Abstract

Software designers are motivated to utilize off-the-shelf software components for rapid application development. Such applications are expected to have high reliability as a result of deploying trusted components. The claims of high reliability need further investigation based on reliability estimation models and techniques that are applicable to component-based applications.

This paper introduces a probabilistic model and a reliability estimation and analysis technique applicable to high-level designs. The technique is named "*Scenario-Based Reliability Estimation*" (SBRE). SBRE is specific for component-based software whose analysis is strictly based on execution scenarios. Using scenarios, we construct a probabilistic model named "*Component-Dependency Graph*" (CDG). CDGs are directed graphs that represent components, component reliabilities, link and interface reliabilities, transitions, transition probabilities, and average execution times of components. In CDGs, component interfaces and link reliabilities are treated as first class element of the model. Based on CDGs, an algorithm is presented to analyze the reliability of the application as function of the reliability of its components and interfaces. A case study illustrates the applicability of the algorithm. The SBRE algorithm is used to identify critical components and critical component interfaces by investigating the sensitivity of the application reliability to changes in the reliabilities of components and their interfaces.

Keywords: Component-Based software, Reliability Analysis, Reliability Modeling, Component-Dependency Graphs

1 Introduction

Component-based software engineering (CBSE) is emerging as a beneficial development paradigm for building software from existing components by assembling these parts together in an interoperable manner. Component-based software development is the process of assembling components (including Commercial Off-The-Shelf components COTS) in an application such that they interact as intended. Each component requires pre-specified services from the other components. CBSE is touted as the approach to improving application qualities, decrease time to market, and improve software maintainability and reliability. However, ensuring a reliable software application is a difficult task even with the use of commercial pre-tested and trusted software components.

As a result, several techniques have emerged to estimate and analyze the reliability of component-based applications. There are can be categorized as:

- *System-level Reliability Estimation*: Reliability is estimated for the application as a whole. For example using system testing, or system level architecture evaluation.
- *Component-Based Reliability Estimation*: The application reliability is estimated using the reliability of the individual components and their interconnection mechanisms.

The first approach treats the software application as a whole. This approach is not usually suitable for component-based applications because it does not consider the composition and integrative property of such systems and doesn't accommodate the reliability growth of individual component. The limitations of this approach to component-based application are discussed in [Horgan+96].

As for the second approach, we need to estimate:

- *Reliability of a Component*: Reliability assessment of the components themselves including COTS components and how those reliability models are affected by the component usage across several applications.
- *Reliability of a Component-Based System*: Reliability assessment of applications developed using software components as their building blocks.

This paper addresses the second problem, and assumes that reliability estimates of the components themselves are available.

1.1 Motivation

In this paper, we are concerned with reliability estimation models and analysis algorithms for component-based software whose analysis is substantially based on execution scenarios. This work is motivated by the need to:

- Estimate the reliability of a component-based application which *doesn't* depend on the availability of *source code* of each component (i.e. fault injection and seeding would not be applicable).
- Develop a probabilistic model and analysis technique for reliability analysis which is applicable at the design-level even before the integration and actual development phase. Many reliability analysis techniques use test cases and fault injection to study the reliability of a component-based system. Using scenarios has the advantage of applicability at *early phases*.
- Study the *sensitivity* of the application reliability to reliabilities of components and interfaces. This would guide the process of identifying critical components and interfaces and analyze the effect of replacing components with new ones with similar interfaces but with improved estimated reliability.
- Incorporate the effect of *interface and component reliabilities* as first class elements in a probabilistic model for reliability analysis.

- Develop a technique to analyze the reliability of applications built from reusable software components. The field of *component-based software engineering* is rapidly emerging to deliver on some of the promises of software reuse by building domain-specific component repositories and developing applications using component from these repositories. This emerging discipline exacerbates research to estimate component reliabilities and analysis the reliability component-based applications.

1.2 Contribution

This paper addresses the problem of reliability modeling and reliability analysis in component based applications. We propose a new technique called *Scenario-Based Reliability Estimation* (SBRE), which builds on the analysis scenarios of a component-based application. A C*omponent Dependency Graph* (CDG) is proposed as a new probabilistic model which incorporates component and interaction probabilities, and their reliabilities. An algorithm is proposed to analyze the reliability of component-based applications using components, interfaces and links reliabilities. The SBRE algorithm is applied to a case study to discuss the variations in the application reliability based on component reliability and interface reliability growth. We also discuss the effect of different usage of components on applications developed from these components.

The contribution of this paper is a new scenario-based technique to model and analyze the sensitivity of the application reliability to component and interface reliabilities. We are not estimating the absolute application reliability over its execution lifetime. Instead, we limit our analysis to the average execution time of a usage scenario.

This paper is organized as follows. Section 2 describes scenario-based analysis for component-based applications. Section 3 defines the elements used in constructing the component dependency graphs (CDG). In Section 4, we discuss the new SBRE algorithm. Section 5 describes the applicability of the algorithm to a case study and show how the algorithm can detect critical components and critical component interfaces. Section 6 discusses related work in reliability of component-based applications and highlights limitations and differences. Finally, we conclude this paper in Section 7.

