SUMMARY

An experimental investigation has been carried out to provide detailed pressure distributions on a wing in close proximity to a tip vortex of known structure generated by a larger, upstream semispan wing. Overall loads calculated by integration of these pressures are checked by independent measurements made with an identical model mounted on a force balance. For certain positions of the following wing, the data are shown to include effects from the unrolled-up portion of the vortex sheet from the generating wing. With the vortex close to the wing, these effects are minimal.

Conventional methods of wing analysis are used to predict the loads on the following wing. Two different versions of strip theory are shown to give uniformly poor results for the loading distribution, although the predictions of overall lift and rolling moment are sometimes acceptable. Modeling the incident vortex with vorticity distributed in the core instead of concentrated at the center is important when the vortex is within a core radius of the wing. Vortex-lattice theory gives good results if the vortex with distributed vorticity is constrained to be rectilinear and the loadings are calculated from linearized pressures. The equivalent relation from reverse-flow theory that can be used to give overall loads is presented. Failure to model accurately the nonlinear contributions to loading is shown to have small impact on the overall results.

## INTRODUCEION

There is considerable practical interest in the ability to calculate the loads induced on a wing surface in a free stream by a nearby streamwise vortex. For example, this ability is important in the analysis of the vortex hazard problem for a small aircraft operating in the wake of a larger aircraft. It is also central to the analysis of helicopter rotor systems and to the design of control or lifting surfaces for missiles or
aircraft if these surfaces are subject to concentrated vortices generated by the nose or by canards. Several investigators have formulated models for calculating induced loads of this type; varying levels of success have been achieved in terms of prediction of overall offect:s.

In spite of the fact that there is a voluminous literature on this subject, there exists a need for experimental data of sufficient detail and completeness to evaluate the theoretical methods. With the exception of the investigation of reference 1 , the existing data lack either detailed measurements of the distribution of loading on the wing or knowledge of the structure of the approaching vortex; reference 1 deais with the case where the vortex-generating wing is at most or the same span as the following wing. Therefore, previous tests of theor"es for cases where the vortex core is at all appreciable compared to the sale of the following wing have been in terms of gross effects, or have requirec. critical assumptions with respect to the nature of the vortizal flow field involved.

The purpose of the work described herein is to provide measurements of sufficient completeness to allow detailed evaluation of existing theories for loads of this type and to conduct such an evaluation. In the particular cases treated, the loads are measured with the following wing at zero angle of attack using pressure taps; the vortux generator is a larger semispan wing. To allow checking of the overall loads calculated by integration of the measured surface pressures, independent measurements are made using an identical model mounted on a force balance. The theoretical methods evaluated are standard methods of wing analysis.

This report describes the experimental arrangement utilized, presents and analyzes the data. The theoretical methods used are described, detailed comparisons with the measurements are made, and shortcomings of the methods are assessed.

## SYMBOLS

| $\mathrm{a}_{0}$ | three-dimensional lift-curve slope |
| :---: | :---: |
| $\mathrm{a}_{\mathrm{OL}_{\mathrm{L}}}, \mathrm{a}_{\mathrm{OR}}$ | lift-curve slopes for wing portions, equation (18) |
| RR | aspect ratio of wing portion, equation (1, ) |
| b | wing span |
| c | wing chord |
| $c_{l}$ | section-lift coefficient |
| $\begin{aligned} & \mathrm{c}_{\mathrm{I}_{\alpha}} \\ & \left(\mathrm{c}_{\ell}\right)_{r o 11} \end{aligned}$ | ```section lift-curve slope section-iif: coefficient for wing in steady roll, equation (1.7)``` |
| $C_{l}$ | rolling-moment coefficient, $\mathrm{R} / \mathrm{q}_{\infty} \mathrm{b} \mathrm{s}$ |
| $\hat{C}_{\ell}$ | rolling-moment coefficient for force model at zero angle of atrack in absence of vortex; tare vailue |
| $C_{L}$ | lift coefficient, $\mathrm{I} / \mathrm{G}_{\infty} \mathrm{S}$ |
| ${ }^{\text {c }}$ | lift coefficient for force model at zero angle of attack in absence of vortex; tare value |
| $C_{p}$ | pressure coefficient (based on corrected pressure), $\left(p-p_{\infty}\right) / q_{\infty}$ |
| $I_{1}, I_{2}, I_{3}$ | exponential integrals, equations (15), (16) and (21) |
| k | constant in model for leading-edge contribution to section lift, equation (4) |
| L | Iift |
| p | static pressure corrected for pressure measured at same point on pressure model at zero angle of attack in absence of vortex; also roll angular velocity, positive right wing down |
| P | ratio of semi-perimeter to span of wing portion, equation (17) |
| $\mathrm{G}_{\infty}$ | free-stream dynamic pressure |
| r | radial. distance from vortex centerline |
| R | rolling moment, positive right wing down |
| $\mathrm{Re}_{\mathrm{c}}$ | Reynolds number based on the chord of the following wing |
| 5 | wing semispan, b/2 |

| S | wing area, be for rectangular wing |
| :---: | :---: |
| $t$ | pseudo time coordinate, equation (1) |
| $\mathrm{V}_{\theta}$ | tangential velocity in vortex, equation (2) |
| $V_{\infty}$ | free-stream velocity |
| w | component normal to wing of velocity due to vortex, equations (9) and (12) |
| $\mathrm{X}, \mathrm{Y}, \mathrm{z}$ | Cartesian coordinates with origin at the centerline of the leading edge of the following wing, cm, figure 1 |
| $Y_{v}, z_{v}$ | coordinates of the vortex center assuming the presence of the wing causes no deflection |
| $\alpha$ | angle of attack |
| $\Delta y_{v}, \Delta z_{v}$ | change in location of the vortex center due to deflection caused by the presence of the wing |
| $\Gamma$ | circulation of vortex at radius, $x$, equation (1); positive for counterclockwise rotation |
| $\Gamma_{0}$ | strength of notential vortex; or circulation of vortex at large $r$ |
| $v$ | pseudo viscosity, equation (1) |

## Subscripts

| $G$ | generating wing |
| $\ell$ | lower wing surface |
| P | pertainirg to a potential vortex |
| $S$ | pertaining to the split-wing version of strip theory |
| $u$ | upper wing surface |
| $v$ | vortex |
| $\infty$ | free stream. |

## APPARAPUS AND INSTRUMENIATION

The experiment was performed in the wind tunnel which is under the jurisdiction of the U. S. Army Air Mobility Research and Development Laboratory at the NASA/Ames Research Center. This is a closed-circuit, atmospheric tunnel with a test section of rectangular cross section 2.1 meters ( 7 ft ) high $r$; 0 metere ( 10 ft ) wide. It is described in more detail in reforence 2 . Whe general arrangement and coordinate system used are shown in rigure 3 . The "generating wing" is a semispan model attached to the tumel scoles with its trailing edge at the center of the tunnel turntable. The geometrical characteristics of this wing are listed in Table I. Its measured lift curve (verified in this investigation) and more geometrical detail are available in reference 3. The "following wing" was mounted by means of a small fuselage to the tunnel traversing system (not shown) with its leading edge two generating-wing chord lengths downstream of the generating wing trailing edge. This strearmise position was chosen to minimize the effects of vortex meander (discussed later) and to coincide with a position where a portion of the velocity field of the vortex had previously been measured (ref. 4). While this close proximity to the generating wing is totally unrepresentative of the vortex hazard problem, minimizing meander and operating in a vortex whose structure is at least partially known greatly facilitate application of theoretical methods. The following wing geometrical characteristics are listed in Table $I$; the exterior lines of the fuselage are shown in figure 2. Provision was made to pitch the following wing-fuselage assembly relative to the traversing system.

There were actually two following wing-fuselage assemblies of identical exterior shape but of different internal construction and instrumentation. One (the "force model") was fabricated of wood and fiberglass and was mounted to the traversing system through a 2.54 cm (1 in.) diameter Task Mark XIVA force balance (balance center at $x=2.59$, $y=0, z=-2.54$ ). The gages used to measure lift and rolling moment were calibrated in the tunnel; the estimated experimental uncertainty for a single measurement of lift is $\pm 5$ percent, for rolling moment $\pm 3$ percent. The other assembly (the "pressure model") was fabricated of aluminum and was instrumented with 371 pxessure taps distributed in chordwise rows on the upper and lower wing surfaces as shown in figure 3. The taps indicated as missing at a particular section in this figure were either omitted because of manufacturing constraints or were found to leak or to be plugged after assembly of the wing to the fuselage.

The pressure taps were installed in the splitt wing in one of the two ways shown in figure 4. The stainless steel tubes from the pressure taps were led out through the wing and fuselage interiors and were connected to nine Scanivalve modules (with internally mounted pressure transcucers) by 0.75 meter ( 30 in.) lengths of flexible tubing. I'he Scanivalve modules were attached to the tunnel traversing mechanism aft: of the model. The electrical leads from the transducers were led out through the tunnel floor to the power supplies, signal conditioning cquipment, and data acçuisition system (described below) located in the tumnel control area. The individual pressure lines were carefully leak checked at several. stages in the construction of the model, including after its final installation in the tunnel.

