania; Boston, Massachusetts; Salt Lake City, Utah; and Baltimore, Maryland), and follow-up was completed by March 2019.

The study was overseen by 4 institutional review boards.²³ Processes conducted within the primary care clinics were viewed as quality improvement and the 6-month survey as research requiring verbal or written informed consent. Sites had varying approaches to obtaining consent for the 6-month survey. In Boston, Salt Lake City, and Pittsburgh, consent was obtained in conjunction with the 6-month survey, while in Baltimore consent was obtained at baseline.

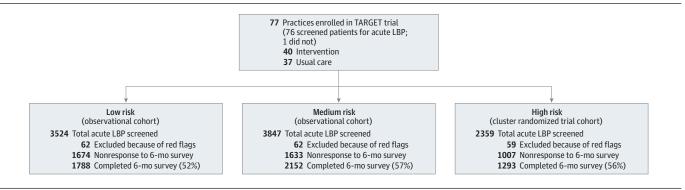

Data Collection

All study data except the 6-month surveys were sourced from existing data fields in the electronic medical records (EMRs). EMR data were collected using standardized data extraction and secure file transfer protocols facilitated via honest brokers.

Cohort Identification

Patients were eligible if they were adults (aged \geq 18 years) and presented with a primary concern of acute, bothersome axial LBP or LBP with associated leg pain. To determine the nature of the concern, a 2-item acute/chronic LBP screening questionnaire was created by adapting the NIH Task Force on

Figure 1. Flow Diagram Depicting Patient Screening for Acute Low Back Pain (LBP) and 6-Month Survey in the Targeted Interventions to Prevent Chronic Low Back Pain in High-Risk Patients (TARGET) Trial

Patients who were identified at baseline as having low and medium risk were only included in the observational component of the TARGET study. Patients screened as high risk were included in the observational and the cluster randomized trial component of the TARGET study. In the cluster randomized trial, patients received either usual care or the intervention (usual care with psychologically informed physical therapy) depending on the clinic where they presented.

Research Standards chronic LBP definition. Patients were considered to have chronic LBP if they reported (1) the presence of pain for more than 3 months and (2) experienced pain at least half the days in the past 6 months. Those not meeting this definition were classified as having acute LBP (**Figure 2**). The date the questionnaire was administered was considered the index (ie, baseline) visit. Data were collected via study tablets or verbally by clinical or administrative personnel and uploaded into the EMR. The LBP concern was verified retrospectively using the *International Classification of Diseases, Ninth Revision (ICD-9)* or *ICD-10 Clinical Modification (ICD-10-CM)* diagnosis codes from the EMR, and patients were excluded if any diagnoses on the index visit indicated a potential red flag for a serious underlying reason for LBP (eg, fracture, cancer).

Risk Stratification

Risk for developing chronic LBP was determined at the index visit using the 9-item version of the SBT.²⁴ The total score ranges from 0 to 9 and includes a psychological subscale score ranging from 0 to 5. Patients were stratified as low-risk (total score \leq 3), medium-risk (total score \geq 4 and subscale score \leq 3), or high risk (total score \geq 4 and subscale score \geq 4).²⁴ The SBT was administered in primary care clinics using the same process as the acute/chronic LBP questionnaire (eFigure 1 in the Supplement).

Outcome

Chronic LBP status at 6 months was ascertained by the acute/chronic LBP questionnaire. The survey was collected electronically, by mail, or by telephone by research personnel.