2 Dynamic Behavior Analysis using Scenarios

Scenarios are means of analyzing applications and understanding their dynamic behavior. Scenarios are useful during design because they bridge the gap between architectures and implementation, they also add behavior analysis capabilities to design structures[Weidenhaupt+98]. One way to model scenarios is using *sequence diagrams*. Sequence diagrams specify interactions between application entities in a timely sequence manner. In particular, they show the entities participating in an interaction, their lifelines (how long they remained active), and their interactions as time proceeds. An *interaction* can be a method invocation to an object (in an object-oriented context), a procedure call, a generated event, or a message exchanged.

Scenarios are used to analyze the dynamic behavior of component-based applications. We adopt *Sequence Diagrams* as means of documenting a scenario for a component-based application. We also use the word *interaction* as a general term to refer to possible types of interaction and collaboration between components.

The notation of sequence diagrams between components is similar to those used for Message Sequence Charts (MSC) or Interaction Diagrams in UML [UML99] with some generalization of the terms. A component sequence diagram is a two-dimension graph: the vertical axe represents time, and the horizontal axe represents different components. Time proceeds down the vertical axe. The time axe can be used as a metric for time measurement. There is no significance to the horizontal ordering of components. A vertical dotted line shows the lifeline of a component, i.e. its existence in the scenario, while the actual execution periods of a component is shown by a vertical rectangle starting and ending at the start and end point of execution of a component. Figure 1 shows an interaction diagram between three components C1, C2, and C3.

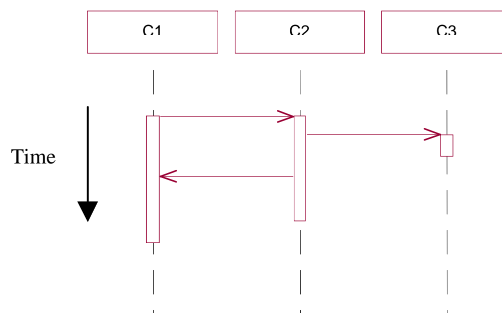

Figure 1 An example of component sequence diagram

Using these sequence diagrams, we are able to collect statistics required for CDG graphs such as average execution time of a component in a scenario, average execution time of a scenario, and possible interactions among components as discussed later.

Scenarios are also related to the concepts of operations and run-types used for operational profiles[Musa+96]. A scenario with specified input variables are similar to an operation run-type. A generic scenario, with less details about specific input values but for specific input domain, is similar to an operation with several run-types. Finally, a profile of the execution probability of scenarios is similar to operation profiles. Operation profiles have long been used to guide testing, development, and performance analysis by identifying frequently executed operations. Here, we use scenarios to derive a probabilistic model for the purpose of reliability analysis of component-based systems. The frequency of scenario and component executions are incorporated in one model, CDG, on which we conduct reliability analysis.

3 Component Dependency Graphs (CDGs)

Staring with the basic notion of control flow graphs, we develop a probabilistic model called component dependency graph. Control flow graphs are the classical method of revealing the structure, decision points, and branches in program code [Pressman97]. A flow graph is a directed graph that consists of a set of nodes and directed edges G=<N,E>. Each node represents one or more program statements. The total number of nodes is the size of the set (N), and a maximum of a NxN directed edges exist in the graph. Each edge represents the transfer of execution control from source to destination. Each edge is an ordered-pair <n1,n2>. Depending on a decision taken at a certain node, the next execution is one of its children.

We adapt the control flow graph principles to component-based applications to represent the dependency between components and possible execution paths. We call this graph "*Component Dependency Graph*", CDG. *In this section we define the graph, and in the following section we describe how to calculate these parameters for a component based application.*

Definition 1: Component Dependency Graph "CDG"

A component dependency graph is defined by $CDG = <N,E,s,t>$, where:

> $<N,E>$ is a directed graph,
> s is the start node, t is a termination node
> N is a set of nodes in the graph, $N=\{n\}$, and
> E is set of edges in the graph, $E=\{e\}$.

Definition 2: A Node "n"

A node n models a component and is defined by the tuple $< C_i, RC_i, AEc_i >$ where:

> C_i is the component name,
> RC_i is the component reliability, and
> AEc_i is its average execution time of he component C_i

Definition 3 : Component Reliability "RC_i"

It is the probability that the component C_i will execute correctly (fault free) during its course of execution.

Definition 4: Average Execution Time of a Component "AEc_i"

It is the average execution time of a component C_i. The execution time of a component varies according to the type of service it provides and the scenario that activates this service.

Definition 5: A Directed Edge "e"

A directed edge *e* models the execution path from one component to another and is defined by the tuple $<T_{ij},RT_{ij},PT_{ij}>$ where:

> T_{ij} is the transition name from node n_i to n_j and denoted $<n_i,n_j>$
> RT_{ij} is the transition reliability, and
> PT_i is the transition probability.

Definition 6: Transition Reliability "RT_{ij}"

It is the probability that data and information sent from component C_i to component C_j will be delivered error-free. This probability includes possible interface errors and possible channel delivery errors, as discussed in Section 4.1.3

Definition 7: Transition Probability PT_{ij}

It is the probability that C_j will execute next given that C_i is currently executing.

Thus, a CDG is defined as follows:

> $CDG = <N,E,s,t>$
> $N = \{n\}$, $E = \{e\}$, *s* and *t* are the start and termination nodes
> $n = < C_i, RC_i, AEc_i >$
> e = $<T_{ij}, RT_{ij}, PT_{ij}>$
> $T_{ij} = <n_i,n_j>$

Figure 2 shows a CDG example consisting of four components.

