Abstract. As climate change has occurred over east Asia since the 1950s, intense interest and debate have arisen concerning the contribution of human activities to the observed warming in past decades. In this study, we investigate regional surface temperature change during the boreal cold season using a recently developed methodology that can successfully identify and separate the dynamically induced temperature (DIT) and radiatively forced temperature (RFT) changes in raw surface air temperature (SAT) data. For regional averages, DIT and RFT contribute 44 and 56 % to the SAT over east Asia, respectively. The DIT changes dominate the SAT decadal variability and are mainly determined by internal climate variability, represented by the North Atlantic Oscillation (NAO), Pacific Decadal Oscillation (PDO), and Atlantic Multi-decadal Oscillation (AMO). Radiatively forced SAT changes have made a major contribution to the global-scale warming trend and the regional-scale enhanced semi-arid warming (ESAW). Such enhanced warming is also found in radiatively forced daily maximum and minimum SAT. The long-term global-mean SAT warming trend is mainly related to radiative forcing produced by global well-mixed greenhouse gases. The regional anthropogenic radiative forcing, however, caused the enhanced warming in the semi-arid region, which may be closely associated with local human activities. Finally, the relationship between the so-called “global warming hiatus” and regional enhanced warming is discussed.

1 Introduction

Asia is arguably the most sensitive area to climate change, because it comprises almost 39 % of the world’s land area (White and Nackoney, 2003; Huang et al., 2013) and supports 4 billion people, which accounts for 66.67 % of the world population. A great portion of its drylands have shown a most significantly enhanced warming in the boreal cold season over mid- to high-latitude areas (Huang et al., 2012, 2015). The regional environment change has a close relationship with local population density and economic development level. Jiang and Hardee (2011) found that economic growth, technological changes, and population growth are the main elements of anthropogenic effects on emissions, which cannot be simulated easily by numerical models (Zhou et al., 2010). More recently, there have been some studies on understanding the implications of population growth, worker structure, and economic intensity for various scenarios of environmental change. The anthropogenic heating resulting from energy consumption has a significant continental-scale warming effect in mid-latitudes to high latitudes in winter based on model simulations (Huang et al., 1998; Higuchi et al., 1999; Shabbar et al., 2001; Zhang et al., 2013). Rapid industrialisation, urbanisation, population growth, and other anthropogenic activities have occurred in east Asia since the late 1980s (Jiang et al., 1998; Dong et al., 2007; Ge, 2009; Maya and David, 2010).

In previous studies, dynamic effects induced by internal variability have been proposed to interpret the rapid warming over continents and non-uniformity of local warming distribution (Wallace et al., 2012). The dynamic factors ex-

hibit their influences on surface temperature changes in terms of circulation changes, such as the North Atlantic Oscillation (NAO), Pacific Decadal Oscillation (PDO), and Atlantic Multi-decadal Oscillation (AMO). Guan et al. (2015) found that the dynamically induced temperature and radiatively forced temperature had opposite contributions to the surface air temperature (SAT) during the warming “hiatus” over the Northern Hemisphere. Most of the obvious patterns occurred over mid-latitudes to high-latitudes where places are known to have been having noticeable zonally averaged warming since 1900 (Ji et al., 2014) and a phenomenon of enhanced warming over the semi-arid region (enhanced semi-arid warming, ESAW) (Huang et al., 2012). The ESAW has been proposed to be caused by various factors, including changes in atmospheric circulations, sea surface temperature, interaction between land and atmosphere, and feedback from snow (Hu and Gao, 1994; Zhang et al., 2001; Huang et al., 2008; Guan et al., 2009; He et al., 2014); but the roles of different factors in the process of ESAW have not been confirmed.

In this study, the roles of different factors in the process of ESAW will be investigated using a recently developed methodology that can successfully identify and separate the dynamically induced temperature (DIT) and radiatively forced temperature (RFT) changes in the raw temperature data. Section 2 introduces the data sets used in this study. Section 3 provides a detailed description of the dynamical adjustment method. Section 4 shows enhanced warming in semi-arid regions and the behaviours of DIT and RFT over different regions of east Asia. It analyses the variability of DIT and the effects of major natural factors that dominate the dynamic temperature change, and shows the change of RFT. Section 5 lists all the main findings, followed by some discussion.