Demographic, Clinical, and Practice Covariates

Patient characteristics included demographic factors (ie, age, sex, race, ethnicity, and health insurance) and clinical characteristics (ie, body mass index, smoking status, LBP diagnosis, psychological comorbidities, self-reported LBP disability). Insurance was collapsed to 4 categories (commercial, Medicare, Medicaid, and other [workers' compensation, self-pay, missing]). LBP diagnoses and psychological comorbidities were identified via *ICD-9* or *ICD-10-CM* diagnostic codes present at the index visit. LBP disability was assessed via the Oswestry Disability Index (ODI), which was administered at the index visit with the SBT and acute/chronic LBP questionnaire.²⁵ The ODI scores range from 0 to 100 and were categorized using the following disability definitions: minimal (0-20), moderate (21-40), severe (41-60), very severe (\geq 61).²⁵ Practice characteristics included geographic location and the national area deprivation index (ADI). The ADI ranks the Census block or neighborhood in terms of socioeconomic disadvantage. We used the validated Neighborhood Atlas Tool to estimate national level ADI scores for each clinic location.²⁶

Nonconcordant Processes of Care

Figure 2. Questionnaire to Classify Acute vs Chronic Low Back Pain

LBP-related processes of care provided by primary care clinicians within 21 days of a patient's index visit were extracted from the EMR. We used international LBP guidelines and codified these

 1. How long has low back pain interfered with your ability to do regular daily activities?

 a. Less than 1 mo

 b. 1-3 mo

 c. More than 3 mo

 2. Think only about the past 6 mo. How often has low back pain interfered with your ability to do regular daily activities?

 a. Less than half the days

 b. Half the days or more than half the days

 Classification criteria:

 Acute = less than 1 mo (Q1a) or 1-3 mo (Q1b), or more than 3 mo and less than half the days (Q1c+Q2a) Chronic = more than 3 mo (Q1c) and half the days or more than half the days (Q2b)

JAMA Network Open. 2021;4(2):e2037371. doi:10.1001/jamanetworkopen.2020.37371

This questionnaire has been adapted from the National Institutes of Health Task Force on Research Standards for Chronic Low Back Pain definition. Q indicates question.

processes of care into 3 categories: pharmacologic therapies, diagnostic imaging, and medical subspecialty referral.¹⁷ We further categorized each process of care as concordant or nonconcordant with these guidelines. Nonconcordant pharmacotherapy was determined using the algorithm provided in eFigure 2 in the Supplement.¹⁷ Briefly, any prescriptions that included opioids were considered nonconcordant. Additionally, prescriptions that included benzodiazepines and/or systemic corticosteroids alone without the presence of nonsteroidal anti-inflammatory drugs or short-term skeletal muscle relaxants were considered nonconcordant. Nonconcordant diagnostic imaging (CT/MRI) scan. Nonconcordant medical subspecialty referral included referrals to nonsurgical or surgical specialties (eg, physiatrists, orthopedists, neurologists, neurosurgeons, or pain specialists). To improve interpretation and analysis, we created a composite variable that represented the total count of categories with nonconcordant processes of care. The minimum composite score was 0 (ie, patient received no nonconcordant processes of care), while the maximum composite score was 3 (ie, patients received nonconcordant processes of care in all 3 categories).

Sample Size

Sample size estimates for the high-risk cohort are reported elsewhere.²⁰ Estimates for low-risk and medium-risk patients were derived from the proportion of patients expected to screen into these 2 strata in the parent trial's primary care clinics.²³ We assumed a mean of 115 patients would screen as low to medium risk per clinic during enrollment of the trial, with 20% transitioning to chronic LBP, an intracluster correlation of 0.01, and a 60% response rate at 6 months. This provided us at minimum a 79% power to detect 30% relative difference in transition to chronic LBP between patient subgroups (eg, SBT stratum) that could be as small as a 1:4 ratio (ie, the subgroup makes up 20% of the sample compared with the remaining 2 subgroups, which make up 80% of the sample).