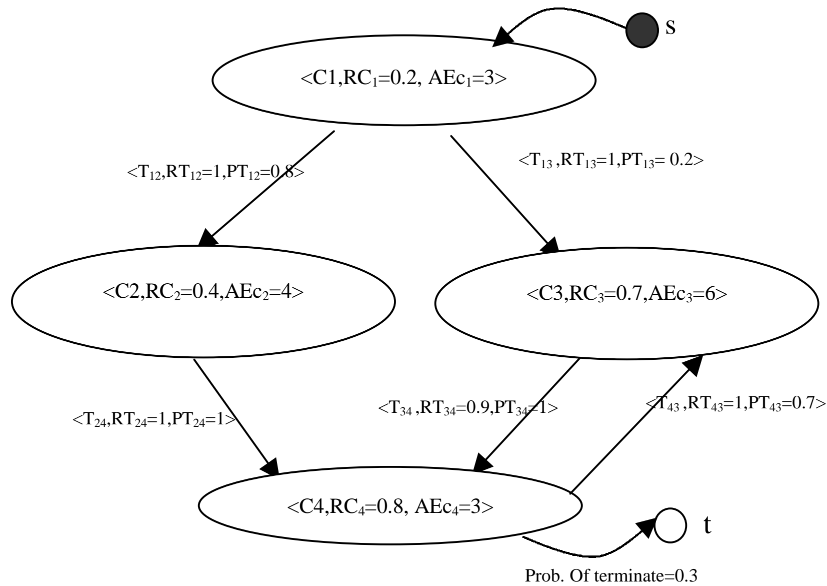

Figure 2 A sample CDG

4 Scenario-based Reliability Estimation (SBRE)

The proposed technique to estimate the reliability of component-based application has three steps:

1. Estimation of the parameters used in reliability model(Section 4.1),
2. Construction of the component dependency graph (Section 4.2)
3. Applying the algorithm for reliability senestivity analysis(Section 4.3).

4.1 Parameters Estimation

4.1.1 Probability of a Scenario "PS_i"

The dynamic behavior of a component-based application can be specified using set of scenarios characterizing the application behavior. Each scenario has a certain probability of execution depending on the nature of the application. The probability of a scenario is the execution frequency of that scenario with respect to all other scenarios and is denoted as PS_i. The execution probabilities should sum to unity:

$$\sum_{i=1}^{S} PS_i = 1 \qquad \textit{Eq 1}$$

where S: is the total number of scenarios in the analysis.

It is usually difficult to exhaustively document all possible scenarios for a certain application usage. In such cases, to estimate PS_i, the concepts of operational profile and equivalence partitioning [Musa+87] could be used to specify scenario categories. The probability of execution of a scenario category can be estimated based on the frequency its occurrence as a fraction of the total set of scenario categories. The estimated parameter PS_i will be used to estimate the probability of transitions and average execution time of components.

4.1.2 Component Reliability "RC_i"

Several techniques have been proposed to estimate the reliability of software component. In this paper, we assume that the reliability of individual components has been calculated (numerical formula) or modeled (mathematical formula). We refer to this estimate as RC_i. Several outlines for component reliability estimation include fault injection techniques, testing, and retrospective analysis. In case of commercial off the shelf components (COTS), other factors can be included, such as vendor's credibility, vendor-side and customer-side testing, and the age of the component. Assessing the reliability of individual components is outside the scope of this paper, however, we identify some techniques to estimate components reliability in the sequel.

McDermid [McDermid98] proposed the following techniques to measure and improve the reliability of software components:

- *Retrospective Analysis or Certification* using the history of component operation and failures.

- *Wrapping* acts as a shelter to buffer inputs and outputs from a component and hence can mask undesirable outputs. Adding a software wrapper around a component may limit the functionality without modifying the component itself. Wrappers can operate on input data (input wrappers), output data (output wrappers), or both.
- *Black box Testing* against the specification of the component and the requirements of the application.
- *Architecture Choices,* choosing the architecture such that the application functionality doesn't heavily rely on a particular component but is achieved by several ones.

Voas [Voas98] discussed some problems in estimating reliability of components. Voas examined a method to determine the quality of Off-the-Shelf components using black box analysis. His certification technique is based on black box testing and fault injection methods[Voas+98].

Everett [Everett99] identified some guideline in estimating the component reliability by identifying the component's static and dynamic properties and characterizing how usage stresses each component. Towards a discipline of trusted commercial software components with high reliability, Meyer *et.al.* [Meyer+98] discussed general principles for establishing trust in components, which include design by contract, formal verification, extensive testing, and component-based software metrics.

4.1.3 Transition Reliability "RT_{ij}"

The reliability of a transition from one component execution to another is the probability that the information is correctly delivered from the source component to the destination in the course of execution. There are two constituents for evaluating transition reliability: Component Interfaces Reliability and Link Reliabilities. Thus, $RT_{ij} = \textit{Interface Reliability} \times \textit{Link Reliability}$

In this paper, we don't describe how to calculate transition reliabilities, however we are more concerned with incorporating them as first class element in the model such that their effect on application reliability could be analyzed. In the following we briefly describe factors affecting interface and link reliabilities.

