Abstract

Background: Studies have demonstrated the role of ulcerative and non-ulcerative sexually transmitted infections (STI) in HIV transmission/acquisition risk; less is understood about the role of non-specific inflammatory genital abnormalities.

Methods: HIV-discordant heterosexual Zambian couples were enrolled into longitudinal follow-up (1994–2012). Multivariable models estimated the effect of genital ulcers and inflammation in both partners on time-to-HIV transmission within the couple. Population-attributable fractions (PAFs) were calculated.

Results: A total of 207 linked infections in women occurred over 2756 couple-years (7.5/ 100 CY) and 171 in men over 3216 CY (5.3/100 CY). Incident HIV among women was associated with a woman's non-STI genital inflammation (adjusted hazard ratio (aHR) = 1.55; PAF = 8%), bilateral inguinal adenopathy (BIA; aHR = 2.33; PAF = 8%), genital ulceration (aHR = 2.08; PAF = 7%) and the man's STI genital inflammation (aHR = 3.33; PAF = 5%), BIA (aHR = 3.35; PAF = 33%) and genital ulceration (aHR = 1.49; PAF = 9%). Infection among men was associated with a man's BIA (aHR = 4.11; PAF = 22%) and genital ulceration (aHR = 3.44; PAF = 15%) as well as with the woman's non-STI genital inflammation (aHR = 1.92; PAF = 13%) and BIA (aHR = 2.76; PAF = 14%). In HIV-M+F- couples, the

[©] The Author 2017. Published by Oxford University Press on behalf of the International Epidemiological Association.

man being uncircumcised. with foreskin smegma. was associated with the woman's seroconversion (aHR = 3.16) relative to being circumcised. In F+M- couples, uncircumcised men with BIA had an increased hazard of seroconversion (aHR = 13.03 with smegma and 4.95 without) relative to being circumcised. Self-reporting of symptoms was low for ulcerative and non-ulcerative STIs.

Conclusions: Our findings confirm the role of STIs and highlight the contribution of nonspecific genital inflammation to both male-to-female and female-to-male HIV transmission/acquisition risk. Studies are needed to characterize pathogenesis of non-specific inflammation including inguinal adenopathy. A better understanding of genital practices could inform interventions.

Key words: Couples' voluntary HIV counselling and testing, discordant couples, HIV risk, genital ulceration and inflammation, longitudinal cohort, Zambia

Key Messages

- Observational research implicates several sexually transmitted infections (STIs) (including *Neisseria gonorrhoeae, Chlamydia trachomatis, Trichomonas vaginalis, Treponema pallidum* and herpes simplex virus 2), primarily as co-factors in HIV acquisition in high-risk women.
- Studies considering the risk conferred by more common genital inflammatory conditions not due to STI are lacking.
- Our findings confirm the contribution of STI and highlight the independent contribution of non-STI inflammatory processes to risk of HIV transmission and acquisition in both men and women.
- Low self-reporting of symptoms of STIs supports routine screening/treatment where possible.
- Studies to characterize pathogenesis of non-specific inflammation leading to development of interventions to reduce HIV transmission are warranted.

Background

In seeking an explanation for differential HIV transmission probabilities regionally and per sex act, genital ulceration and inflammation (GUI) emerged as important transmission co-factors in the late 1980s and early 1990s.¹⁻³ Decades of observational research implicate several inflammatory sexually transmitted infections (STIs) including gonorrhea, chlamydia, trichomonas and ulcerative STIs as well as syphilis and herpes simplex virus type 2 (HSV-2). Reviews^{4,5} indicate that few studies consider the effect of GUIs in both sexual partners on HIV risk, or address non-STI inflammatory abnormalities such as candida, bacterial vaginosis (BV), genital discharge or inflammation more broadly.⁶⁻⁹ Inflammatory processes can recruit HIV-infected or target cells to the genitalia, thereby increasing risks of both transmission and acquisition. Studies of inflammatory markers confirm that cells are associated with high viral loads (VL) in cervico-vaginal fluids,¹⁰ and cytokine markers¹¹⁻¹⁴ and innate antimicrobial responses^{15,16}

are linked to HIV acquisition. Causes of these inflammatory processes warrant closer investigation.