Statistical Analysis

We compared baseline demographic, clinical, practice, and process of care characteristics between patients with and without 6-month follow-up surveys using χ^2 tests. In these comparisons, we adjusted for clustering at the clinic level using Taylor series linearization for variance estimation. We described the rate of transition to chronic LBP at 6 months for each independent variable across the SBT risk stratum and for all strata combined. Univariate and multivariable associations between the independent variables and transition to chronic LBP were assessed using a generalized linear mixed model with a logit link controlling for the cluster design with a random clinic effect. All variables entered into the multivariable models were categorical and treated as fixed effects with significance of *P* < .15 for further consideration. All multivariable models controlled for site as a fixed effect. SBT risk strata and the composite nonconcordant process of care score remained in the model, and a backward stepwise elimination with significance set at *P* < .15 was used to arrive at a final multivariable model. Potential selection bias due to the large proportion of patients with missing 6-month data was addressed by applying stabilized inverse probability weights to the multivariable model.²⁷ Data analysis was conducted with SAS version 9.4 (SAS Institute). Statistical significance was set at *P* < .05, and all tests were 2-tailed.

Results

The final cohort of 5233 patients with acute LBP and 6-month surveys (Figure 1) were mostly women (3029 [58%]) and White individuals (4353 [83%]) with overweight (1599 [31%]) or obesity (2308 [44%]). Most patients were diagnosed with axial LBP (3883 [74%]), and 292 (6%) had an anxiety or depression diagnosis. Risk stratification in the final cohort showed 1788 (34%) were low risk; 2152 (41%), medium risk; and 1293 (25%), high risk for developing chronic LBP. Across risk levels, 1544 patients (30%) received prescriptions for nonrecommended medications (999 [65%] received

JAMA Network Open. 2021;4(2):e2037371. doi:10.1001/jamanetworkopen.2020.37371

opioids); 1245 (24%) received an radiography or CT/MRI order; and 333 (6%) were referred to a medical specialist (207 [62%] surgeons) within 21 days of the index visit (**Table 1**). The survey nonresponse rate was 45% (4314 of 9547). Nonresponders were less likely to be White individuals, to have overweight or obesity, to not currently smoke, to be prescribed nonconcordant pharmacologic therapies, or to receive care from the Intermountain Healthcare or University of Pittsburgh Medical Center systems (Table 1).

The overall unadjusted acute to chronic LBP transition rate at 6 months was 32% (1666 of 5233). The unadjusted rates by low-risk, medium-risk, and high-risk stratum were 19% (333), 33% (703), and 49% (630), respectively. Positive univariate associations were found between chronic LBP at 6 months and exposure to nonconcordant pharmacotherapies (606 of 1544 [39%] vs 1060 of 3689 [29%]; P < .001), diagnostic imaging (447 of 1245 [36%] vs 1219 of 3988 [31%]; P < .001), and referral to medical subspecialists (176 of 333 [53%] vs 1490 of 4900 [30%]; P < .001). As the composite nonconcordant processes of care score increased from 0 to 3, the rates of transition increased in a stepwise fashion from 27% (724 of 2722) to 53% (20 of 38) (P < .001) (**Table 2**).

Factors Associated With Transition to Chronic LBP From the Multivariable Model

In the multivariable model, SBT risk strata were positively associated with the development of chronic LBP when controlling for all other variables. Compared with patients in the low-risk category, the adjusted odds ratio (aOR) of developing chronic LBP was 2.45 (95% CI, 2.00-2.98) times higher for those in the high-risk category and 1.59 (95% CI, 1.33-1.89) times higher for those in the medium-risk category (P < .001) (**Table 3**). Furthermore, there was a stepwise linear relationship across each SBT stratum (P for trend < .001).

Baseline disability was positively associated with transition to chronic LBP. The aOR for developing chronic LBP was 1.16 (95% CI, 0.97-1.39) times higher for moderate disability, 1.82 (95% CI, 1.48-2.24) times higher for severe disability, and 2.08 (95% CI, 1.60-2.68) times higher for very severe disability compared with minimal disability (P < .001) (Table 3). Other significant independent factors included health insurance (eg, Medicaid: aOR, 1.91; 95% CI, 1.53-2.38; P < .001), body mass index (eg, obesity: aOR, 1.52; 95% CI, 1.28-1.80; P < .001), smoking status (aOR, 1.56; 95% CI, 1.29-1.89; P < .001), diagnosis at the index visit (back and leg pain: aOR, 1.16; 95% CI, 1.00-1.35; P = .04), and psychological comorbidities (aOR, 1.66; 95% CI, 1.28-2.15; P < .001).