1) Component Interface Reliability

This is defined as the probability that two interacting components will have matching interfaces. A component interface defines how it interacts with other components. Interfaces describe the import and export relationship with other components. A set of exported interfaces specifies the functionality that this component can provide. A set of imported interfaces specifies the functionalities that this component requires from other external components which is needed in the work progress of the component execution. A mismatch in an interface can be as a result of:

- Incompatibility in the structure and sequence of messages exchanged between components.
- Timing issues as related to requests coming in/from a component

- Incompatibilities in data format and types and incompatibilities in message protocols (sync/ Async/ Publish and Read / ,…)
- Incompatibility in a component role in an interaction. The role should define which component is the client or server. Client/Server relationship is defined by the import/export interface specifications.

Formal specification of component interfaces is an approach to improve their reliability. Interface reliability is a topic of several literatures, for example [Delamaro+96, Voas+96]. Here, we are more concerned with how to incorporate them in reliability analysis of component-based applications.

2) Link Reliability

Reliability of a link (also refered to as a delivery channel) is the probability of correct delivery of messages exchanged between distributed components. This factor is essential in the case of components distribution across a network. Heimdahl *et.al.* [Heimdahl+98] showed that almost 35% of errors were related to interface mismatches between components and their underlying environment which includes communication channels. In addition to component interface mismatches, distribution across a network adds more factors affecting link reliabilities. A message exchanged between component in a distributed environment is exposed to operating system calls, the underlying hardware technology, communication subsystems, and the physical network itself. This adds new sources of failures and risks as related to (for example):

- Failure to detect and respond to operating system and communication event
- Physical network problems such as delays, congestion, physical failures, and liveness constraint on a communication link.
- Incompatibilities in timing and protocols between sending and receiving sides.

Studying factors affecting link reliabilities is outside the scope of this paper, however, we incorporate this parameter in the reliability model and in the reliability analysis algorithm.

4.1.4 Average Execution Time of the application "AE_{appl}"

The average execution time of the application (AE_{appl}) is given by:

$$AE_{appl} = \sum_{k=1}^{S} PS_k \times Time(S_k) \qquad Eq\ 2$$

where:

PS_k : is the probability of execution of scenario S_k ,
S: Total number of scenarios,
$Time(S_k)$ is the average execution time of scenario S_k

4.1.5 Average Execution Time of a Component "AEc_i"

The parameter AEc_i is the average execution time in which a component C_i is active and running. It is calculated using the equation:

$$AEc_i = \sum_{k=1}^{S} PS_k * Time(C_i)_{C_i \in S_k} \qquad Eq\ 3$$

where:

PS_k : is the probability of execution of scenario S_k ,

S: Total number of scenarios,

Time(C_i) is the execution time of C_i , measured as the sum of its active time along its lifeline (vertical rectangles as represented in the scenario diagram), and

C_i is said to belong to S_k if it participates in the execution of scenario S_k

4.1.6 Transition Probability "PT_{ij}"

The parameter PT_{ij} is the probability of transition from one component to another. It is estimated using the number of interactions between two components in the analysis scenarios. PT_{ij} is calculated as follows:

$$PT_{ij} = \sum_{k=1}^{S} PS_k * \left(\frac{|Interact(C_i, C_j)|}{|Interact(C_i, C_l)|_{l=1,..,N}} \right)_{C_i, C_j \in S_k} \qquad Eq\ 4$$

where:

S : Number of scenarios,

PS_k : is the probability of execution of scenario S_k ,

N : number of components in the application,and

|Interact(C_i,C_j)| : is the number of times C_i interacts with C_j in a given scenario.

The sum of transition probabilities from any component should be unity:

$$\sum_{j=1}^{N} PT_{ij} = 1 \qquad Eq\ 5$$

4.2 CDG Construction

In this phase, the component dependency graph is constructed using the parameters evaluated in the previous section. The following steps outlines the process of constructing the CDG graph:

- Using the application analysis scenarios, estimate the probability of execution of each scenario (PS_i) by estimating the frequency of execution of each scenario relative to all other scenarios. (Section 4.1.1)
- Estimate the reliability of components (RC_i) and interfaces (RT_{ij}) (outside the scope of this paper, see Sections 4.1.2 and 4.1.3)
- Calculate the average execution time for a run of the application AE_{appl} using the average execution time of a scenario, the probability of execution of a scenario and *Eq 2* Section 4.1.4
- For each scenario, calculate the execution time of each component (from the timeline of the sequence diagram) and the transition probability from one component to another.
- Calculate the average execution time of each component (AEc_i) using the execution time of a component in each scenario, the probability of a scenario, and *Eq 3* Section 4.1.5

- Calculate the transition probability from one component to another for all scenarios (PT_{ij}) using the probability of a scenario, the transition probabilities between components in each scenario, and *Eq 4* Section 4.1.6).
- Construct the CDG according to the definition in Section 3

4.3 Reliability Analysis

After constructing the model (the component-dependency graph), we can analyze the reliability of the application as function of reliability of components and transitions as follows.