Though antiretroviral treatment (ART) reduces HIV-1 transmission,¹⁷ it does not alter genital cytokine levels in HIV+ women,¹⁸ and adherence and retention are poor in Zambia.^{19–22} Low-cost strategies that reduce HIV risk independently of ART remain imperative. Building on what is known about the impact of inflammation and ulceration in heterosexual HIV transmission, we quantify the risk and population-attributable fraction (PAF) associated with a wide range of both sexually transmitted and more common non-sexually transmitted GUIs among ART-naïve Zambian serodiscordant couples over 18 years of follow-up.

Methods

Ethics

This study was approved by the Office for Human Research Protections-registered Institutional Review Boards at Emory University and the University of Zambia. Joint written informed consent was obtained from all participating couples.

Study participants and staff

Heterosexual HIV serodiscordant couples (M+F- or F+M-) were recruited from couples' voluntary HIV counselling and testing (CVCT) in Lusaka, Zambia.^{23,24} Enrolment was continuous in the open cohort through 1994-2012 and follow-up continued quarterly. Risk reduction counselling was provided at enrolment and at every visit. Free outpatient health care was provided by Zambian registered nurses, clinical officers or general medicine physicians, and specialists in internal medicine, obstetrics and gynaecology, and laboratory diagnostics. Clinical and laboratory staff received training in good clinical practices and standard operating procedures, including quality assurance and control. Couples were censored if either partner died or was lost to follow-up, the couple separated or the HIV+ partner initiated ART. Criteria for ART changed over time after it became available in government clinics, based on evolving World health organization (WHO) guidelines (CD4 < 200cells/ml pre-2006, < 350 cells/ml post-2006).²⁵ HIV+ participants were referred for ART; those confirmed to have initiated ART were discharged from the cohort to reduce possible confusion from enrolment in multiple programmes.

Longitudinal data collection

Procedures changed over time as a function of available resources and study priorities. Over 1994-2002, both partners were seen quarterly and had routine genital examinations. Beginning in 2003, physical and genital examinations were performed at baseline, annually and when symptoms were reported. Plasma banking for VL testing began in 1999, and p24 antigen enzyme-linked immunosorbent assay (ELISA) screening began in 2003. Over 2007-08, HIV partners were seen at months 0,1,2 and3, and quarterly at which time sexual exposures were assessed by self-report or biological markers of condomless sex.²⁶ HIV partners with one or more exposures received monthly HIV testing until the next quarterly visit, at which time the assessment was repeated. Over 2008-12, all HIV partners were tested for HIV monthly. When HSV-2 ELISA was available in 2005, these tests were run on banked and new baseline samples. Due to funding constraints, follow-up was truncated at 36 months (2010) and 24 months (2011).

Exposures of interest

Exposures measured at baseline and follow-up visits included: self-reported genital ulcer, urethral or vaginal discharge, dysuria or dyspareunia; genital examination findings including external or internal genital inflammation (redness, swelling, exudate, discharge, irritation or tenderness) or genital or perianal ulceration (including erosion or friability); and laboratory studies including rapid plasma regain (RPR; BD Macro-VueTM, Becton-Dickinson Europe, with Treponema pallidum haemagglutination assays (TPHAs) confirmation when available²⁷); vaginal wet mount for detection of trichomonas, clue cells (BV) and candida, including potassium hydroxide (KOH) preparations for the whiff test (BV).28,29 Gonorrhea culture and Gram staining both routinely and in the presence of endocervical pus was piloted, but very few positive results were obtained. These expensive and time-consuming procedures were discontinued and diagnosis was based on endocervical or urethral discharge.