Exposure to nonconcordant care was associated with increased odds of developing chronic LBP (P < .001). The aORs for developing chronic LBP were 1.39 (95% CI, 1.21-2.32), 1.88 (95% CI, 1.53-2.32), and 2.16 (95% CI, 1.10-4.25) times higher for exposure to 1, 2, or 3 nonconcordant processes of care, respectively, compared with O nonconcordant processes of care (P < .001) (Table 3). Additionally, there was a positive linear association between the number of nonconcordant processes of care and risk of developing chronic LBP (P for trend = .04).

Inverse Probability Weighted Multivariable Model

The multivariable model was reexamined using stabilized inverse probability weighting, and the results closely matched the direction and magnitude of the aORs in the original model, except for minor differences in the width of the confidence intervals (Table 3). The linear associations between the transition to chronic LBP and SBT strata (*P* for trend < .001) and the number of nonconcordant processes of care (*P* for trend = .02) remained significant.

Discussion

We present the results of a large prospective, multicenter study conducted to determine the proportion of patients who transitioned from acute to chronic LBP in primary care settings across 4 geographically dispersed health systems. Based on the NIH Task Force definition, the overall transition to chronic LBP was 32%. The risk of transition was linearly associated with baseline SBT category and whether early care was nonconcordant with current practice guidelines. Collectively,

Table 1. Descriptive Summary of the Inception Cohort (continued)

Abbreviations: SBT, Subgroups for Targeted Treatment Back tool; UPMC, University of Pittsburgh Medical Center.

^a Other included American Indian or Alaska Native, Asian, Hawaiian or Pacific Islander, and multirace.

^b Body mass index calculated as weight in kilograms divided by height in meters squared.

these results indicate that the transition from acute to chronic LBP is much greater than historically appreciated, the SBT can estimate risk of transition, and lack of guideline adherence may increase transition rates. These results expand SBT's capabilities to include the transition to chronic LBP using the NIH operational definition and reinforce the importance of LBP guidelines.

Practice guidelines do not consistently recommend the use of risk stratification tools, such as the SBT, for acute LBP, likely due to the prevailing perception that acute LBP has a favorable prognosis.¹⁷ The SBT was designed to tailor treatments based on risk of persistent functional limitations. In clinical practice, it may be tempting to focus on high-risk groups given the high transition rate to chronic LBP. However, it should be noted that more than 60% of the 1666 patients who developed chronic LBP at 6 months were in the low-risk (333 patients) and medium-risk (703) groups. Even though the rate of transition to chronic LBP is lower in these groups, most patients with acute LBP (>75%) fall into these strata. As a result, uniformly applying a minimalist approach (eg, advice, reassurance) to all patients with acute LBP without considering SBT risk status is unwarranted and may lead to suboptimal care.¹⁷ Conversely, uniformly administering resource intensive, multimodal interventions across the entire acute LBP population is unwarranted and may result in low-value care.^{5,28} To ensure appropriate treatment intensity and cost-effectiveness, future research should consider both patient phenotype and the prevalence within each SBT stratum to identify effective and scalable interventions.^{29,30}

In this cohort, patient demographic and clinical factors associated with the chronic LBP transition included obesity, smoking, insurance coverage, LBP with leg pain, baseline disability, and diagnosed depression/anxiety. The role that these factors play in the transition to chronic LBP cannot

^c Other included American Indian or Alaska Native, Asian, Hawaiian or Pacific Islander, and multirace.

^a Overall term was significantly associated with Subgroups for Targeted Treatment Back tool risk level at *P* < .05.

^d Body mass index calculated as weight in kilograms divided by height in meters squared.