2 Data sets and study area

This study uses monthly precipitation, monthly mean temperature, and monthly daily maximum and minimum temperature from the land-only TS3.21 data set obtained from the Climate Research Unit at the University of East Anglia (Mitchell and Jones, 2005). The data cover the period of 1901–2012 with a high spatial resolution of $0.5^\circ \times 0.5^\circ$. The regionally average cold season mean-temperature trend of region k is calculated using

$$\bar{T}_k = \frac{\sum_{i=1}^{N_k} W_{ki} \times T_{ki}}{\sum_{i=1}^{N_k} W_{ki}}, \quad (1)$$

where N_k is the number of grids in region k , T_{ki} is the cold season mean-temperature of grid i in region k , and $W_{ki} = \cos(\theta_i \times \pi/180)$, with θ_i is the latitude of the grid i . The cold

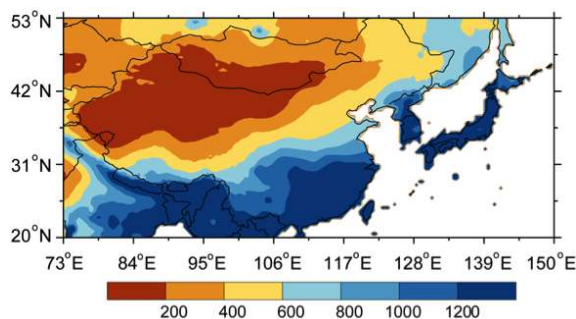

Figure 1. Spatial distribution of annual mean precipitation from 1961 to 1990 (mm year^{-1}).

season mean-temperature trend of region k is calculated by a least squares method based on the time series of \bar{T}_k .

The contribution of cold season mean RFT (DIT) to raw cold season mean temperature is calculated as formula (2):

$$\text{CR} = \frac{1}{n} \sum_{i=1}^n \left(\frac{\tilde{T}_i^2}{T_i^2} \right) \times 100\%, \quad (2)$$

where n is the number of years of temperature data set, \tilde{T}_i is the cold season mean radiatively forced temperature or dynamically induced temperature of year i ; T_i is the raw cold season mean temperature of year i .

The study area is between 20 and 53° N, and between 73 and 150° E, which comprises much of east Asia. The distribution of 30-year averaged annual precipitation from 1961 to 1990 (Fig. 1) illustrates most of the semi-arid region (annual precipitation between 200 and 600 mm year^{-1}) located in the northeast; and most of the arid region is in the northwest. It exhibits a generally increased pattern of annual precipitation from northwest to southeast. Although precipitation is related to surface temperature, the long-term mean precipitation is the simplest index for classifying climate regions (Huang et al., 2012).

3 Dynamical adjustment methodology

The dynamical adjustment method was first proposed by Wallace et al. (2012) and used to analyse the non-uniformity of the spatial warming over the Northern Hemisphere. The SAT, or the raw temperature data, are divided into two parts by the dynamical adjustment method: DIT and RFT. Wallace et al. (2012) claimed the dynamical adjustment method can remove the dynamic component of the SAT induced by the atmospheric circulation pattern from the raw SAT in the cold season (November–April) over land areas poleward of 20° N.

The dynamical adjustment methodology used in this study has been improved by Smoliak et al. (2015). The exact process of partial least squares (PLS) is to derive monthly dynamical adjustment of the Northern Hemisphere land surface

Figure 2. Time series of regionally averaged temperature anomalies of raw (black), dynamically induced (blue), and radiatively forced (red) temperatures in the cold season (November to March) from 1902 to 2011 over east Asia.