<u>*Algorithm*</u>
Procedure SBRE
Parameters
    consumes CDG, AE_{appl},
    produces R_{appl}
Initialization:
    $R_{appl} = 0$, Time = 0, $R_{temp} = 1$
Algorithm
    push tuple $<C_1, RC_1, AEc_1>$, Time, R_{temp}
    while Stack not EMPTY do
        pop $< C_i, RC_i, AEc_i >$, Time, R_{temp}
        if Time > AE_{appl} or $C_i = t$ (terminating node)
            $R_{appl} \mathrel{+}= R_{temp}$ (OR path)
        else
            $\forall < C_j, RC_j, AEc_j > \in$ children(C_i)
            push ($<C_j, RC_j, AEc_j>$, Time += AEc_i , $R_{temp} = R_{temp} * RC_i * RT_{ij} * PTi_j$)
        end
    end while

The algorithm simply expands all branches of the CDG starting from the start node. The width expansions of the tree represent logical "OR" paths and are hence translated to summation of reliabilities. The depth of each path represents the consecutive execution of components, the logical "AND" and is hence translated to multiplication of reliabilities. The "AND" paths take into consideration the interface and link reliabilities (RT_{ij}) between components. The depth expansion of a path terminates when the summation of execution time of that thread sums to the average execution time of the application or when the next node is a terminating node.

Due to the probabilistic nature of the dependency graph, several loops might exist. In calculating the reliability of the application using the SBRE algorithm outlined above, the algorithm may loop between two or more components. However, these loops don't lead to a deadlock by virtue of using the average execution time of the application to terminate the depth traversal of the graph. Therefore, deadlocks are not possible in executing the algorithm and a termination of the algorithm execution is evident.

The reliability of an "AND" path is neither too pessimistic nor too optimistic. This is because the path is either truncated with a termination node, a natural end of an application execution, or with an execution time limit which is the average execution time of a scenario.

The algorithm assumes that each component is wrapped such that failures in one component do not propagate[Khoshgoftaar+99] to another component in the "AND" path and hence independent assumption could be valid.

5 Case Study

In this section we illustrate the applicability of the proposed technique to a simple component-based application. The application was developed for simulation of waiting queues[1] in which we deal with customers lining up at checkout counters at supermarkets, immigration posts, or self-serve car wash. The application is built by composing software components. Those components were developed as a part of an educational experiment in software reuse at West Virginia University [Yacoub+99]. In this experiment, a domain specific library of components was developed for the purpose of producing applications that simulate the behavior of waiting queues. Domain engineering activities were conducted to develop reusable software components. The domain was defined by a set of software components, a generic architecture for communicating components, and a set of possible execution scenarios.

For the purpose of this paper, we limit our discussion to one application developed from those reusable assets, the checkout counter. First, we briefly describe the system architecture and its constituting components, then we construct the component dependency graph (CDG). Based on the application's CDG (proposed in Section 3), we use the SBRE algorithm (proposed in Section 4) to investigate the reliability of the application based on the reliability of its components and the reliability of components interfaces and links.

5.1 The Architecture

Figure 3 describes the architecture of the application using the UML package diagram [UML99]. The architecture of the application is centered around a dynamic event list as the communication vehicle of events between cooperating components. In addition to the *EventList* component , the primary components in the architecture are *ArrivalGen*, a *QueuingFacility*, a *ServiceFacility*, a *Measurement* recorder, and a *ScheduleManager*. Those components are implemented in an object-oriented (OO) language. The communication between components (invocations) follows the form of method calls. Some of these components could have several classes and others have just one class.

---

[1] "Simulation of Waiting Queues" is our case study i.e. the application whose reliability is to be analyzed. This should not be confused with the simulation technique for reliability estimation in [Gokhale+98b]

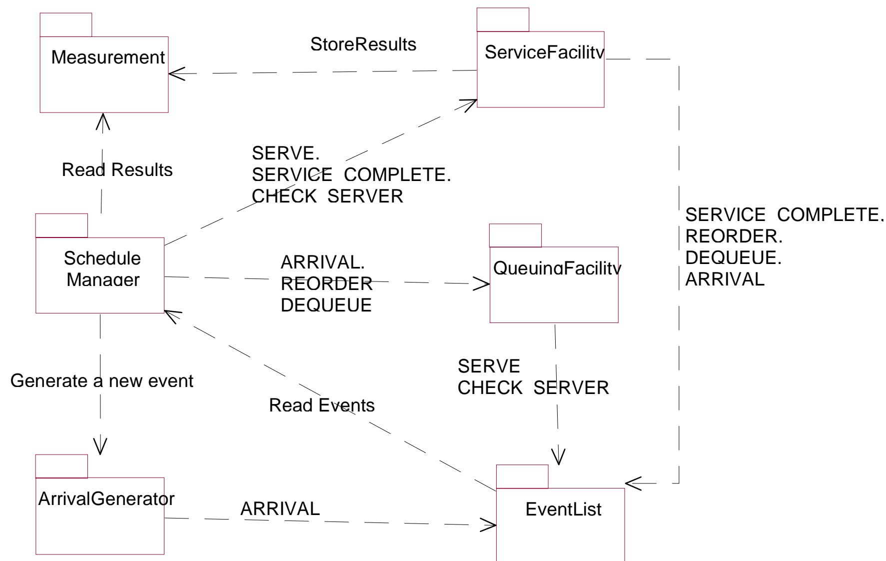

Figure 3 The Application Architecture

The *EventList* component serves as the holder of all events. The analysis identified a set of six events that depict all scenarios necessary for the execution of the application. Events are maintained in the *EventList* and are sorted in a time-ordered fashion. Each event triggers a specific execution scenario.

The *ArrivalGen* component was designed to use a distribution function to generate the time of arrival of the next customer. The distribution function determines the time of the next customer arrival, in our case study we used uniformly distributed random generator. *ArrivalGen* component is invoked by *ScheduleManager* component to generate customer arrivals.