^b Overall term was significant in a univariate logistic regression model controlling for the clustered study design of chronic low back pain status at 6 months in the combined risk levels at *P* < .05.

be ignored; however, many of these factors are difficult to change or nonmodifiable altogether. Importantly, our findings demonstrate that independent of these factors, exposure to nonconcordant processes of care during the early phase of treatment was associated with developing chronic LBP. Nearly half of patients (48%) received at least 1 discordant process of care within 3 weeks of the index visit. Even after controlling for patient characteristics (eg, obesity) and clinical characteristics (eg, baseline disability), increasing numbers of nonconcordant management approaches increased the likelihood of having chronic LBP at 6 months. These rates of nonconcordant processes of care are similar to those reported in a claims analysis from 2.5 million individuals newly diagnosed with LBP.⁵ The independent association between nonconcordant care and risk of developing chronic LBP highlights the need to identify strategies that facilitate LBP guideline implementation.

Successful management of LBP is a vexing problem, and health systems have been challenged to develop innovative solutions.^{29,31} Once chronic, LBP is particularly problematic to manage; thus, preventing the transition from acute to chronic LBP is important. Primary care physicians worldwide are under enormous pressure to do more with less, which is the basis for the SBT risk stratification approach.³² However, LBP guidelines have yet to consistently recommend the use of risk stratification, and implementing this approach in primary care is proving to be difficult.^{33,34} One reason for poor implementation may trace back to physicians' musculoskeletal training.³⁵ Medical educators have recognized for years that training in musculoskeletal medicine is suboptimal for medical students, residents, and general practitioners.³⁵⁻³⁷ Placing a greater emphasis on a highly prevalent condition, such as LBP, during training may improve implementation at the individual level.

- ^b Other included American Indian or Alaska Native, Asian, Hawaiian or Pacific Islander, and multirace.
- ^c Body mass index calculated as weight in kilograms divided by height in meters squared.

^a The median (interquartile range) of the inverse probability weights equaled 0.94 (0.49-6.15).

Other possible reasons for poor implementation include high caseloads and the overwhelming volume of guidelines directed at primary care; typical physicians would need an estimated 18 hours per day to address all guideline recommendations.³⁸ It is time to test supportive models of care to assist primary care practitioners in addressing this substantial public health problem. Evidence from other conditions suggests that organizational strategies that incorporate nonphysician health professionals (eg, nurse practitioners or physician assistants) to comanage cases can improve guideline adherence in primary care.³⁹ The Primary Spine Practitioner is another model proposed in the United States in which chiropractors and physical therapists serve as the initial or early point of contact for patients with LBP.⁴⁰ Another potentially beneficial organizational strategy is the use of multidisciplinary teams comprised of medical specialists and other health professionals (eg, integrated practice units).⁴¹⁻⁴³ Future studies need to evaluate whether different models of care in conjunction with risk stratification can improve guideline concordance, patient outcomes, and decrease the total cost of care.

Limitations

This study has limitations. We used survey methods to collect 6-month outcomes due to the large sample size and pragmatic nature of the study. Our response rate was 55%, which would be considered low by standards of a clinical efficacy trial. However, response rates in the range of 50% to 60% are considered to pose minimal risk of nonresponse bias when using survey methods. In addition, our inverse probability weighted analysis accounted for selection bias due to nonresponse and confirmed our original conclusions.^{27,44,45}

In this study, we relied on EMR data to develop the clinical profile of patients with acute LBP. Although widely generalizable, EMR data may not reflect all pertinent clinical findings, conditions, or comorbidities considered or addressed by the physician, nor do they include all potential confounders that may affect the transition to chronic LBP or necessitate deviation from guidelines. For example, nonconcordant care may be provided to patients with more complex acute LBP. We cannot completely rule out residual confounding; however, we controlled for a broad set of factors associated with higher clinical severity (baseline disability and LBP with leg pain) and factors that complicate management (body mass index, smoking, psychological comorbidities, and SBT risk status).⁴⁶

Conclusions

This large inception cohort study found that the transition from acute to chronic LBP was substantial and the SBT was a robust prognostic tool. Early exposure to guideline nonconcordant care was significantly and independently associated with the transition to chronic LBP after accounting for patient demographic and clinical characteristics, such as obesity, smoking, baseline disability, and psychological comorbidities. These findings suggest that an emphasis should be placed on discovering strategies to successfully implement guideline concordant care in the primary care setting to reduce the development of chronic LBP.