The pressure transducers used were all of the differential type; their reference sides were manifolded to the static pressure from the standard tunnel "q" probe. This static pressure (as well as the total pressure from this probe) was also input to a port on each Scanivalve. Because all pressures recorded were to be converted to pressure coefficient form before use, this procedure effectively allowed each transducer to be calibrated on each cycle of the associated Scanivalve. The ranges of the transducers used varied from $1.72 \mathrm{kPa}(0.25 \mathrm{psi})$ to 17.2 kPa (2.5 psi); pressure taps located nearest the trailing edge were connected to the transducers with the smallest ranges for best resolution.

To allow determination of the mean vortex position under various conditions (which are described later), a dual-beam, two-color backscatter laser Doppler velocimeter furnished by the Large-Scale Aerodynamics Branch at the NASA/Ames Research Center was used. For a giver test condition, the two beams were positioned so that on the average they bracketed the vortex core, as described in reference 4, and the mean vortex position was determined from knowledge of the LDV focus location. The LDV beams were made visible by injecting vaporized mineral oil into the tunnel in one of two ways: aither a conventional resistance heating smoke wand was placed with its tip near the tip of the generating wing (in which case the vortex was smokefilled in a clear free stream), or the entire tunnel was filled with vapor formed by an air-blast atomizer (in which case the vortex core was clear in a smoky free stream). In this latter technique, the smoke was ducted into the tunnel in the diffuser section just downstream of the test section. Both techniques proved useful in different ${ }^{*}$ facets of this investigation.

One final piece of instrumentation was provided to allow assessment of the instantaneous deviation of the vortex Erom its mean position (meander). This information allows conditional sampling of the data from the force model. Using this procedure, only data collected when the vortex is in its mean position are used to calculate rolling moment and lift. This approach is not possible with the pressure model because of inaderuate frequency response of the pressure instrumentation due to the (relatively) long pieces of small diameter tubing reguired to connect the tapster Scanivalves. The instrument used to provide this instantaneouspositisi i formation is a vorticity meter (sketched in figure 5) specially des.get tor this purpose. The maximum diameter of the blaces is approximately equal to the measured diameter of the vortex core (ref. 4) and the device was constructed to allow rapid response to rotational speed changes (the calculated time constant of this instrument is on the order of $10 \mathrm{~m} / \mathrm{sec}$ ). When the position of the vorticity meter is adjusted to coincide with the mean vortex position, decrease in its rotational speed is an indication of movement of the vortex away from this mean position. By averaging only force model data associated with a vorticity-meter rotational speed which is above some value, and then increasing this threshold value, one can gain an understanding of the sensitivity of vortex-induced lift and rolling moment to deviation from vortex mean position. This approach cannot, of course, eliminate the contribution to these quantities from the meander velocity of the vortex in its mean position. The conditionally sampled data will include this contribution.

The vorticity meter lateral and vertical positions were adjusted to coincide with the mean vortex position (as determined by the LDV) for a given location of the force model. It was always located three followingwing chord lengths downstream of the following-wing leading edge ( $x=3 c$ ). The response of the vorticity meter to the vortex motion is illustrated in figure 6 which is a tracing of the rotational speed output obtained on an oscillograph for a case where the wing was very close to the vortex. Although no vigorous calibration of the rotational speed was maintained (because only relative values were to be used in the conditional sampling process), it is known that the peak speed obtained in this tracing is in excess of $940 \mathrm{rad} / \mathrm{sec}(9000 \mathrm{rpm})$. It is clear from this figure that the frequency response of the vorticity meter is adequate for it to serve as an indicator of relative vortex position.

The data acquisition system in the tunnel can simultaneously digitize up to 12 analog inputs and punch these values on computer cards for later reduction. One of these analog input channels was always used for the output of the "q" probe transducer. In testing with the force model, for each position of the wing relative to the mean vortex position, this system was used to record the instantaneous signals from the balance and vorticity meter at approximately 100 different instants in time. Note that conditional sampling was not practical at data-acguisition time but was done later during data reduction. With the pressure model, the pressure transducer in each of the nine scanivalves was connected to an analog input channel (after appropriate amplification). Because the Scanivalves had to be cycled through all the ports, a period of about 30 seconds was required to record the pressure field on the whole wing. This process was repeated on the order of 20 times to generate an average of the pressure at each point on the wing.

## TEST CONDIIIONS AND PROCEDURES

## Vortex structure and Location

As previously mentioned, the streamwise position of the following wing was chosen to coincide with one of the measurement planes in an earlier study of the structure of the tip vortex from this generating wing (ref. 4). In that study, the identical generating wing was mounted in a similar way (vertically) in the test section of the other 2.1 meter by 3.0 meter ( 7 - by 10 -foot) wind tunnel at the Ames Research Center and a rapid-scanning LDV was used to obtain lateral traverses of tancencial velocity through the vortex core.

Figure 7 shows the resulting profile (for $\alpha_{G}=12^{\circ}, V_{\infty}=24 \mathrm{~m} / \mathrm{sec}$ ) in the streamwise plane of interest here. In this figure, the tangential velocity (corrected for tunnel wall images)'is normalized by the freestream velocity and the radial coordinate is normalized by the span of the generating wing. The center of the vortex is taken tio be equidistant between the positions of maximum measured tangential velocity. A reasonable degree of symmetry is exhibited between the two sides of the traverse, except just at the edge of the core $\left(r / b_{G} \approx 0.01\right)$ and for $r / b_{G} \geqslant 0.08$. One may not, of course, infer any further degree of symmetry for the vortex from this, for this close to the wing one would expect neither that the vortex is axisymmetric nor that it is fully rolled up (e.g., see refs. l,

5-8). In fact, the small asymnetry noted at large $r / b_{G}$ in figure 7 may be evidence of the unrolled-up portion of the wake (ref. 7). lhe effects on the following wing of the unrolled-up portion of the wake are apparent in some of the data discussed in a later section.

Having duly noted that the vortex at this location is not axisymmetric, we will nevertheless proceed to represent its velocity distribution by two axisymmetric models. These models are used later as input to theoretical calculations of the lift and rolling moments induced on the following wing. This approach is dictated by a desire to determine the accuracy achievable by simple modeling, as well as by a lack of detailed data on the asymmetric structure. The two models are shown in figure 7. The first is a simple potential vortex with strength determined by fitting the experimentrl velocity distribution for $r / b_{G}>0.02$. The second has vorticity distributed in accord with that in a two-dimensional, laminar, unsteady vortex (an "aged" vortex):

$$
\begin{equation*}
\frac{\Gamma}{\Gamma_{0}}=1-e^{-r^{2} / 4 v t} \tag{1}
\end{equation*}
$$

This equation can be recast in the form:

$$
\begin{equation*}
\frac{r V_{\theta}}{b_{G} V_{\infty}}=\left(\frac{\Gamma_{0}}{2 \pi V_{\infty} b_{G}}\right)\left[1-e^{-\left(r / b_{G}\right)^{2}\left(b_{G}^{2} / 4 \nu t\right)}\right] \tag{2}
\end{equation*}
$$

In applying this model, $\Gamma_{0}$, the circulation of the vortex at large $r$, is taken to be equal to the circulation of the potential vortex of the first model. The combination $b \frac{2}{G} / 4 \nu t$ is chosen to provide best agreement to the experimental data as replotted in the form of figure 8 . As a result of these procedures, $\Gamma_{o} / 2 \pi V_{\infty} b_{G}=9.68 \times 10^{-3}, b_{G}^{2} / 4 v t=1.052 \times 10^{4}$. It is of some interest to note that $\Gamma_{0}$ determined in this way is 77 percent of the value calculated from the maximum section-lift coefficient measured on this wing at $\alpha_{G}=12^{\circ}$ (as reported in ref. 9). This is suggestive of the extent of the rolling-up process at this streamwise location.
${ }^{*}$ This max
A.1. data in the present investigation were taken with $V_{\infty}=49 \mathrm{~m} / \mathrm{ser}$ : (160 fps) which corresponds to a dynamic pressure of 1.44 kPa ( 30 psf ). The generating wing was always at $\alpha_{g}=12.6$ : Because these values are somewhat different from the conditions used to generate the data of figures 7 and $8\left(V_{\infty}=24 \mathrm{~m} / \mathrm{sec}, \alpha_{G}=12^{\circ}\right)$, the constants just calculated must be adjusted before they are applied to the present situation. Because the roll-up process is essentially inviscid, no correction is applied for the change in Reynolds number (the $V_{\infty}$ discrepancy). It is further assumed that the small ( $0.6^{\circ}$ ) discropancy in $\alpha_{G}$ has no effect on the distribution of vorticity ( $b_{G}^{2} / 4 \nu t$ unchanged) but that the effect on the total shed vorticity is linear in $\alpha_{G}$. This leads to the final. value, $\Gamma_{o} / 2 \pi V_{\infty} b_{G}=10.14 \times 1 n^{-3}$.