temperature field in a point-wise manner, namely, the temperature time series of each grid point is a predictand. The sea level pressure (SLP) data are standardised and the temperature time series are high-pass filtered by removing the cold season mean from the mean for each month within a given cold season and then are standardised prior to carrying out the following dynamical adjustment steps. (1) Correlate the grid-point temperature time series with the SLP field to generate a one-point cross-correlation map. (2) Project the monthly SLP field onto the correlation pattern, weight each grid point by the cosine of its latitude to obtain the first PLS predictor time series Z_1 . (3) Regress this PLS predictor Z_1 out of both the each grid-point temperature time series and its SLP predictor field, using conventional least squares fitting procedures, which can obtain a residual temperature time series and residual SLP field. Repeat these steps on the residual temperature time series and residual SLP field to obtain the respective PLS predictor Z_2 and Z_3, \dots, Z_n , which are mutually orthogonal, taking care to high-pass filter each successive residual temperature time series prior to calculating correction patterns (step 1). In our study, the improved dynamical adjustment methodology (Smoliak et al., 2015) has been applied to the temperature data set and three predictors are retained, which are determined by cross-validation.

Following the process stated above, the components associated with changes of atmospheric circulation patterns that are expressed in terms of SLP are partitioned, and referred to as DIT variability. The residual part is associated with radiatively forced factors, called the RFT. The RFT is considered as a result of build-up of greenhouse gases (GHGs), stratospheric ozone depletion, volcanic eruption, aerosol emission, and local anthropogenic forcing. In the semi-arid region of east Asia that we are interested in, non-radiative factors resulting from thermodynamic processes are also a part of RFT. As their proportion is small over the semi-arid regions, their effects in RFT are ignored in this study. Therefore, we can use the dynamical adjustment method to identify the roles of DIT and RFT in the process of enhanced warming.

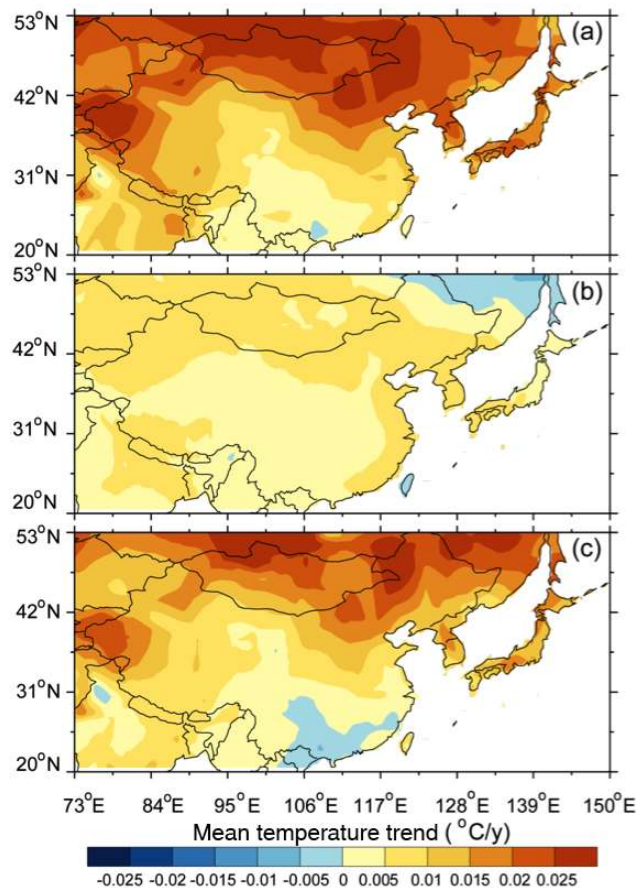

Figure 3. Spatial distribution of cold season trend of raw (a), dynamically induced (b), and radiatively forced (c) temperatures from 1902 to 2011 over east Asia.

4 Results analysis

Figure 2 compares the variation of cold season mean SAT of raw, dynamically and radiatively forced temperatures over east Asia in the period of 1902–2011. The curves exhibit a warming trend in the past century as a whole and an obvious warming from the 1970s to the 1990s. Then, there appears to have been a stop in the raw temperature change (black line) from about 2000 until now. The DIT (blue line) exhibits obvious decadal variability, with a relatively warming period from the 1970s to the 1990s and an obvious cooling period from 2000 to 2011 in the cold season. The RFT (red line) shows a rapid increasing rate since the late 1970s, which is consistent with the raw temperature data. The different evolutions of DIT and RFT indicate that the DIT and RFT played different roles in determining the raw temperature variability.