Conflict of Interest Disclosures: Dr Delitto reported receiving grants from the National Institutes of Health outside the submitted work. Dr Sowa reported receiving grants from the National Institutes of Health outside the submitted work. Dr George reported receiving grants from the National Institutes of Health and receiving personal fees from Rehab Essentials and MedRisk outside the submitted work. No other disclosures were reported.

Funding/Support: This research work was funded by award PCS-1402-10867 from the Patient-Centered Outcomes Research Institute.

Role of the Funder/Sponsor: The funder was not involved in decisions related to the design and conduct of the study; collection, management, analysis, and interpretation of the data; preparation, review, or approval of the manuscript; and decision to submit the manuscript for publication.

Additional Contributions: The TARGET trial investigative team would like to acknowledge the leadership teams at UPMC; Chief Medical and Scientific Officer, Steven Shapiro, MD; the President of Community Medicine Incorporated, Fran Solano, MD; and Chief Quality Officer, Tami Minnier, MSN, for their support throughout all phases of the TARGET trial. We would also like to acknowledge our patient and payer stakeholders for their valuable input in the design and interpretation of the TARGET trial. Patient stakeholders included Marie Tamasy (Pittsburgh), Jewel Cash (Boston), Scott Lake (Salt Lake City), Penny Cohen (American Chronic Pain Society), and Beth E. Brown (Arthritis Foundation). Payer stakeholders included Pamela Peele, PhD, and Michael Parkinson, MD (UPMC-Health Plan), and David Elton, DC (OPTUM Health). Provider stakeholders included Russell Phillips, MD (Harvard Medical School Center for Primary Care), and William Boissonnault, DPT (American Physical Therapy Association). We would also like to acknowledge the team members from Boston Medical Center, including clinic site champions Laura Goldman, MD, Stephanie Charles, MD, Jonathan Berz, MD, Stephen Tringale, MD, Jennifer Lo, MD, and Katherine Gergen Barnett, MD. We are grateful to those who designed and executed data extraction, including Associate Chief Medical Information Officer Rebecca Mishuris, MD, Director of Clinical Research Informatics for Boston University William Adams, MD, Medical Director of the Boston HealthNet Charles Williams, MD, and Clinical Data Warehouse Research Manager Linda Rosen. We wish to also thank Karen Mattie, PT, DPT, MS, Director of Rehabilitation Services, and Christopher Joyce, DPT, PhD, who provided physical therapy leadership. Lastly, we appreciate the hard work of our research staff at Boston Medical Center who collected baseline and 6-month survey data, including Chelsey Lemaster, MD, MPH, Dorothy Plumb, MA, Salvatore D'Amico, BS, Jessica Howard, MA, MPH, Alex Femia, Samia Jaffar, MPH, Iniya Rajendran, MD, Bhumi Patel, MPH, Kristin Mikhail, MS, MPH, Frank Liu, Shweta Palakkode, Sumedha Javalikar, MPH, and Kimberly Prescod. Mss Tamasy and Cash and Mr Lake received consulting fees and travel reimbursement; Ms Cohen and Drs Phillips and Boissonnault

received honoraria and travel reimbursement; Dr Parkinson received honoraria; and Dr Elton received travel reimbursement.

Additional Information: Access to deidentified data will be made available by by Inter-university Consortium for Political and Social Research (ICPSR) at the University of Michigan by no later than July 01, 2021. Requests for access to the data can be made at https://www.icpsr.umich.edu/web/pages/.