Diagnosis and treatment were based on the best available information including self-report, physical examination and laboratory results. Incident positive RPR prompted treatment of both partners for syphilis,²⁷ and self-report or clinical diagnosis of RPR-negative ulcer was treated based on clinical presentation and HSV-2 serology. Urethral discharge or dysuria in men, or endocervical discharge were detected, both partners were treated for gonorrhea and chlamydia. Both partners were treated when trichomonas was detected on vaginal wet mount, and women with candida or BV were treated given symptoms. Unilateral inguinal adenopathy (UIA) and bilateral inguinal adenopathy (BIA) were not treated.

Composite variables

For each 3-monthly interval, composite variables were created. The genital inflammation composite had two mutually exclusive levels: inflammatory STIs (clinical or laboratory diagnosis or treatment of gonorrhea, chlamydia or trichomonas); or non-inflammatory STIs (reported discharge, dysuria, dyspareunia; observed discharge or inflammation of external or internal genitalia; and/or laboratory diagnosis of candida or BV) with no indication of an inflammatory STI. The composite for genital ulcer included observed or reported ulcers and/or incident positive RPR.

Other covariates

We measured: baseline age, years cohabiting, income, literacy, current pregnancy and number of previous pregnancies, clinical and laboratory stage as developed by our group for Kigali and modified for Zambia^{30,31} and VL of HIV+ partners;³² male circumcision (MC); HSV-2 serological positivity; STI and number of sexual partners in the past year; and contraceptive method. Time-varying measures of unprotected sex with the study partner, sperm present on a vaginal swab wet mount, contraceptive use and pregnancy were measured.

Outcome of interest

The outcome was time-to-incident HIV infection genetically linked to the study partner. HIV testing of HIV partners was conducted at 1- to 3-monthly intervals using rapid serological tests.³³ When possible, plasma from the last antibody-negative sample was tested by p24 ELISA and RNA polymerase chain reaction (PCR). To determine if infections were linked or acquired outside the partnership, conserved nucleotide sequences (gag, gp120, gp41, long terminal repeat regions) from both partners were PCR-amplified, and pairwise genetic distances were calculated for these sequenced regions.^{34,35} Date of infection was defined based on available data, as the minimum of: the midpoint between the last negative and first positive antibody date (only eight seroconverters had more than 6 months between last negative and first positive visits); 2 weeks before first antigen-positive test date; or 2 weeks before first VL-positive/antibody-negative test date.

Data analysis

Analyses were conducted with SASv9.4 (SAS Institute, Cary, NC). Couples experiencing unlinked seroconversion were excluded from analysis.

HIV incidence

HIV incidence rates (the number of incident infections per couple-year (CY) of follow-up from enrolment until either the outcome occurred or the couple were censored) were calculated by months since enrolment, to explore cohort effects, and differences were evaluated by log-rank tests for linear trend. Months since enrolment were also dichotomized (months > 0-3 versus > 3), and differences evaluated by mid-*P* exact tests to compare incidence prior to joint testing and counselling (months > 0-3, reflecting transmissions occurring in the seroconversion window before CVCT) compared with rates for > 3 months of follow-up.

Exposures

Exposures are described stratified by HIV transmission status using counts and percentages (categorical variables), means and standard deviations (normal continuous variables) and medians and interquartile ranges (non-normal continuous variables). Bivariable associations were evaluated via unadjusted Cox models. Crude hazard ratios (HRs), 95% confidence intervals (CIs), and *P*-values are reported. We also calculated the proportion of patients with STI diagnoses that reported symptoms before diagnosis, for 1994-2002.

Multivariable models

Multivariable Cox models accounting for repeated observations evaluated predictors of time-to-HIV infection. Confounding was assessed using a data-based criteria method to identify variables that changed the point estimate of any exposure of interest by +/-10%. Candidate variables were evaluated for multi-collinearity (condition indices > 30, variance decomposition proportions > 0.5); collinear variables with weaker associations with the outcome were removed. The proportional hazards assumption was confirmed for time-independent covariates. We explored for potential interaction by: cohabitation length (< 1 year versus \geq 1 year); circumcision and smegma; and circumcision, smegma and BIA. A 'generalized' R-squared statistic (with > 60% thought to be meaningful) was calculated for each model as:³⁶

$$R^2 = 1 - e^{-\left(\frac{LRT}{n}\right)}$$

where LRT (likelihood ratio test) is the difference between the -2log likelihood for the null model with no covariates and the fitted model, and n is the number of observations. Adjusted hazard ratios (aHRs) are reported.