Figure 3 shows the spatial distribution of raw, DIT, and RFT trends over east Asia in the period of 1902–2011. Figure 3a exhibits a gradually increasing warming pattern from south to north and a strong warming trend located over northern east Asia, especially in Mongolia and northeast China.

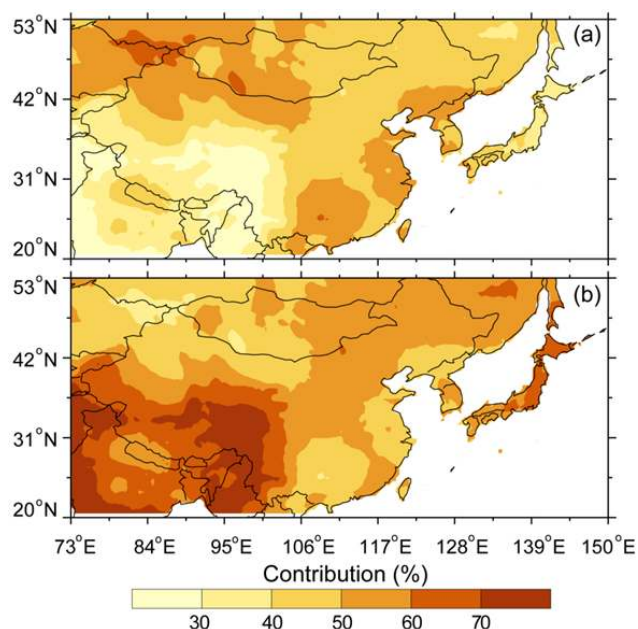

Figure 4. Spatial distribution of contribution of dynamically induced (a) and radiatively forced (b) temperatures to raw cold-season temperature from 1902 to 2011 over east Asia.

The rate of warming was less than $0.005\text{ }^{\circ}\text{C year}^{-1}$ in the south of 40°N , with a small scale of cooling region over the southwest. The distribution of DIT trend (Fig. 3b) shows a basic warming background of east Asia. The warming rate over most areas was less than $0.01\text{ }^{\circ}\text{C year}^{-1}$, with a higher value in the northern part than in the southern part of east Asia as a whole, and a cooling scale was located in the northeast of east Asia. The distribution of the RFT trend (Fig. 3c) exhibits a similar distribution to that of the raw temperature. It shows an obvious warming over the northern area of east Asia, which reached $0.025\text{ }^{\circ}\text{C year}^{-1}$ in some regions. A larger scale of cooling located in the southern region demonstrates that the cooling in the raw temperature was due to the radiative factors. The difference of DIT trend distribution from RFT indicates that the influence of radiative forcing on regional temperature changes was quite different to the influence of dynamic factors during the period of 1902–2011.

Figure 4 gives the distributions of contributions of DIT and RFT to the raw temperature in the cold season over east Asia in the period of 1902–2011. The dynamic contribution to the raw temperature (Fig. 4a) has high values over the northwest and along the coastal area of southeast China, but the peak value is much less than its radiative value. In the spatial distribution of RFT contribution (Fig. 4b), the positive centres were located over the northeast and southwest areas, and the values were much higher than those in Fig. 4a. Figure 4 illustrates that regional temperature is mostly determined by RFT. This regional discrepancy is confirmed by the contributions of DIT (blue line) and RFT (red line) to the cold

Figure 5. Contributions of dynamically induced (blue) and radiatively forced (red) temperatures to the raw temperature as a function of annual precipitation in the cold season from 1902 to 2011 over east Asia.

Figure 6. Regionally averaged cold season mean-temperature trend as a function of annual precipitation for raw (black), dynamically induced (blue), and radiatively forced (red) temperatures in the cold season from 1902 to 2011 over east Asia.

season raw temperature as a function of annual precipitation over east Asia (Fig. 5). Figure 5 shows that the RFT made a greater contribution than the DIT over the whole region. The contribution of RFT increased as the annual precipitation increased. Opposite to the radiative contribution, the dynamical contribution decreased with the increase of annual precipitation.