The *QueuingFacility* component consists of a set of queue categories, where each queue category contains one or more queues. This component contains three OO classes representing the facility interface, categories, and queues. Events that indicate an action for a queue category or a queue are delegated to the queue facility, which delegates the action to the appropriate queue category. For our case study, we used two categories for checkout counters, *Normal* and *Express*, and one queue for each category. The *QueuingFacility* component processes the events: REORDER, ARRIVAL, and DEQUEUE

The *ServiceFacility* component consists of a set of server categories, where each server category contains one or more servers. This component contains three OO classes representing the facility interface, categories and servers. The servers are also identified by sequentially generated numbers, and each server contains the identification number of its associated queue. Events that indicate an action for a service category or a server are delegated to the *ServiceFacility*, which delegates the action to the appropriate service category. For our case study, we used two categories, *Normal* and *Express*, and one server for each category. The ServiceFacility component processes the event SERVE, SERVICE_COMPLETE, and CHECK_SERVER.

The *Measurement* component hosts the statistical information each time a customer object completes its number of service units. This information is maintained by the *Measurement* component until the

completion of the simulation. At the end of the simulation, the *Measurement* component calculates the averages and totals.

The *ScheduleManager* component serves as the main routine for the simulation. It repeatedly dispatches events from the event list and delegates actions based on the event type. The *ScheduleManager* activates the number and type of queue and server components that are specific to the application, and then repeatedly removes the first event from the *EventList* and dispatches it to the appropriate component.

5.2 Scenarios

The interaction between components in the application is analyzed using six execution scenarios. Each scenario is triggered by an event. The following summarizes the analysis scenarios (sequence diagram for all scenarios are shown in Appendix A):

- ARRIVAL: This scenario describes the sequence of actions taken by components to process the arrival of a new customer to the queuing facility.
- REORDER: This scenario is executed when it is required to reorder the customer in the queue category when a queue is empty and could carry customers from a busy queue.
- DEQUEUE: This scenario is executed when a server is ready to serve a customer from its waiting queue.
- SERVE: This scenario is executed when a customer is de-queued and needs to be served.
- SERVICE_COMPLETE: This scenario is executed whenever a customer finishes its service at a station.
- CHECK_SERVER: This scenario is executed to check whether a server is available to serve a customer.

5.3 The Component Dependency Graph

Calculating PS_i

Based on the execution profile of the application, the probabilities of execution of the six scenarios are lists in table (1). These probabilities are calculated based on the several execution runs for the application and averaging the number of execution of each scenario.

Calculating RC_i and RT_{ij}

We will not estimate the reliability of the components and transitions, however we will use these two parameters to discuss the sensitivity of the application reliability to the variations in the reliability of components and transitions as shown later.

Calculating AE_{appl}

The average execution time of the application (based on the execution of one scenario) is calculated using the average execution time of each scenario and the probability of execution of a scenario. Using *Eq 2* in Section 4.1.4,then, $AE_{appl} = 23.5$

Scenario Name	*Probability of a Scenario (PS_i)*	*Average Execution Time of a Scenario Time(S_k))*
ARRIVAL	0.145	41.43
SERVE	0.145	34.46
DEQUEUE	0.28	14.02
SERVICE_COMPLETE	0.145	31.93
CHECK_SERVER	0.14	20.83
REORDER	0.145	6.06

Table 1 Average Execution Time of a Scenario

Calculating AEc_i

The average execution time of each component is calculated using *Eq 3* Section 4.1.5, the probability of execution of each scenario, and the execution time of a component for that scenario. Table 2 lists the average execution time of each component.

Component Name	*Average Execution Time of a component AEc_I*
ArrivalGen	2
ScheduleManager	5
ServiceFacility	7
QueuingFacility	5
EventList	14
Measurement	0.8

Table 2 Average Execution Time of each Component

Calculating PT_{ij}

Using analysis scenarios (Appendix A), the probability of execution of each scenario Table 1 and *Eq 4* in Section 4.1.6, then the transition probabilities PT_{ij} are calculated and shown in Figure 4. Using the parameter calculated from the previous subsection, and the CDG tuplet definitions of Section 3, we construct the CDG shown in Figure 4.

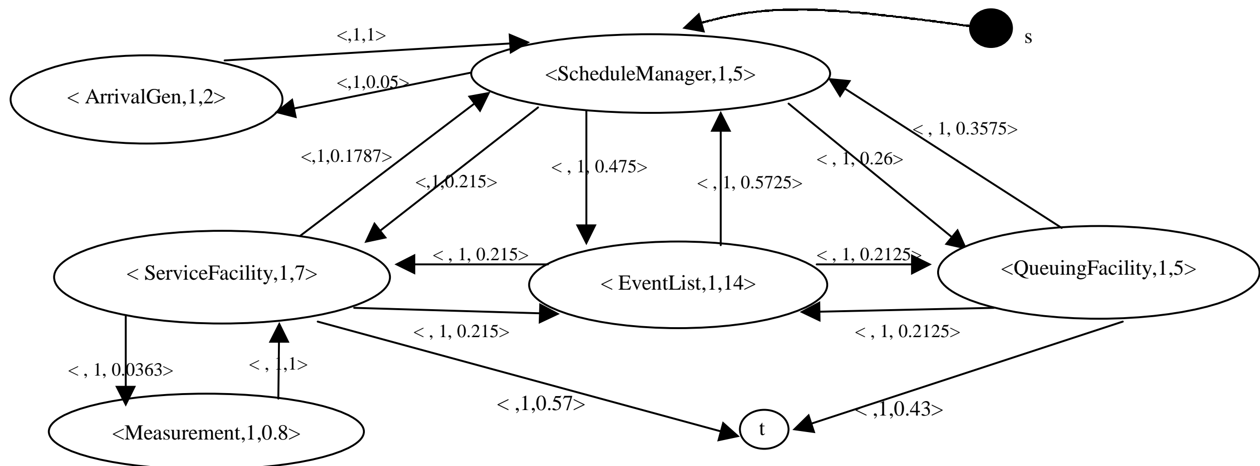

Figure 4 CDG of the application[2]