The position of tife wre furbed vortex (in the absence of a following wing) was estaklished using the LDV described earlier. To allow for positioning of the vorticity meter, it was also necessary to measure the perturbed vortex location at $x / c=3$ as a function of following-wing position again using the LDV. Because of the window arrangement in the tunnel, this proredure was possible only with the vortex over the left wing. Measurements were made for $y_{v} / s=-0.5$ over a range of positive $z_{v} / c$. The deflection of the vortex from its unperturbed location is shown in figure 9. These deflections were also used to position the vorticity meter for the data taken with the force model for $y_{V} / s=0.5$.

## Tests with the Force Model

Most of the testing with the force model was done using the arrangement shown in figure 1 (following wing horizontal, angle of attack nominally zero) with the vorticity meter appropriately positioned. The vortex positions at which data were taken are shown in Table 2 along with the run number assigned to that data. Notice that the coordinates in this table are for the unperturbed position of the vortex relative to the force model. Although in these terms the vortex would appear to be beneath the wing (for $z_{v} / c<0$ ), in actuality the wing caused the vortex to deflect upward as shown for $z_{v} / c>0$ in figure 9. The minimum $z_{v} / c$ position shown $\left(z_{v} / c=-0.18\right)$ is for the case where the wing was observed to bifurcate the vortex

As is also shown in Table 2, some data were obtained with the follow ing wing vertical (rotated $90^{\circ}$ counterclockwise, looking upstream), but still nominally at zero angle of attack. Because the coordinate system
shown in figure 1 is taken to be fixed in the model., with the wing vertical a vertical sweep of the model corresponds to varying $y_{v} / s$, a lateral. sweep to varying $z_{v} / c$. Runs taken at the intersection of the lateral and vertical sweeps are listed under both kinds of sweeps in Table 2 .

To account for small imperfections in its construction, the loads on the force model were also obtained with the generating wing set to generate zero lift. For this measurement, the force model (still nominally at zero angle of attack) was set horizontal and was located well above the generating wing's wake. These loads $\left(\hat{C}_{I}=0.0858, \hat{C}_{\ell}=-0.00866\right.$, run 43) were applied as tares to all the other data from the force model; the resultant values $\left(C_{L}, C_{\ell}\right)$ are thus induced solely by the presence of the vortex (under the assumption that for the positions occupied by the following wing, variatiors in the flow angularity in the free stream are small). The lift curve for the force mociel was also obtained (runs 43-48).

As previously mentioned, the capability existed for conditionally sampling the data from the force model using the thtational speed output of the vorticity meter as an indication of instantaneous vortex position. Nonlinear effects of small changes in vortex position would be removed from the average values determined in this way, and one would expect the resulting mean values to converge and the standard deviation to be reduced as more of the data where the vortex is "out-of-position" are excluded. However, the effects of decreasing the sample size apparently offset the effects of eliminating data for which the vortex was out-of-position, for no such behavior for mean and standard deviation was observed. Therefore, values from the force model presented in this report are averages of all the samples collected at a given test condition.

## Tests with the Pressure Model

All of the testing with the pressure model was done with the pressure instrumented wing horizontal. The vortex positions at which data were obtained are shown in Table 3. As with the force model, the loads in the absence of the vortex were measured (run 69) and all results corrected for these tare values. This process, when applied to the pressure at each tap location, results in $C_{p}$, the local pressure coefficient from which the effects of the wing thickness and any construction irregularities have been removed. The lift curve for the pressure model was also measured (runs 50-51, 59-74).

As mentioned previously, for each mun approximatoly 20 samples of the pressure at each pressure-tap location were recorded. At each tap location, these values were averaged, converted to $C_{p}$, and integrated chordwise to define the span loading as follows*:

$$
\begin{align*}
c_{\ell}= & \int_{0}^{1} \frac{p_{\ell}-p_{u}}{q_{\infty}} d(x / c)=\int_{0}^{05} \frac{p_{\ell}-p_{u}}{q_{\infty}} d(x / c)+\int_{05}^{9} c_{p_{\ell}} d(x / c) \\
& -\int_{.05}^{9} c_{p_{u}} d(x / c)+\int_{.9}^{1} \frac{p_{\ell}-p_{u}}{g_{\infty}} d(x / c) \tag{3}
\end{align*}
$$

The second and third terms on the right-hand side of this equation are evaluated by a straightforward numerical integration of the data using the trapezoidal rule. The fourth term provides a negligible contribution. The first term, however, provides a substantial contribution, although it involves only a small region in the wing which cannot be adequately instrumented with pressure taps in a model of this scale. Therefore, the contribution of this term was modeled hy the relation

$$
\begin{equation*}
\int_{0}^{05} \frac{p_{\ell}-p_{u}}{q_{\infty}} d(x / c)=\left.k\left(c_{p_{\ell}}-c_{p_{u}}\right)\right|_{\frac{x}{c}=0.05} \tag{4}
\end{equation*}
$$

where $k$ was determined to be 0.0639 from two-dimensional section data for an NACA 0012 wing (ref. 10). This procedure should be quite accurate over most of the wing as long as the local angle of attack induced by the vortex does not become too large.

Span loading as calculated by equations (3) and (4) is integrated again to get the overall wing lift and rolling-moment coefficients:

[^0]\[

$$
\begin{gather*}
c_{I}=\frac{L}{q_{\infty} S}=\frac{1}{2} \int_{-1}^{I} c_{\ell} d(y / s)  \tag{5}\\
c_{\ell}=\frac{R}{q_{\infty} b S}=\frac{1}{4} \int_{-1}^{1}(y / s) c_{\ell} d(y / s) \tag{6}
\end{gather*}
$$
\]

These equations, vaiid for a rectangular wing, are evaluated dy the trapezoidal rule making use of the fact that $c_{\ell}=0$ at $y / s= \pm 1$. Linear interpolation is used through the fuselage location.

## PRESENPATION AND DISCUSSION OF EXPERIMENTAL RESULTS

All of the data acquired in this investigation are tabulated in Appendix A. In this section, selected results are presented and discussed.

The Following wing in the<br>Absence of the Vortex

In figure 10, the integrated lift coefficients for both the force and pressure models are shown as functions of angle of attack. With the exception of one apparently anomalous data point, the agreement for lift derived from the two models is good (within the uncertainty of the force data, $\pm 5$ percent). Predictions of the lift curve from a vortex-lattice program (described later) and from the method of reference 11 are shown for comparison and agree with the data to within this same order of accuracy. It is shown in reference 12 that for the low Reynolds number of this test $\left(\mathrm{Re}_{\mathrm{c}}=330,000\right)$ the lift curve becomes nonlinear for $\alpha$ greater than about $10^{\circ}$. The error bands on the data points from the force model show the standard deviation of those measurements. Because of the assumptions required to integrate the pressure data, accuracy of these data is best assessed by comparison to the force model data and to the theoretical estimates.

An example of the span loading measured by means of the pressure model is shown in figure 11. A decrease in section lift in the immediate vicinity of the fuselage is evident. Good ayreement is shown with span
loading calculated by the vortex-lattice program. The break in this calculated curve at the fuselage location indicates that this program as currently configured does not calculate the lift carry-over onto the fuselage.

The Following wing in the
Presence of the Vortex
Measured rolling moment and lift are shown in figures $12(a)$ and (b), respectively, with the vortex at different heights above the right halfsemispan. Measurements from the force and pressure models are shown; in both cases, the following model was horizontal. Good repeatability and reasonable agreement between measurements with the different models is evident. The standard deviation of the measurements from the force model in the presence of the vortex is approximately represented by the symbol size in these figures. Note that this approximately bounds the effects of meander in these data.

The span loadings measured on the pressure model at the conditions of figure 12 are shown in figures 13 (a) through (f). In these figures, the (unperturbed) position of the vortex relative to the wing and the approximate core size are shown to scale. With the vortex far from the wing, as in figure 13 (a), the loading directly under the vortex should be essentially zero. It is seen that $c_{\ell}$ is substantially nonzero at $y / s=0.5$, and that because of the mild gradient of the span loading, the discrepancy is considerably more than could be attributed to uncertainty in the vortex position. Further, $c_{\ell}$ at $y / s=0.5$ is nearer to zero with the vortex somewhat closer to the wing, figure 13 (b). The likely source for this behavior is the unrolled-up portion of the wake from the generating wing;es mentioned earlier, at the streamwise position of the following wing, a substantial amount of the shed vorticity is not rolled up into a symmetric vortex (see sketch on following page). While we propose to do no modeling of the residual vortex sheet to investigate this point further, it is reasonable to suppose that the behavior observed in figures 13 (a) and (b) is due to the fact that more of the wing is exposed

[^1]to this sheet as the separation between the rolled-up vortex and wing increases; additionally, its effects become proportionally more important as those of the vortex are diminished by distance.