According to Huang et al. (2012), the enhanced warming occurred over the semi-arid regions. Figure 6 shows the long-term trends of DIT and RFT as a function of annual-mean precipitation. It illustrates that the RFT made a major contribution to the regional variation and showed a similar curve as the raw temperature over different regions. Both the raw data and RFT reached the peak in the area of $300\text{--}400\text{ mm year}^{-1}$. The fact that the peaks of cold season mean-temperature trend of both raw data and RFT occurred over semi-arid regions indicates that the radiative factors had dominant roles in the process of enhanced warming over the semi-arid re-

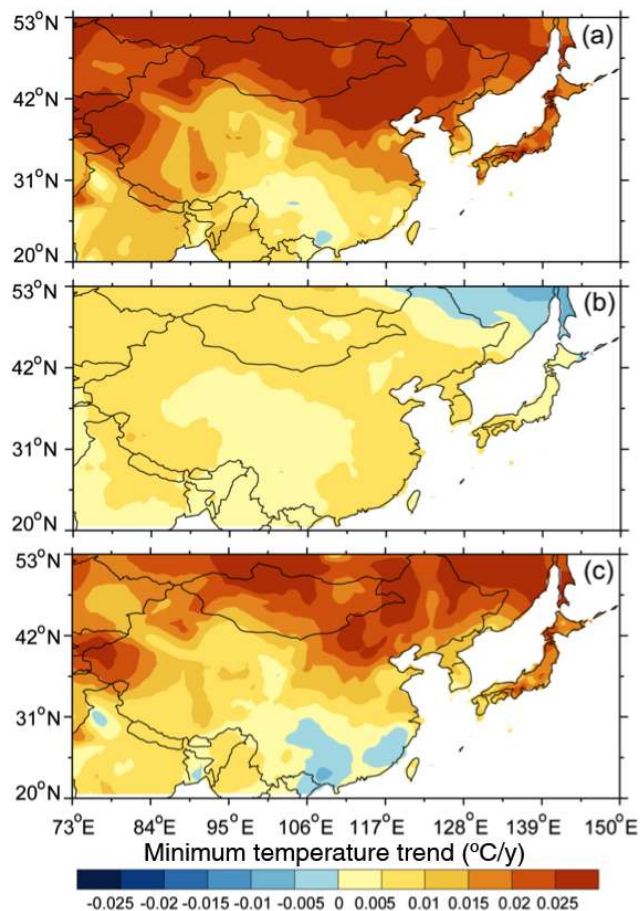

Figure 7. Same as Fig. 3, except for daily minimum temperatures.

gions. Conversely, the DIT trend did not show an obvious difference as a function of annual mean precipitation. It kept a mean rate of $0.005\text{ °C year}^{-1}$, which is far lower than the $0.017\text{ °C year}^{-1}$ of the highest value in the drylands of the RFT trend. The greater warming rate in the semi-arid region that appeared in both raw temperature and RFT indicated that enhanced warming occurring in drylands is mainly associated with RFT. This extends understanding of the ESAW (Huang et al., 2012), and suggests that the role of radiative forcing was critical in the process of warming over east Asia. These results are not limited to the monthly-mean temperatures. Figure 7 shows the distributions of raw, dynamically induced, and radiatively forced daily minimum cold season mean-temperature trends over east Asia in the period of 1902–2011. The raw daily minimum temperature illustrates a similar distribution to the raw monthly-mean temperature, with a stronger warming trend over northern east Asia, especially over Mongolia and northeast China. The dynamically induced daily minimum temperature (Fig. 7b) shows a warming pattern over most areas, with a small cooling in the area along the northeast China. The RFT trend (Fig. 7c) had an