Population-attributable fractions

PAFs were calculated for genital inflammation and ulceration composites using standard formulae^{37–39} with aHRs as the measure of relative risk:^{40–42}

$$PAF = \left[\frac{(aHR-1)}{aHR}\right] * p$$

where p is the proportion of cases exposed. Confidence intervals around PAFs were calculated.^{43,44}

Sub-analyses

For the data collected over 1994-2002, we explored interactions between circumcision, foreskin smegma and BIA in men.

Sensitivity analyses

To explore the possibility of GUI exposure misclassification, we built models assuming a random 15% of exposures preceding seroconversion were incorrectly classified as negative, and another model assuming 15% of GUI exposures preceding seroconversion were incorrectly classified as positive. We also constructed a model after multiple imputation, carried out using Markov Chain Monte Carlo methods which assume that the variables have a joint multivariate normal distribution. Simulation studies indicate that this common imputation method typically leads to robust estimates regardless of true normality.^{45,46}

Results

Follow-up and transmission

A total of 1348 M+F- couples were followed for a median of 430 (interquartile range = 767) days; 207 linked transmissions occurred in women over 2756 CY (7.5/100 CY; 95% CI: 6.5-8.6). Follow-up among 1601 F+M- couples was a median of 448 (interquartile range = 730) days; 171 linked transmissions occurred in men over 3216 CY (5.3/ 100 CY; 95% CI: 4.5-6.2). During this time, 45 unlinked infections occurred in women and 55 in men; these couples were excluded from analysis. Among study couples, 57% had at least 1 year of follow-up, 35% had \geq 2 years and 22% had \geq 3 years.

HIV incidence

Incidence in women decreased between > 0-3 months (13.0/ 100 CY; 95% CI: 9.4-17.5) versus > 3 months of follow-up (6.7/100 CY; 95% CI: 5.7-7.8) (P < 0.001, Figure 1A). This was also true for men: > 0-3 months (8.7/100 CY; 95% CI: 6.0-12.2) versus > 3 months (4.8/100 CY; 95% CI: 4.0-5.7) (P < 0.001, Figure 1B). Rates of transmission from M+Fwere consistently higher than for F+M-. Follow-up time was predictive in unadjusted and adjusted models (> 0-3 months versus > 3 months, P < 0.001).

Baseline exposures

Exposures associated with transmission included lower men's and women's ages, fewer years cohabiting, fewer previous pregnancies and increasing baseline VL of the HIV+ partner (Table 1). Among M+F- couples, the woman's illiteracy and pregnancy at baseline were associated with transmission. Among F+M- couples, the man being uncircumcised was associated with transmission.

Time-varying exposures

Time-varying exposures associated with male-to-female transmission included non-STI inflammation in women and STI inflammation, genital ulceration and BIA in both partners (Table 2). Female-to-male transmission was associated with non-STI genital inflammation and BIA in both partners and genital ulceration in men.

Multivariable models

Collinear variables included men's and women's ages, ages and years cohabiting and age and number of previous pregnancies (Tables 3 and 4). Women's age was retained. There was no interaction by cohabitation length. Genital ulcer of HIV+ women was not included in multivariable models because of lower statistical significance and magnitude of the crude point estimate.

Incident HIV among women was associated with the woman's non-STI genital inflammation (aHR = 1.6; PAF = 8%), BIA (aHR = 2.3; PAF = 8%) and genital ulceration (aHR = 2.1; PAF = 7%), and the man's STI genital inflammation (aHR = 3.3; PAF = 5%), BIA (aHR = 3.4; PAF = 33%) and genital ulceration (aHR = 1.5; PAF = 9%). The 'generalized' R-squared statistic was 63%.