When the vortex is closer to the wing (and the effects of the un-rolled-up wake are minimal), one would expect to see evidence of the nonlinear suction lift and vortex-bending contributions to surface pressure discussed in Appendix B. The "bump" in the span loading curves of figures 13 (c) and (d) at $y / s=0.55$ presumably represents these effects (as previously observed in reference 13). Note that because the nonlinear suction and vortex-bending pressures peak directly under the vortex (see Appendix B), this bump is an indication of the perturbed vortex location.

It is reported in reference 13 that when the vortex gets still closer to the wing, bursting occurs and the suction peak disappears. This seems to be the case in figures $13(e)$ and ( $f$ ) which have no "bump" at $\mathrm{y} / \mathrm{s}=0.55$. Remember that the $\mathrm{z}_{\mathrm{v}} / \mathrm{c}$ position reported in figure 13 is the unperturbed location. The vortex is bifurcated by the wing in figure 13 (f). The span-load distribution remains smooth even for this extreme condition.

Further effects of the unrolled-up wake are evident in figures 14 (a) and (b). In these figures, the rolling-moment and lift coefficients measured with the force model are shown for $y_{v} / s=-0.5$. Measurements are shown with the following model horizontal and vertical. It is clear that changing the attitude of the model relative to the wake causes a substantial change in rolling moment and that this change is increased as $z_{v} / C$ increases. The effect of lift is seen to be small.

The remainder of the data gathered in this investigation were for varying $y_{v} / s$ at $z_{v} / c=0.05$. These data are shown in figures $15(a)$ and (b). Measurements with the pressure model horizontal and the force model both horizontal and vertical are included, as are some theoretical results discussed in the next section. The rolling-moment coefficient data of figure 15 (a) essentially confirm the above remarks; that is, measurements made with the force and pressure models horizontal agree reasonaioly well, while those made with the force model vertical show substantial disagreement. The lift-coefficient results of figure 15 (b) again show small effects of model attitude.

To illustrate the detailed loading distributions that result in the integrated values presented to this point, a series of isometric plots of the pressure coefficient on the top and bottom wing surfaces is given in figures $16(a)$ through (f). The position of the vortex for these figures is the same as for figures 13 (a) through (f); that is, $\mathrm{y}_{\mathrm{v}} / \mathrm{s} \quad 1.5$ and $z_{v} / c$ varies from 1.73 to -0.18 . The spanwise station $y_{v} / s=0.5$ is marked with an arrow in these figures. The pressure coefficients plotted have been adjusted for the tare run; that is, the pressure distribution due to thickness (and any irregularities in the wing) has been subtracted out. The coefficients measured at taps located forward of $x / c=0.05$ are not plotted in these figures because they were not used in the integration of loads, as discussed previously. The curve shown at the wing center line on the top surface is the measured pressure distribution there, although it was also not used in the integration. Obviously, no pressures could be measured on the bottom wing surface at the centerline.

In the earlier comments about figures $13(c)$ and (d), notice was made of the "bump" in the loadings at $y / s=0.55$. The surface pressures resulting in these loadings are shown in figures 16 ( $c$ ) and (d). Particular attention should be directed to the top wing surface; $y / s=0.55$ is the spanwise station just to the right of the arrow. The chordwise distribution at this station (and to a lesser degree the distribution at the station marked with the arrow) contrasts markedly with the distributions shown at the other spanwise stations. The (relatively) large negative pressure coefficients existing over the mid and aft portions of the wing at $\mathrm{y} / \mathrm{s}=0.55$ result in a locally increased $c_{\ell}$ (the "bump"). These augmented pressure coefficients are interpreted as the net of the nonlinear suction lift and vortex-bending contributions. As the vortex
approaches the wing, figure $1.6(e)$, and is bilurcated, figure $16(f)$, the increased loading over the mid and aft portions of the wing disappears. The pressure distributions far from the vortex in all these figures resemble standard section data and suggest that that portion of the flow field might be mode'.ed in a straightforward fashion using strip theory. The success of this theoretical approach (and others) is assessed in the next section. Some more detrils of pressure distributions are presented in support of specific points.

## DESCRIPTION OF THEORETICAL METHODS AND COMPARISON WITH DATA

Three standard methods of linear wing analysis (strip theory, vortexlattice theory, and reverse-flow theory) are used to predict the loads on the wing due to the vortex. The boundary, conditions used in these calculations consist of the induced velocity field from either a potential vortex or the "aged" vortex of equation (1), with the constants required for the description of the vortex structure determined as described earlier. The methods are applied assuming that the presence of the wing does not alter the vcrtex structure; that is, the vortex remains rectilinear and the incident velocity field is unchanged from that existing for the isolated vortex. Because the vortex models used take no account of the presence of the unrolled-up vortex sheet discussed earlier, the models are applied only with the vortex close to the wing where the effects of this sheet are minimal.

## Strip Theory

Several versions of this simple approach have been applied to this problem in prior investigations, with varying claims of success (see, for example, refs. $1,7,14$, or 15).

Using strip theory, each infinitesimal element of the wing is considered to be independent of the others, and the load on each element is assumed to be calculable from the local section angle of attack. Thus for a rectangular wing

$$
\begin{align*}
& c_{L}=\frac{1}{2 s} \int_{-s}^{s} c_{L_{\alpha}} \frac{w^{v}}{V_{\infty}} d y  \tag{7}\\
& c_{\ell}=\frac{1}{4 s^{2}} \int_{-s}^{s} c_{L_{\alpha}} Y \frac{w_{v}}{V_{\infty}} d y \tag{8}
\end{align*}
$$

where $c_{I_{\alpha}}$ is the section lift-curve slope and $w_{v} / v_{\infty}$ is the local section angle of attack. Previous applications of this method differ in the amount of empiricism used in the sperification of $\mathrm{c}_{\mathrm{L}_{\alpha}}$ and $\mathrm{w}_{\mathrm{v}} / \mathrm{V}_{\infty}$.

In this section, two versions of strip theory (differing in the treatment of $\mathrm{c}_{\mathrm{L}_{\alpha}}$ ) are used to illustrate the fundamental features of the method. In the first version, ${ }^{{ }^{L_{\alpha}}}$ is assumed to be constant over the entire wing and equal to $a_{0}$, the three-dimensional lift-curve slope $\left(a_{0}=4.58 / \mathrm{radian}=0.08 /\right.$ degree $i s$ used, see fig. 10). Both descriptions of the vortical velocity field developed earlier are used in conjunction with this assumption. If the vortex is to be represented as potential, application of the Biot Savart law yields

$$
\begin{equation*}
\left.\frac{w_{v}}{V_{\infty}}\right|_{P}=-\left(\frac{\Gamma_{0}}{2 \pi V_{\infty}}\right)_{\left(y_{v}-y\right)^{2}+z_{v}^{2}}^{y_{v}-y} \tag{9}
\end{equation*}
$$

and

$$
\begin{gather*}
c_{L_{P}}=\left(\frac{a_{0}}{4 s}\right)\left(\frac{\Gamma_{0}}{2 \pi V_{\infty}}\right) \ln \left[\frac{\left(y_{v}-s\right)^{2}+z_{v}^{2}}{\left(y_{v}+s\right)^{2}+z_{v}^{2}}\right] \\
c_{l_{P}}=-\left(\frac{a_{0}}{2 s}\right)\left(\frac{\Gamma_{0}}{2 \pi V_{\infty}}\right)\left\{1-\frac{z_{v}}{2 s}\left[\tan ^{-1}\left(\frac{y_{v}+s}{z_{v}}\right)\right.\right. \\
\left.\left.-\tan ^{-2}\left(\frac{y_{v}-s}{z_{v}}\right)\right]-\frac{y_{v}}{4 s} \ln \left[\frac{\left(y_{v}+s\right)^{2}+z_{v}^{2}}{\left(y_{v}-s\right)^{2}+z_{v}^{2}}\right]\right\} \tag{11}
\end{gather*}
$$

I: the vortex is represented by equation (1) (an "aged" vortex),

$$
\begin{equation*}
\left.\frac{w_{V}}{V_{\infty}}\right|_{A}=\left.\frac{w_{V}}{V_{\infty}}\right|_{P}\left\{1-e^{-\left[\left(y_{v}-y\right)^{2}+z_{v}^{2}\right] / 4 v t}\right\} \tag{1.2}
\end{equation*}
$$

and

$$
\begin{gather*}
c_{L_{A}}=c_{L_{p}}+\left(\frac{a}{4 s}\right)\left(\frac{\Gamma_{0}}{2 \pi V_{c o}}\right)\left(I_{I}-I_{z}\right)  \tag{13}\\
c_{\ell_{A}}=c_{\ell_{P}}-\left(\frac{a_{0}}{4 s^{z}}\right)\left(\frac{\Gamma_{0}}{2 \pi V_{m}}\right)\left[\frac{Y_{V}}{2}\left(I_{I}-I_{2}\right)\right. \\
\left.-\int_{Y_{V}}-s \quad \frac{\eta^{2} e^{-\left(\eta_{1}^{2}+z_{V}^{2}\right) / 4 v t}}{\eta^{2}+z_{v}^{2}} d \eta\right] \tag{14}
\end{gather*}
$$