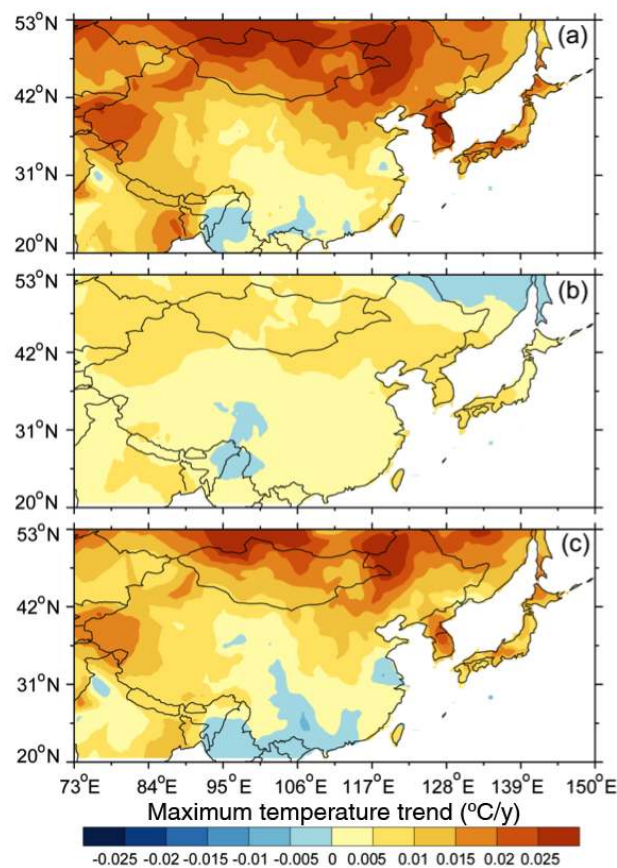

Figure 8. Same as Fig. 3, except for daily maximum temperatures.

obvious warming over the northern area, with a smaller cooling over south China than in the monthly-mean temperature.

Figure 8 shows the distributions of raw, dynamically induced, and radiatively forced daily maximum cold season mean-temperature trends over east Asia in the period of 1902–2011. The raw daily maximum cold season mean-temperature trend (Fig. 8a) was positive over northern east

Asia, especially over Mongolia; but the warming extent was apparently less than that in the daily minimum temperature. The cooling in the southern part was larger than that in the daily minimum temperature. The dynamically induced daily

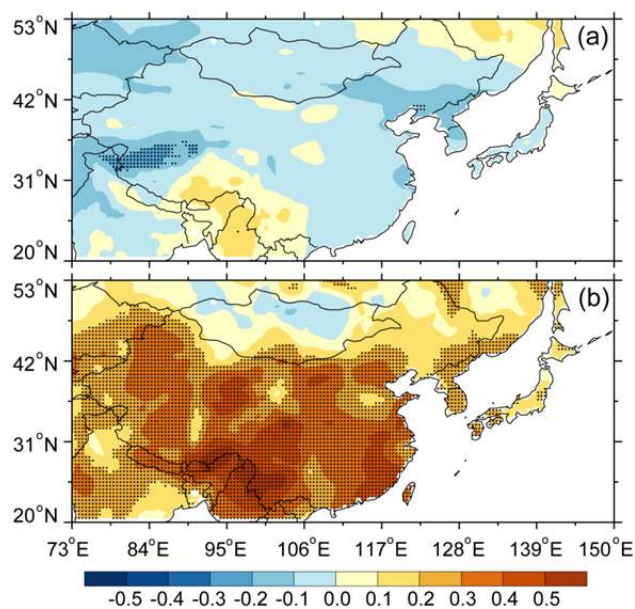

Figure 13. Spatial distribution of correlation coefficient between ensemble-mean CMIP5 simulations and dynamically induced temperature (a), and between ensemble-mean CMIP5 simulations and radiatively forced temperature (b) in the cold season from 1902 to 2011 over east Asia.

maximum temperature (Fig. 8b) shows a slight warming over most areas, with a cooling located in northeast China. The RFT trend (Fig. 8c) exhibits an obvious warming over the northern area, with a larger cooling scale over south China than daily minimum temperature, shown in Fig. 7c.