---

[2] Transition names are omitted from the transition tuplets

5.4 Applying the SBRE Algorithm

We have implemented the SBRE algorithm defined in Section 4, and applied it to the CDG of the application (Figure 4). Our objective is to analyze the sensitivity of the application reliability as a function of the components reliabilities and transitions reliabilities (interfaces and links) for a period of average scenario execution time. We also discuss how different usage scenarios affect the application reliability.

5.4.1 Reliability of the application as function of Component Reliability

Using the SBRE algorithm we are able to investigate the variation in the reliability of the application as a function of the reliability of individual components. The graph in Figure 5 shows the reliability of the application as function of the reliability of one component at a time while the reliability of other components are fixed (equal to 1 for the sake of comparison).

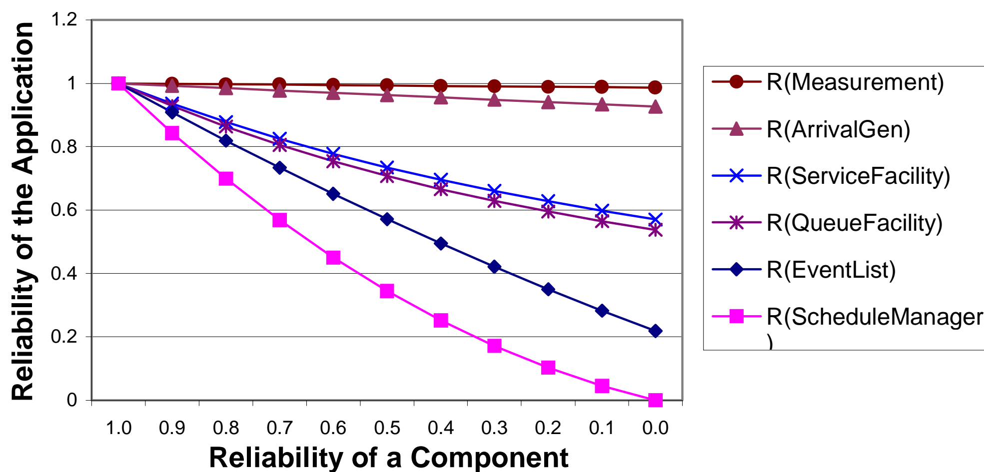

Figure 5 Application Reliability as function of Component Reliabilities (one at a time)

Table (3) is the tabular representation of the graph in Figure 5. The first column is the reliability values of a component. Each of the following columns shows the reliability of the application when reliability of the component between brackets varies according to the first column.

Component Reliability	R_{appl} *(Measurement)*	R_{appl} *(ArrivalGen)*	R_{appl} *(ServiceFacility)*	R_{appl} *(QueuingFacility)*	R_{appl} *(EventList)*	R_{appl} *(ScheduleManager)*
0.9	0.999	0.993	0.956	0.951	0.917	0.850
0.8	0.998	0.985	0.913	0.903	0.838	0.712

5.4.2 Reliability of the application as function of Transition Reliability

Using the SBRE algorithm we are able to investigate the variation in the reliability of the application as a function of the reliability of the transition (interfaces and links) between components. The following graph shows the reliability of the application as function of the reliability of some transitions one at a time while the reliability of other components and transitions are fixed (equal 1 for the sake of comparison).

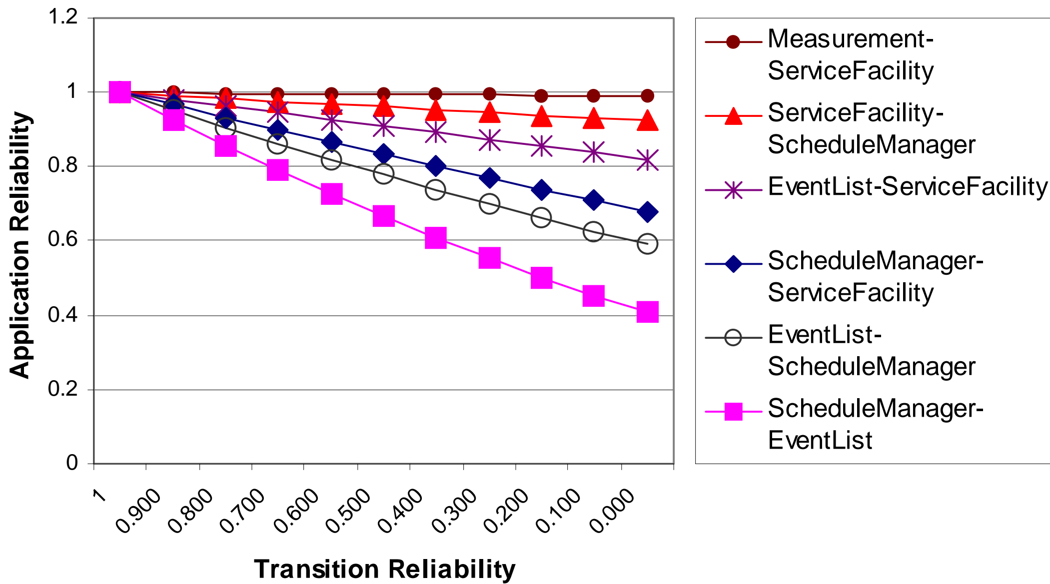

Figure 6 Application Reliability as function of transition reliabilities (one at a time)

Table (4) is the tabular representation of the graph in Figure 6. The first column represents transition reliabilities. Each of the following columns shows the reliability of the application when reliability of the transition between the two components between brackets varies according to the first column.