The last term on the right-hand side of equation (14) is evaluated numerically. $I_{1}$ and $I_{2}$ are the exponential integrals

$$
\begin{align*}
& I_{1}=\int_{t_{1}}^{\infty} \frac{e^{-t}}{t} d t  \tag{15}\\
& I_{2}=\int_{t_{2}}^{\infty} \frac{e^{-t}}{t} d t \tag{16}
\end{align*}
$$

with $t_{1}=\left[\left(y_{v}-s\right)^{2}+z_{v}^{2}\right] / 4 v t$ and $t_{2}=\left[\left(y_{v}+s\right)^{2}+z_{v}^{2}\right] / 4 v t$.
The second version of strip theory used here is based on the reasoning (set forth in reference 15) that the portions of the wing on either side of the vortex act as separate wings, each with its own (constant) value of lift-curve slope. The lift-curve slope for either portion of the wing is determined from

$$
\begin{equation*}
c_{L_{\alpha}}=\frac{2 W R}{P \cdot R+2} \tag{17}
\end{equation*}
$$

where $\mathbb{R}$ is the aspect ratio and $P$ is the ratio of semi-perimeter to span, each evaluated for the wing portion treated as a separate wing. Thus for the rectangular wing treated here,

$$
\begin{align*}
c_{L_{\alpha}} & =a_{o_{L}}=\frac{2 \pi\left(\frac{b}{c}\right)\left(1+\frac{y_{v}}{s}\right)}{\left(\frac{b}{c}\right)\left(1+\frac{y_{V}}{s}\right)+6} \tag{18}
\end{align*} \quad, \quad-1 \leq \frac{y}{s} \leq \frac{y_{V}}{s}
$$

Specifying $c_{L_{\infty}}$ as double-valued at $y_{v} / s$ causes no problems in equation (7) or (8) because $w_{v} / v_{\infty}$ vanishes there.

In this second (split-wing) version of strip theory, the aged-vortex relation of equation (12) is used to describe the distribution of section angle of attack. Thus

$$
\begin{align*}
C_{L_{S, A}}= & \left(\frac{1}{4 s}\right)\left(\frac{\Gamma_{O}}{2 \pi V_{\infty}}\right)\left\{a_{o_{L}}\left[\ln \frac{z_{V}^{2}}{\left(y_{V}+s\right)^{2}+z_{V}^{2}}+I_{3}-I_{2}\right]\right. \\
& \left.+a_{o_{R}}\left[\ln \frac{\left(y_{V}-s\right)^{2}+z_{V}^{2}}{z_{V}^{2}}+I_{1}-I_{B}\right]\right\} \tag{19}
\end{align*}
$$

and

$$
c_{L_{S, A}}=-\left(\frac{1}{4 s^{2}}\right)\left(\frac{\Gamma_{O}}{2 \pi V_{\infty}}\right)\left\{a _ { o _ { L } } \left[s+y_{v}-z_{v} \tan ^{-1}\left(\frac{y_{V}+s}{z_{v}}\right)\right.\right.
$$

$$
\left.+\frac{Y_{v}}{2} \ln \frac{z_{v}^{2}}{\left(y_{v}+s\right)^{2}+z_{v}^{2}}-\frac{y_{v}}{2}\left(I_{2}-I_{3}\right)-\int_{0}^{Y_{v}^{+s}} \frac{\eta^{2} e^{-\left(\eta^{2}-1 z_{v}^{2}\right) / 4 v t}}{\eta^{2}+z_{v}^{2}} d \eta\right]
$$

$$
+a_{o_{R}}\left[s-y_{v}+z_{v} \tan ^{-1}\left(\frac{y_{v}-s}{z_{v}}\right)+\frac{y_{v}}{2} \ln \frac{\left(y_{v}-s\right)^{2}+z_{v}^{2}}{z_{v}^{2}}\right.
$$

$$
\begin{equation*}
\left.\left.-\frac{y_{v}}{2}\left(I_{3}-I_{1}\right)-\int_{0}^{s-y_{v}} \frac{\eta^{2} e^{-\left(\eta^{2}+z_{v}^{2}\right) / 4 v t}}{\eta^{2}+z_{v}^{2}} d \eta\right]\right\} \tag{20}
\end{equation*}
$$

where $I_{3}$ is the exponential integral

$$
\begin{equation*}
I_{3}=\int_{\frac{z_{v}^{2}}{4 v t}}^{\infty} \frac{e^{-t}}{t} d t \tag{21}
\end{equation*}
$$

The integrals involving $\eta$ in equation (20) are evaluated numerically. Predictions of rolling moment from equations (11), (14), and (20) are shown for $z_{v} / c=0.05$ in figure $15(a)$. The predictions shown ignore the effects of the image vortices present because of the tunnel walls. Inclusion of the closest eight of these images results in very small changes in the coefficients ( 0.002 in $C_{\ell}, 0.01$ in $C_{L}$ ); the effects of these images are therefore neglected in all subsequent calc"lations.

ORIGINAL PAGE IS<br>OF POOR QUALITY

It is seen that the best overall agreement with data js obtajned for the approach of equation (14) which uses $c_{I_{1}}=a_{o}$ for the whole wing in conjunction with the aged vortex. However, the agreement attained by this method is quite variable. Near $y_{v} / s=0$, agreement within about 10 percent is attained; at $y_{v} / s=0.5$, the discrepancy is nearly 40 percent; but at $y_{v} / s=0.9$, there is excellent agreement: Examination of the lift coefficient results of figure 15 (b) reveals a similarly varying level of agreement for this method (eq. (13)); here, however, the whole-wing method in conjunction with a potential vortex (eq. (l0)) leads to virtually identical results, while the split-wing method (eq. (19)) exhibits considerably improved agreement with data for all $y_{v} / s_{\text {. }}$

The reason for this geemingly erratic behavior is apparent from examination of the predicted and measured span loadings in figures 17 (a) and (b) . These figures show cases where the agreement with data for rolling moment coefficient from equation (14) is poor and excellent, respectively. The span loadings predicted using the whole-wing and spilt-wing versions of strip theory and equation (12) are shown; that from the whole-wing approach and equation (9) (not shown) differs from the whole-wing, equation (12) approach only in the immediate vicinity of the vortex where $\left|c_{\ell}\right|$ becomes very large. Predictions from vortex-lattice theory are also shown and are discussed later. It is clear in both figures that both versions of strip theory do a poor job of predicting the spanwise distribution of loading. This is particularly obvious near the vortex where the strorg spanwise gradients invalidate the assumption of no interference between adjacent strips. Therefore, where strip theory gives good results it is fortuitous. Compensating errors occur at different positions on the wing.

In the context of linear theory, there are two major possible sources for these (offsetting) errors. The first is that mutual interaction between adjacent wing sections is important. The second is that the aged vortex of equation (1) is a poor representation of the velocity field that exists when the vortex is close to the following wing; that is, the previously mentioned deflection and possible bursting of the vortex are not represented by this model and may have strong effects on the induced loading. The first possible source of error is removed by applying vortex-lattice theory (or reverse-flow theory) to the problem with the vortex assumed rectilinear and represented by equation (12). These approaches are now described. The second possible source of error is discussed subsequently.

## Vortex-Lattice Pheory - Rectilinear Vortex

The vortex-lattice method is an implementation of linear, potential theory wherein the wing and fuselage are represented by a network of distributed singularities. The particular implementation used in this work is described in references 16 and 17. In the present work, it was found adequate to model each wing panel by 20 spanwise rows of 4 chordwise horseshoe vortices. The fuselage is modeled as a circular cylincter with diameter of $4.47 \mathrm{~cm}(1.75 \mathrm{in}$.$) and its axis cojncident with the x-axis$ shown in figure 1 . The image of the incident vortex in this cylinder is required : maintain the flow tangency condition on its surface; a second image at fre cylinder's axis is required to mantain the proper circulation at infinity.

Once the wing perturbation velocities are calculated by the linear theory of the vortex-lattice program, they can be used in any desired pressure-velocity relationship to calculate the surface pressures on the wing. These pressures are then integrated to get lift and rolling moment. It is shown in Appendix $B$ that the contributions to surface pressure of the nonlinear terms present in the Bernoulli pressure relation are of the same order and of opposite sign from the contributions due to vortex bending. Therefore, in the present treatment of a rectilinear vortex, it is appropriate to use the linear pressure-velocity relation. However, for illustrative purposes, examples of loadings calculated from Bernoulii pressures are also included.