In order to distinguish the contributions to regionally averaged cold season mean-temperature trends, raw, DIT, and RFT minimum and maximum trends are shown as a function of annual-mean precipitation in Figs. 9 and 10, respectively. The daily minimum (Fig. 9) had a higher warming rate than the daily maximum (Fig. 10) over all regions, espe-

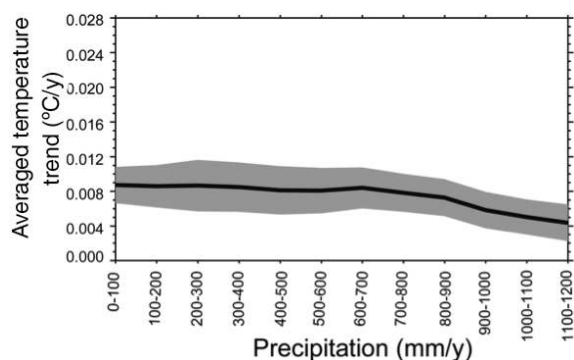

Figure 14. Regional averaged cold season mean-temperature trend as a function of climatological annual mean precipitation over east Asia for ensemble-mean CMIP5 simulations in cold season from 1902 to 2011, shading denotes 95 % confidence intervals.

cially in the drylands. The peaks of RFT over the drylands in both daily minimum and maximum temperatures indicate the dominating role of radiative effects in the regional warming. Similar to monthly-mean temperature, the DIT trend did not show much variation with increasing annual-mean precipitation in both daily minimum and maximum temperatures. The higher values of RFT of both daily minimum and maximum temperatures in the drylands emphasise the major role of RFT in the local enhanced warming process.

The DIT was mainly dominated by major dynamic factors, such as the NAO (Li et al., 2013), PDO (Trenberth and Hurrell, 1994; Kosaka and Xie, 2013), and AMO (Wyatt et al., 2012; Wyatt and Curry, 2014). The correlation coefficients between DIT and NAO/PDO/AMO (Fig. 11) illustrate the influences of these dynamic factors. Figure 11a shows the distribution of the correlation coefficient between the NAO and the DIT. It exhibits positive correlations over most of the east Asia region, significant at the 95 % confidence level over Mongolia, Inner Mongolia, and northeast China; and it exhibits negative correlations over India and southwest China, also significant at the 95 % confidence level. This indicates a strong positive influence of the NAO on the DIT over the northern area and the negative effect over the southwest of east Asia. Figure 11b is the correlation coefficient between PDO and DIT. Only the negative correlation coefficients over the boundary of China and India pass the confidence level of 95 %. In south China and north China, there were positive and negative patterns, respectively. Meanwhile, the negative correlative coefficients between the AMO index and DIT (Fig. 11c) covered most of the region of east Asia, except for a small positive region in the southwest of east Asia. The general spatial distribution is opposite to the distribution of the NAO.

The RFT variability is always considered as a result of GHGs, land cover change, human activities, clouds (Huang et al., 2005, 2006), and aerosols (Huang et al., 2011; Li et al., 2011). The fast industrialisation process over east Asia

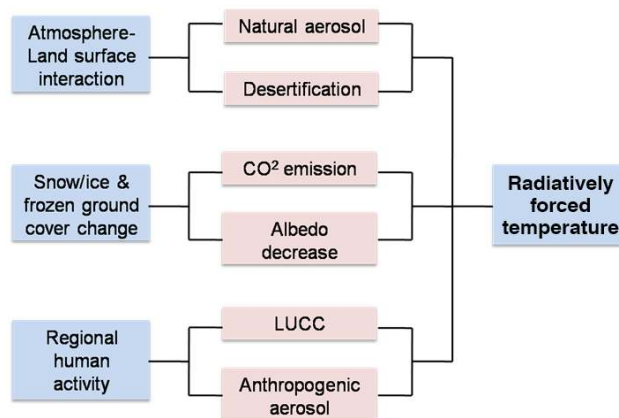

Figure 15. Schematic diagram of radiatively forced temperature. LUCC represents land use and land cover change.