Figure 1. HIV seroincidence rates per 100 couple years (CY) and 95% confidence interval bars among Zambian women and men in HIV discordant relationships, Ns indicate number of seroconversions occurring in each time interval.

BIA of man: Yes BIA of man: No				13.03	4.97 e	34.17	< 0.0001

Foreskin smegma recorded from 1994-2002. P-values are two-tailed from Cox models. Adjusted point estimate for genital ulcer of woman in F+M- primary model (not included in final models): aHR = 0.94, 95% CI:0.55-1.62 (P = 0.84).

a 'Generalized' R-squared = 0.63 for M+F- couples (primary model).

^b Generalized' R-squared = 0.80 for F+M- couples (primary model).

^cCircumcised at baseline or ever during follow-up.

^dControlling for the primary model variables.

^eSmall sample size; a measure of association could not be estimated.

Infection among men was associated with the woman's non-STI genital inflammation (aHR = 1.9; PAF = 13%) and BIA (aHR = 2.8; PAF = 14%), and the man's BIA (aHR = 4.1; PAF = 22%) and genital ulceration (aHR = 3.4; PAF = 15%). The 'generalized'R-squared statistic was 80%.

In M+F- couples, 84% of trichomonas were detected without self-reported discharge; 78% (men) and 92% (women) of incident positive RPR results were detected with no self-reported genital ulcers; 32% (men) and 71% (women) of incident RPR-negative ulcers were detected without self- reported ulcer; and 28% (men) and 98% (women) of cases of gonorrhea and chlamydia were diagnosed with no self-reported symptoms.

In F+M- couples, 86% of trichomonas were detected without self-reported discharge; 90% (men and women) of incident positive RPR results were detected with no self-reported genital ulcers; 20% (men) and 65% (women) of incident RPR-negative ulcers were detected without self-reported ulcer; and 20% (men) and 92% (women) of cases of gonorrhea and chlamydia were diagnosed with no self-reported symptoms.

1994-2002 sub-analyses

In M+F- couples, being uncircumcised with foreskin smegma was associated with seroconversion (aHR = 3.2) relative to being circumcised. In F+M- couples, uncircumcised men with BIA had an increased hazard of seroconversion (aHR = 5.0 without smegma, aHR = 13.0 with smegma) relative to being circumcised (Table 3).

Sensitivity analyses

If 15% of GUI exposures before seroconversion were misclassified as false-negative, GUI exposures are more hazardous than in primary analyses (Appendix 1, available as Supplementary data at *IJE* online), whereas if 15% of these GUI exposures were misclassified as false-positive, estimates were tempered toward the null (Appendix 2, available as Supplementary data at *IJE* online). For every variable in primary analyses, 87% of M+F- and F+Mcases were complete, and multiple imputation results were similar to primary analyses, with slightly more hazardous point estimates (Appendix 3, available as Supplementary data at *IJE* online).

Discussion

Our findings confirm the role of ulcerative STIs and highlight the contribution of non-ulcerative STIs and nonspecific genital inflammation in HIV transmission risk in both donor and recipient in both M+F- and F+M- couples. The high PAF contributed by BIA merits further investigation. Genital practices may be a contributing factor and should be investigated.

As in other studies,^{40,47} ulcerative STIs contributed to a substantial PAF of transmission in both men and women donors and women seroconverters. Most incident ulcers diagnoses were asymptomatic and detected during routine physical examinations or screening. Syphilis is common in Zambia,⁴⁸ and routine RPR screening is inexpensive and does not require sophisticated laboratory equipment or electricity, and penicillin treatment is inexpensive with no documented resistance.²⁷

We did not find prevalent HSV-2 antibody associated with HIV transmission in our analysis, but this is not surprising as only a minority of HSV-2 antibody-positive persons developed detectable ulcers. When RPR-negative ulcers were detected, they were generally assumed to be herpetic and

Foreskin smegma recorded from 1994-2002.

treated with acyclovir when it became available. Though Phase III clinical trials of acyclovir for HSV-2 antibody-positivity have not decreased HIV risk,^{49–51} acyclovir treatment of visible ulcers in RPR- patients is still advisable. Men and women could be encouraged to examine external genitalia and seek treatment for visible ulcers.