Integrated rolling moment and lift' calculated in these ways are shown in figures 15 (a) and (b) which are for $z v / c=0.05$; vortex-lattice calculations were made at $y_{v} / s=0.2,0.5$ and 0.9 . Except with the vortex very neax the wing tip, agreement with the rolling-moment data is good for calculations using either linear or Bernoulli pressures. At $Y_{V} / s=0.9$, neither method does very well but the method using Bernoulli. pressures is slightly better. The agreement with the lift data is of the same order as the agreement between data from the force and pressure models.

As before, examination of the distribution of loading can lend some insight into the behavior of the overall results. Returning to figure 17 (a), we see the span loading for a case ( $y_{V} / s=0.5$ ) where both linear and Bernoulli pressure calculations resulted in good agreement with data, with the linear pressure calculation doing slightly better. The improvement in span loading gained by accounting for mutual interaction between
wing sections is immediately obvious by contrasting the agreement of either vortex-lattice approach to data with that of strip theory. It is seen that the loads are calculated quite well, except in the immediate vicinity of the vorter location. Using the Bernoulli relation leads to no particular improverant here; the agreement is slightly better on the left of the vortex, slightly worse on the right side. The similar behavior shown in figure 17 (b) leads to slightly improved agreement using the Bernoulli pressures, because the area to the right of the vortex is off the wing. The span loadings from vortex-lattice theory shown in figure 1.7 (b) result in porier agreement with data for rolling moment than for lift probably because the area of greatest discrepancy has a large moment arm in the rolling-moment calculation.

Some further understanding of the level of agreement achieved by these vortex-lattice methods is derived by examining the most detailed output of these methods, surface-pressure coefficients. It is particularly instructive to compare the spanwise distribution of pressure at a constant chordwise position. Figures 18 (a) and (b) show measured and calculated pressures due to the vortex on the top and bottom wing surfaces, respectively. The measured pressures are for $x / c=0.65$. The calculated pressures are for $x / c=0.688$. In this region of the wing, this small discrepancy in chordwise position is not important for the purposes of the present discussion. The pressure distributions on both surfaces emphasize again that the agreement with data achieved is good, except near the vortex. On the upper surface, the calculated suction peak (using Bernoulli pressures) is overemphasized and slightly mislocated, indicating that the vortex has in fact moved slightly to the right. On the lower wing surface (fig. 18 (b)), there is also a calculated and a measured suction peak. Here, however, the calculated peak is underemphasized and too far to the right. It is clear from these remarks that while using the Bernoulli pressure relation does qualitatively represent some real effects in the calculation, its use in conjunction with the assumption of an unaltered vortex structure does not lead to improved agreement for loading over a calculation made using linear pressures and a rectilinear vortex. Improvement in the accuracy of prediction would seem to depend on an accurate representation of the effects of the wing on the vortex. The improvements to be gained, however, do not appear to warrant the effort required.

## Reverse-Flow Theory

Under the assumption of a rectilinear vortex, reverse-flow theory (refs. 18 and 19 ) can be used to calculate the induced rolling moment and the theory is equivalent to that of the preceding section. After an initial calculation of the span loading in the appropriate reverse flow, subsequent calculation of rolling moment for any vortex position is reduced to a simple quadrature. Although the loading distribution is not an output of this method, the calculation is of the same accuracy as that of the preceding section. Reverse-flow theory is therefore a very economic approach, as long as details of the loading are not required.

The reverse flow relation for rolling moment is

$$
\begin{equation*}
c_{\ell}=-\frac{1}{4 s^{2}} \int_{-s}^{s}\left(\frac{{ }_{v}}{V_{c o}}\right)\left(\frac{V_{\infty}}{p}\right)\left(c_{f}\right)_{r o l l} d y \tag{22}
\end{equation*}
$$

where $\left(c_{\ell}\right)$ roll is the span loading distribution for the rectangular wing in steady roll at roll angular velocity p. Either vortex model can be used for $w_{v} / V_{\infty}$. In this investigation, $\left(c_{l}\right)$ roli was calculated using vortex-lattice theory and equation (22) was applied using wv/ $V_{\infty}$ from equation (12). It was verified that the results from this approach are equivalent to those from vortex-lattice theory (using linear pressures).

Some Remarks on Calculations Including Vortex Bending

As mentioned previously, it is shown in Appendix $B$ that for a point vortex, contributions to loading from vortex bending and nonlineax terms in the Bernoulli pressure relation are of the same order and of opposite sign. To achieve agreement improved over that demonstrated in the previous sections would therefore seem to require satisfactory modeling of vortex bending as well as inclusion of the Bernoulli terms.

The vortex-lattice program used in this investigation incorporates a vortex-tracking scheme based on slender-body theory. This scheme is a simplified version $心$ the analysis for the cruciform wing case discussed in references 19,20 , and 21 . It is inappropriate for use here, however, because it does not take into account the upwash field ahead of the rectangular wing which results in the large vertical deflections of the

# ORIGINAL PAGE IS 

OF POOR QUALITY
vortex shown in figure 9. But: even if a more complet.e tracking schome were devised, it would not lead to sully satisfactory res lts for the case with the vortex very close to the wing. In this situation the vorticity is more widely distributed and neither equation (9) nor (12) is applicable; higher order accuracy would require proper accounting for the full mutual interaction of the vortex and the wing.

This requirement is fortunately not of marjor concern. The accuracy achieved through the straightforward application of strictiy linear analysis in conjunction with a rectilinear vortex model should be entirely satisfactory for most purposes.

CONCLUDING REMARKS
This investigation has resulted in detailed measurements of the loads on a wing in close proximity to a tip vortex generated by a larger, upstream semispan wing. These measurements show that over most of the wing these loads are due to the spanwise varying angle of attack induced by the vortex. For a limited range of wing-vortex spacings, there are also contributions to the loading from vortex bending and the nonlinear terms in the Bernoulli pressure relation. It is demonstrated, however, that failure to model these last two effects results in only a small penalty in predictive accuracy.

Good agreement of the integrated pressure measurements with overall loads measured by means of a force balance is attained. With the vortex very much above the wing, however, the data are shown to include effects of the unrolled-up portion of the vortex sheet emanating from the generating wing. These effects are also evident with the following model rolled $90^{\circ}$ relative to its normal position.

An attempt was made to minimize the effects of vortex meander on the measurements by conditionally sampling the data, using the output of a vorticity meter to indicate vortex instantaneous position. Because the conditional sampling process used here resulted in reduced sample sizes, no improvements were attained over averages calculated using all the data.

Various theoretical methods were used to compute the loads for the experimental cases for which the effects of the unrolled-up wake are minimal. Straightforward applications of strir theory resulted in a varying level of agreement with the measurements. Comparison of the predicted and measured span loadings reveals uniformly poor accuracy, however,
indicating that the limited success strip theory does achieve i.s fortuitous. In these comparisons, two models for the vortex velocity field were used; one a simple potential vortex, the other allowing for distributed vorticity in the core. Both models are based on previously published uDV traverses of the vortex of interest at the appropriate streamwise station. Allowance for the finite vortical core improved agreement slightly over calculations made with the potential vortex model.

Loads predicted using linearized pressures from vortex-latetice theory applied in conjunction with a rectilinear vortex model (with distributed vorticity) are within about 15 percent of measurements unless the vortex is very close to the wing tip. Agreement with measured span loadings is good except in the immediate vicinity of the vortex. The reverse-flow theorem, which can be used to calculate overall loads to the same accuracy, is presented.

The use of pressures calculated using the Bernoulli relation in conjunction with vortex-lattice theory and a rectilinear vortex does not result in improved agreement for loading although it does improve agreement for pressure distribution somewhat. Improvement in predictions should result from accounting for the interference of the wing on the vortex path, unless the wing is very close to the vortex. In this case, the resultant more widely distributed vorticity would have to be modeled.

In summary, economic predictions of overall loads of sufficient accuracy for most applications can be achieved by using reverse-flow theory. If the predictions are for cases where the vortex is within a core radius of the wing, a vortex model with a core should be used. If detailed loading distributions are required, fully linearized vortexlattice theory gives good results. Significant improvements in accuracy beyond this situation are likely to be obtained only by accounting fully for mutual wing-vortex interference.

## APPENDIX 7

TABULATED EXPERTMENTAL DATA

All of the reduced data from this invostigation are listed by run number* in rables A.l through A.5. In this appendix, the organization of these tables and the nomenclature used are explained.

Table A. 1 contains the results from testing with the force model. The average values for $C_{L}$ and $C_{\ell}$ shown are the averages using all the data taken at a particular test condition, after correction for the novortex loads $\left(\hat{C}_{L}, \hat{C}_{\ell}\right)$. The standard deviation for each quantity is also shown, as are the wing orientation (horizontal or vertical) and the angle of attack of the force model (zero except for the lift-curve runs).

The integrated average results from the pressure model are shown in Table A. 2 (after correction for the no-vortex loads, run 69). The format of this computer printout is now described. $J$ and $Y$ are the spanwise row number and $y / s$ location, respectively, of a chordwise row of pressure taps (as shown in figure 3).