produced more anthropogenic GHGs and aerosols, and impacted the local climate change (Qian et al., 2009, 2011). In order to manifest the effects of radiative in RFT, a comparison between RFT and a 20-model ensemble mean of CMIP5 simulations (Table 1) (Taylor et al., 2012) over the east Asia is plotted (Fig. 12), which shows a notable consistent warming trend between RFT and simulated SAT from the 1970s to the late 1990. The distributions of correlation coefficients of DIT and RFT with simulated temperature of CMIP5 in the period of 1902–2011 are expressed in Fig. 13a and b. Figure 13a exhibits a negative pattern over most of the area except for the boundary between northwest China and Russia and southwest east Asia; but in Fig. 13b, the correlation coefficient of RFT with CMIP5 ensemble mean temperature has a positive pattern over most of China, which passes the 95 % confidence level, excluding the northeast of China and Mongolia. It indicates that the forced temperature changes in CMIP5 have a closer relationship with RFT and DIT. The high positive correlation coefficient between RFT and the multi-model ensemble mean of CMIP5 indicates that the radiatively forced influence takes a major proportion in simulated temperature change. Multi-model ensemble mean cold season mean-temperature trends shown as a function of annual precipitation in Fig. 14 contrast the regional RFT trends over the drylands shown in Fig. 6. It illustrates that the enhanced warming over the semi-arid regions led by the RFT does not appear in the multi-model ensemble mean temperature. In contrast to observations, the CMIP5 simulations exhibit a uniform temperature change over east Asia. The significant difference between RFT and simulated temperatures over the drylands indicates that the enhanced warming over semi-arid region was not mainly related to radiative forcing produced in models, such as GHGs, land cover change, and aerosol. It is more likely related to regional factors not well represented in the models.

5 Summary and discussion

Our results provide evidence that the enhanced warming in the drylands was induced by the RFT. The DIT and RFT extracted from the raw temperature had different contributions in the process of temperature change. For the regionally averaged values, the DIT and RFT contributed 44 and 56 % to the SAT over east Asia, respectively. The DIT that was dominated by the NAO, PDO, and AMO varied on decadal timescales. The RFT changes were the major contributions to the global-scale warming trend and the regional-scale enhanced warming in the semi-arid regions. Guan et al. (2015) found that the radiatively forced temperature has shown a warming trend in the past decades. The local processes dominated the enhanced warming in the semi-arid regions. These possible local processes have been listed in Fig. 15.

The regional RFT was mainly induced by the interaction among atmosphere, land surface, snow/ice and frozen ground cover change, and regional human activities. For example, the drying of sandy or rocky soil by higher temperatures would increase surface albedo, reflecting more solar radiation back to the space. And the substantial decline of snow/ice and frozen ground change in the past 30 years, particularly from early spring through summer (Zhai and Zhou, 1997), may cause the surface temperature to increase in the cold season via the influence on albedo. The thickness of seasonally frozen ground has decreased in response to winter warming (Lemke et al., 2007), which will emit more CO₂ into the atmosphere. The net radiation in the semi-arid regions will become a radiation sink of heat relative to the

surrounding regions. Mulitza et al. (2010) found that local anthropogenic dust aerosols associated with human activities (Chen et al., 2010) such as agriculture and industrial activity accounted for 43 % of the total dust burden in the atmosphere. The radiatively forced effect of aerosol may be another key process in the enhanced warming of the semi-arid region. More investigations are needed to quantify the contribution of different local processes.

Our results also explained the co-existence of regional warming and the warming hiatus across the entire Northern Hemisphere. The major interpretation of the warming trend slowdown (WTS) claimed that natural variability played an important role in global temperature variability (Easterling and Wehner, 2009; Wyatt et al., 2012; Wyatt and Curry, 2014; Kosaka and Xie, 2013). The RFT had a warming contribution which offset the cooling effect of DIT, and resulted in a hiatus over the Northern Hemisphere (Guan et al., 2015). According to the results of our study, the RFT had made a major contribution to global warming, where the most obvious warming appeared in the drylands. And we conclude that the long-term global-mean SAT warming trend was mainly related to the radiative forcing produced by the global, well-mixed GHGs. However, the regional anthropogenic radiative forcing caused the enhanced warming in the semi-arid regions. Therefore, the hiatus as a phenomenon of global scale was not in conflict with the regionally enhanced warming in the semi-arid regions.