Inflammatory STIs in HIV+ men were risk factors for women's HIV acquisition. As with ulcers, many inflammatory STIs were asymptomatic – particularly in women who cannot inspect their internal genitalia – and were diagnosed during routine physical examination or screening. Many countries, including Zambia, rely on syndromic STI detection, an approach associated with reduced HIV incidence in neighbouring Tanzania.⁵² In contrast, mass population treatment of presumptive STI has not resulted in reduced HIV incidence in most settings.⁵³ New diagnostics for gonorrhea, chlamydia and trichomonas may be useful in screening asymptomatic disease.⁵⁴

Inflammation not due to STI included reported symptoms, visible abnormalities on genital examination, and/or diagnosed candida or BV. Non-STI inflammation in women was associated both transmission and acquisition. BIA contributed a surprisingly high PAF to transmission in both HIV+ and HIV- men and women. Lymphadenopathy is non-specific and typically as reaction to infection; HIVassociated lymphadenopathy can last 2-3 months.55 To develop testable interventions to reduce discharge and nonspecific inflammation without compromising genital integrity, an understanding of current genital practices is needed. In Zambia, as in many sub-Saharan African countries, women engage in intra-vaginal practices in response to discharge, genital disturbance, or for cultural reasons, which can lead to inflammatory processes, abrasion and increased STI risk.56-58 Additionally, highly diverse nonlactobacillus-dominated bacterial communities have been associated with inflammation facilitating HIV transmission,^{59–61} and a better understanding of the microbiome is needed.^{62–64} Education ideally before initiation of sexual activity, to increase recognition and management of abnormal vaginal discharges, odours or discomfort, is indicated.

As expected, lack of circumcision was independently predictive of seroconversion in F+M- couples. BIA was not associated with increased risk of seroconversion in circumcised HIV- men. Being uncircumcised with smegma was associated with risk of both transmitting and acquiring HIV. The presence of smegma increased the risk associated with BIA. We support the scale-up targeted voluntary MC for HIV- men with HIV+ partners. In settings like Zambia where circumcision is not a tradition and MC is low, research on men's genital hygiene practices is needed. Foreskin smegma has been associated with inguinal adenopathy in Rwandan men,⁶⁵ and a study of Ugandan men found foreskin inflammation to be associated with higher VL and smegma.⁶⁶

We observed a decrease in infections at the time of enrolment versus subsequent months, paralleling the reported onset of condom use after CVCT. These data suggest GUIs contribute a substantial proportion of new HIV infections in ART-naïve serodiscordant couples after CVCT. In Zambia, virological failure, transmitted resistance^{21,67,68} and GUI-associated transmission of multiple HIV-variants^{66,69,70} have been noted.

Limitations

We previously published analyses of possible selective enrolment and retention biases which may limit generalizability.⁷¹ A possible selection bias for healthier index partners and information bias in self-reported exposure variables could be differential by risk, biasing our results in an unknown direction. It is possible that couples with GUIs were more likely to have follow-up visits, though baseline STIs were not associated with retention.⁷¹ Though we attempt to control for unprotected sex to assess the independent effect of genital inflammation, uncontrolled confounding could make the latter a proxy measure of unprotected sex.

Conclusions

Our findings confirm the role of STIs and highlight the contribution of non-specific genital inflammation to HIV transmission and acquisition risk in both HIV+ and HIV- men and women. A multipronged approach will be needed that maximizes detection, management and prevention. More research to develop low-cost, sustainable interventions to reduce genital co-factors for HIV transmission is warranted.