IIFT is $c_{\ell}$ integrated from this row of taps using equations (3) and (4). ALPHASUBS is a fictional section angle of attack (in degrees) defined by the pressure difference between the upper and lower wing surfaces at $x / c=0.05$ according to the relation

$$
\begin{equation*}
\text { ALPHASUBS }=\left.2.63\left(C_{P_{\ell}}-C_{P_{u}}\right)\right|_{x / c}=0.05 \tag{A.1}
\end{equation*}
$$

The constant in this relation was derived from two-dimensional wing section data (ref. 10). IUFT FROM ALPHASI $3 S$ is the product of ALPHASUBS and the two-dimensional section lift-curve slope for the NACA 0012 section (0.107/degree, ref. 10). This result, if appreciably different than $c_{f}$ is an indication that the section pressure distribution will not be well modeled by considerations involving only induced angle of attack (e.g., strip theory). CI LDNG EDGE is the contribution of equation (4) to LIFT. Table $A .2$ also contains integrated $\operatorname{lift}$ and rolling moment ( $C_{L}$ and $C_{\ell}$ ) on the left and right wings, as well as the totai vaiues from equations (5) and (6). Finally, the overall integrated values from ALPHASUBS and the conditions in the tunnel free stream for the particular run are shown. *rables 2 and 3 are a guide to the test conditions for a given run number.

Table A. 3 contains the average pressure coefficients (after correction for the no-vortex loads) at all of the pressure tap locations. I is the pressure tap number in a given chordwise row according to figure 3 . $X$ is the $x / c$ coordinate of that tap, $y$ is $y / s$ as before. A series of asterisks indicates a missing pressure tap. Table A. 4 follows the same format, but the values listed are the standard deviations associated with the mean pressure coefficients in Table A.3.

Table A. 5 contains the tare values for the pressure model in the absence of the vortex (run 69). Tables A.5(a), (b) and (c) follow the formats of Tables A.2, A.3, and A. 4 respectively.

## APPENDIX B

## SLENDER-BCDY ESTIMATE OF THE CONTRIBUTIONS TO SURFACE PRESSURE OF VORTEX BENDING AND . IVONLINEAR VELOCITY TERMS

Consider a general planar wing at zero angle of attack under the influence of a potential vortex at $Y_{v}, z_{v}$ in a sree stream of velocity $V_{\infty}$. In general, the velocity potential on the wing will have the functional form

$$
\begin{equation*}
\phi_{W}=\phi_{W}\left(x, y, s, Y V_{V}, Z_{V}\right) \tag{B,1}
\end{equation*}
$$

The velocity components are

$$
\begin{align*}
u=\frac{\partial \phi_{w}}{\partial x}+\frac{\partial \phi_{w}}{\partial s} \frac{d s}{d x} & +\frac{\partial \phi_{w}}{\partial y_{v}} \frac{d y_{v}}{d x}+\frac{\partial \phi_{w}}{\partial z_{v}} \frac{d z_{v}}{d x}  \tag{B.2}\\
v & =\frac{\partial \phi_{w}}{\partial y}  \tag{B.3}\\
w & =\frac{\partial \phi_{w}}{\phi z} \tag{B.4}
\end{align*}
$$

The condition $w=0$ depresents the boundary condition for the planar lifting surface. The derivatives $d y_{V} / d x$ and $d z_{v} / d x$ in equation (B.2) can be written

$$
\left.\begin{array}{l}
\frac{d y_{v}}{d x}=\frac{d y_{v}}{d t} \frac{d t}{d x}=\frac{v_{v}}{v_{\infty}}  \tag{B.5}\\
\frac{d z_{v}}{d x}=\frac{d z_{v}}{d t} \frac{d t}{d x}=\frac{w_{v}}{v_{\infty}}
\end{array}\right\}
$$

where $v_{v}$ and $w_{v}$ are the components of the velocity of the vortex in the crossflow plane. For a rectangular wing, equation (B.2) becomes

$$
\begin{equation*}
u=\frac{\partial \phi_{w}}{\partial x}+u_{v} \tag{B.6}
\end{equation*}
$$

where

$$
\begin{equation*}
u_{v}=\frac{\partial \phi_{w}}{\partial y_{v}} \frac{v_{v}}{v_{\infty}}+\frac{\partial \phi_{w}}{\partial z_{v}} \frac{w_{v}}{v_{\infty}} \tag{B.7}
\end{equation*}
$$

The pressure coefficient can be calculated from these velocity components using either the linearized relation

$$
\begin{equation*}
c_{p}=-\frac{2 u}{V_{\infty}} \tag{B.8}
\end{equation*}
$$

or the Bernoulli relation

$$
\begin{equation*}
c_{p}=-\frac{2 u}{V_{\infty}}-\frac{\left(v^{2}+w^{2}\right)}{v_{\infty}^{2}} \tag{B.9}
\end{equation*}
$$

In the foilowing, the contribution to either pressure coefficient of $u v$ (vortex bending) and the contribution of the nonlinear terms in equation (B.9) are evaluated, using a slender-body solution for $\phi_{W}$. It is shown that these contributions are of the same order. Thus, if either contribution is included in an analysis, both should be. Note that this conclusion cannot be assumed to hold if the presence of the wing appreciably modifies the vortex structure from that used here; that is, if the point vortex becomes a cloud of distributed vorticity.

The potential $\phi_{W}$ is solved for by application of the methods of conformal transformation. In the crossflow plane, we have the lifting surface lying along the y-axis on the interval $-s \leq y \leq s$ with a vortex of strength $\Gamma$ at $\left(y_{v}, z_{v}\right)$. We will transform the lifting surface from a line into a circle with the flow undistorted at infinity.

$$
\begin{equation*}
\sigma=\xi+i \eta=r e^{i \theta} \quad \tau=y+i z \tag{B.10}
\end{equation*}
$$

The equations of the transformations are (ref. 19)

$$
\left.\begin{array}{l}
s=2 r_{0} \\
\tau=\sigma+\frac{r_{0}^{2}}{\sigma}  \tag{B.11}\\
\frac{\sigma}{r_{0}}=\frac{\tau}{s}+\sqrt{\frac{\tau^{2}}{s^{2}}}-1
\end{array}\right\}
$$

The vortex at $\rho e^{i \phi}$ in the $\sigma$ plane is related to that in the $\tau$ plane as follows:

$$
\begin{equation*}
y_{v}+i z_{v}=\rho e^{i \dot{\phi}}+\frac{r_{0}^{2}}{\rho} e^{-i \phi} \tag{B.12}
\end{equation*}
$$

$$
\left.\begin{array}{l}
y_{V}=\left(\rho+\frac{r_{0}^{2}}{\rho}\right) \cos \phi  \tag{B.1.3}\\
z_{V}=\left(\rho-\frac{r_{0}^{2}}{\rho}\right) \sin \phi
\end{array}\right\}
$$

A point on the lifting surface is related to one on the circle through the relationship

$$
\begin{equation*}
y=2 r_{0} \cos \theta \tag{3.14}
\end{equation*}
$$

It is simple to write down the complex potential in the $\sigma$ plane. The vortex at $\sigma_{v}$ in the $\sigma$ plane has an image rortex at $r_{0}^{2} / \sigma$ of opposite sign with a vortex at the center of the circle to preserve the circulation at infinity. The entire complex potential is thus

$$
\begin{equation*}
W(\sigma)=-\frac{i \Gamma}{2 \pi}\left[\ln \left(\sigma-\sigma_{v}\right)-\ln \left(\sigma-\frac{r_{o}^{2}}{\sigma_{v}}\right)+\ln \sigma\right] \tag{B.1.5}
\end{equation*}
$$

and

$$
\begin{equation*}
\Phi(\sigma)=\frac{\Gamma}{2 \pi}\left[\arg \left(\sigma-\sigma_{V}\right)-\arg \left(\sigma-\frac{r_{0}^{2}}{\bar{\sigma}_{V}}\right)+\arg \sigma\right] \tag{B.16}
\end{equation*}
$$

On the wing

$$
\sigma=r_{0} e^{i \theta}
$$

so that

$$
\begin{align*}
\arg \left(\sigma-\sigma_{v}\right) & =\arg \left(r_{0} e^{i \theta}-\rho e^{i \phi}\right) \\
& =\tan ^{-1}\left(\frac{r_{0} \sin \theta-\rho \sin \phi}{r_{0} \cos \theta-\rho \cos \phi}\right) \tag{B.I7}
\end{align*}
$$

$$
\begin{align*}
\arg \left(\sigma-\frac{r_{0}^{2}}{\bar{\sigma}}\right) & =\arg \left(r_{0} e^{i \theta}-\frac{r_{0}^{2}}{\rho} e^{i \phi}\right) \\
& =\arg r_{0}+\arg \left(\rho e^{i \theta}-r_{o} e^{i \phi}\right) \\
& =\tan ^{-1}\left(\frac{\rho \sin \theta-r_{0} \sin \phi}{\rho \cos \theta-r_{0} \cos \phi}\right) \tag{B.18}
\end{align*}
$$

On the wing the potential is thus

$$
\begin{align*}
\Phi_{\mathrm{w}}= & \frac{\Gamma}{2 \pi}\left[\tan ^{-1}\left(\frac{r_{0} \sin \theta-\rho \sin \phi}{r_{0} \cos \theta-\rho \cos \phi}\right)\right. \\
& \left.-\tan ^{-1}\left(\frac{\rho \sin \theta-r_{0} \sin \phi}{\rho \cos \theta-r_{0} \cos \phi}\right)+\theta\right] \tag{B.19}
\end{align*}
$$

After a considerable amount of algebra, the derivatives $\partial \phi_{\mathrm{w}} / \partial y_{v}$ and $\partial \phi_{W} / \partial z_{V}$ appearing in equation (B.7) are

$$
\left.\begin{array}{l}
\frac{\partial \Phi_{w}}{\partial y_{V}}=\left(\frac{\Gamma}{2 \pi}\right) \frac{\rho\left(\rho^{2}-r_{0}^{2}\right)\left[2 r_{0} \rho \sin (\theta-\phi) \cos -\left(\rho^{2}+r_{0}^{2}\right) \sin \phi\right]}{\left[r_{0}^{2}+\rho^{2}-2 r_{0} \rho \cos (\theta-\phi)\right]\left(r_{0}^{4}+\rho^{4}-2 r_{0}^{2} \rho^{2} \cos 2 \phi\right)} \\
\frac{\partial \phi_{w}}{\partial z_{v}}=\left(\frac{\Gamma}{2 \pi}\right) \frac{\rho\left[2 r_{0} \rho\left(\rho^{2}+r_{0}^{2}\right) \sin (\theta-\phi) \sin \phi+\left(\rho^{2}-r_{0}^{2}\right) 2 \cos \phi\right]}{\left[r_{0}^{2}+\rho^{2}-2 r_{0} \rho \cos (\theta-\phi)\right]\left(r_{0}^{4}+\rho^{4}-2 r_{0}^{2} \rho^{2} \cos 2 \phi\right)} \tag{B.20}
\end{array}\right\}(:
$$

If the conjugate of the complex velocity of the vortex in the $\sigma$ plane is denoted $v_{v}-i W_{v}$, then

$$
\begin{equation*}
v_{v}-i W_{v}=\lim _{\sigma \rightarrow \sigma_{V}} \frac{d}{d \sigma}\left[W(\sigma)+\frac{i \Gamma}{2 \pi} \ln \left(\sigma-\sigma_{v}\right)\right] \tag{B.21}
\end{equation*}
$$

The vortex velocity in the $\tau$ plane is not related to that in the 0 plane by the usual conformal transformation, but is given by the following expression from reference 19.

$$
v_{v}-i w_{v}=\left.\left(v_{v}-i w_{v}\right) \frac{d \sigma}{d \tau}\right|_{\tau=\tau v}-\left.\frac{i \Gamma}{4 \pi} \frac{d^{2} \sigma / d \tau^{2}}{d \sigma / d \tau}\right|_{\tau=\tau_{v}}
$$

or

$$
\begin{aligned}
v_{v}-i w_{v}=\left\{\frac{i \Gamma}{2 \pi} \frac{d \sigma}{d \tau} \frac{d}{d \sigma}\left[\ln \left(\sigma-\frac{r_{0}^{2}}{\bar{\sigma}_{v}}\right)-\ln \sigma\right]-\frac{i \Gamma}{4 \pi}\left(\frac{d \tau}{d \sigma}\right)\left(\frac{d^{2} \sigma}{d \tau^{2}}\right)\right\}_{\tau \rightarrow \tau} \\
\sigma \rightarrow v_{v}
\end{aligned}
$$

It can be shown that

$$
\begin{align*}
v_{v}= & \frac{\Gamma}{2 \pi}\left[\frac{\rho}{\left(\rho^{2}-r_{0}^{2}\right)\left(\rho^{4}+r_{0}^{4}-2 r_{0}^{2} \rho^{2} \cos 2 \phi\right)^{2}}\right]\left\{\left[\left(\rho^{2}+r_{0}^{2}\right)\left(\rho^{6}+r_{0}^{6}\right)\right.\right. \\
& \left.\left.+r_{0}^{2} \rho^{2}\left(\rho^{4}+r_{0}^{4}\right)\right] \sin \phi-2 r_{0}^{4} \rho^{4} \sin 3 \phi\right\}-\frac{\Gamma \rho}{2 \pi} \frac{\left(\rho^{2}+r_{0}^{2}\right) \sin \phi}{\left(\rho^{4}+r_{0}^{4}-2 r_{0}^{2} \rho^{2} \cos 2 \phi\right)} \tag{B.23}
\end{align*}
$$

and

$$
\begin{align*}
w_{v}= & \frac{-\Gamma}{2 \pi} \rho \cos \phi \frac{\left(\rho^{2}+r_{0}^{2}\right)\left(\rho^{4}+r_{0}^{4}\right)}{\left(\rho^{4}+r_{0}^{4}-2 r_{0}^{2} \rho^{2} \cos 2 \phi\right)^{2}} \\
& \left.+\frac{\Gamma \rho}{2 \pi} \frac{\left(\rho^{2}-r_{0}^{2}\right) \cos \phi}{\left(\rho^{4}+r_{0}^{4}-2 r_{0}^{2} \rho^{2} \cos 2 \phi\right.}\right) \tag{B.24}
\end{align*}
$$

Substituting equations (B.20), (B.23) and (B.24) into the definition of $u_{v}$, equation ( $B, 7$ ), we find

$$
\begin{align*}
& \frac{u_{v}}{V_{\infty}}=\left(\frac{\Gamma}{2 \pi V_{\infty}}\right)^{2} \frac{\rho^{2}\left[4 r_{0}^{3} \rho^{3} \sin (\epsilon-\phi) \sin \phi \cos \phi-\left(\rho^{2}+r_{0}^{2}\right)\left(\rho^{4}+r_{0}^{4}-2 r_{0}^{2} \rho^{2} \cos ^{2} \phi\right)\right]}{\left[\rho^{2}+r_{0}^{2}-2 r_{0} \rho \cos (\theta-\phi)\right]\left(\rho^{4}+r_{0}^{4}-2 r_{0}^{2} \rho^{2} \cos 2 \phi\right)^{2}} \\
&+\left(\frac{\Gamma}{2 \pi V_{\infty}}\right)^{2} \frac{\rho^{2}\left(\rho^{2}-r_{0}^{2}\right)}{\left[\rho^{2}+r_{0}^{2}-2 r_{0} \rho \cos (\theta-\phi)\right]\left(\rho^{4}+r_{0}^{4}-2 r_{0}^{2} \rho \cos ^{2} \cos 2 \phi\right)} \tag{B.25}
\end{align*}
$$

To allow calculation of the contribution to pressure of the squared terms, we need v. Now,

$$
\begin{equation*}
\mathrm{v}=\frac{\partial \phi_{\mathrm{w}}}{\partial Y}=\left.\frac{\partial \phi_{\mathrm{w}}}{\partial \theta} \frac{\partial \theta}{\partial Y}\right|_{\mathrm{r}_{0}}=-\frac{I}{2 r_{0} \sin \theta} \frac{\partial \phi_{\mathrm{w}}}{\partial \theta} \tag{B.26}
\end{equation*}
$$

so

$$
\begin{equation*}
\frac{\mathrm{v}}{\mathrm{~V}_{\infty}}=\left(\frac{\Gamma}{2 \pi V_{\infty}}\right)\left(\frac{1}{2 r_{0} \sin \theta}\right)\left\{\frac{\left(\rho^{2}-r_{0}^{2}\right)}{\left[r_{0}^{2}+\rho^{2}-2 r_{0} \rho \cos (\theta-\phi)\right]}-1\right\} \tag{B.27}
\end{equation*}
$$

The relations just derived were used in an illustrative calculation. The case considered was for $y_{V} / s=0.5, z_{v} / c=0.25$. This choice of $z_{v /} / c$ eliminates complications brought about by the use of the potential vortex model, for it removes the vortex core from contact with the wing.

The surface pressure distribution due to vortex bending has been calculated by means of equations (B.25) and the relation

$$
\begin{equation*}
c_{p_{u_{v}}}=-\frac{2 u_{v}}{v_{\infty}} \tag{B.28}
\end{equation*}
$$

The surface pressure distribution associated with $-v^{?} / v_{\infty}^{2}$ as calculated from equations (B.9) and (B.27) has also been determined. The results are shown in figure 19.

It is noted that the surface pressure distribution for vortex hending produces uniformly positive pressure on the upper surface of the right half of the wing with a peak at the lateral vortex position. The distribution due to $-v^{2} / V_{\infty}^{2}$ is negative everywhere; the negative pressure peak is about twice the magnitude of the positive pressure peak, but it is about half the breadth. Thus, these effects are of comparable order.