Transition Reliability	R_{appl} *(Measurement, ServiceFacility)*	R_{appl} *(ServiceFacility, ScheduleManager)*	R_{appl} *(EventList ,ServiceFacility)*	R_{appl} *(ScheduleManager, ServiceFacility)*	R_{appl} *(EventList, ScheduleManager)*	R_{appl} *(ScheduleManager, EventList)*

Table 4 Tabular Representation of Figure 6

5.4.3 Reliability of the application as function of the Scenario Profile

Software components are developed as reusable assets for multiple usage in applications development. Each application may use the components in a similar or different operational environment. The disparity in the manner the application uses a component has a substantial effect on the sensitivity of the application reliability to changes in the reliability of that component. Our model accounts for changes in component usage using probability of each scenario (PS_i in Section 4.1.1). We will refer to the set of probabilities of scenarios for an application as a *Profile*. For our case study, the usage of the components will differ from one application to another, e.g supermarket, immigration posts, car wash service, ..etc. and is also function of the inter-arrival time of customer and the limits on maximum service time requested. For illustration purposes, we will consider four cases only. These cases were generated by varying the maximum requested service time and the maximum limit on the period between customers inter-arrival time. The Profiles for the four cases is shown in Table 5.

	ARRIVAL	SERVE	DEQUEUE	SERVICE_COMPLETE	CHECK_SERVER	REORDER
Profile1	0.950	0.011	0.011	0.011	0.006	0.011
Profile2	0.704	0.073	0.075	0.072	0.003	0.073
Profile3	0.553	0.107	0.115	0.107	0.011	0.107
Profile4	0.145	0.145	0.28	0.145	0.14	0.145

Table 5 Probabilities of each scenario for four different usage profiles

We can analyze the reliability of the application as function of the reliability of each component for different usage (Profiles). We have selected the three components *EventList*, *QueueFacility* and *ServiceFacility*. The reliability of the application as function of the reliability of each of those component is plotted in Figure 7. For each graph, we have plotted the sensitivity of the application reliability to the component reliability for the four profiles of Table 5.

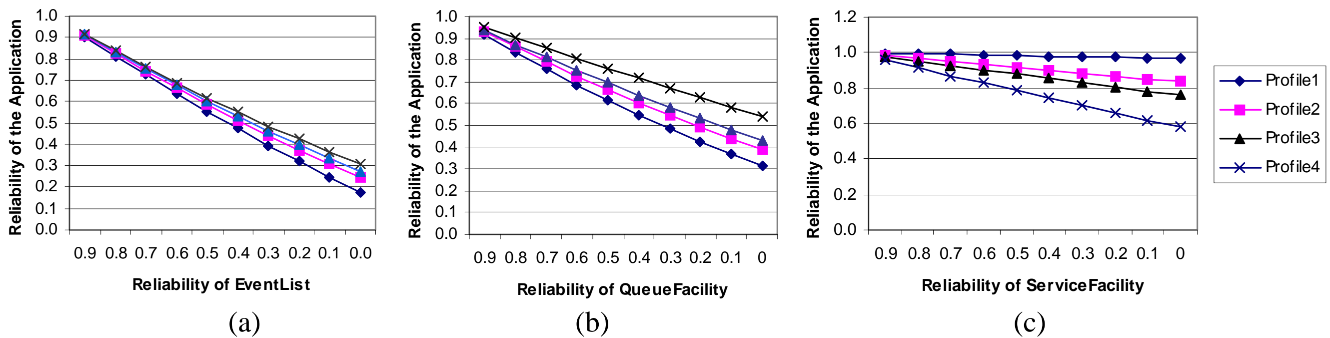

Figure 7 Application reliaiblity as function of scenario profiles

5.5 Results

- From Figure 5, the application reliability varies significantly with the variation in the reliability of the components *ScheduleManager* and *EventList*. As the reliability of those component decreases the application reliability dramatically decreases. This is due to the fact that those two components are the heart of the simulation application and therefore any faults in those components will easily propagate and affect the correct operation of the application.
- From Figure 5, the reliability of the application doesn't vary significantly with the variation in the reliability of the *Measurement* component. This is due to the nature of that component which is recording of simulation results and is only invoked few times in recording and retrieving statistics.
- From Figure 6, the transition reliability between components can significantly affect the reliability of the application. For example, the interface and/or link between the *ScheduleManager* and *EventList* components can significantly deteriorate the reliability of the overall application if there are mismatches or error in data flow between those components.
- From Figure 7, the senestivity of the application reliability to changes in the component reliabilities varies according to usage of components. For example, the application reliability becomes more sensitive to the reliability of the components *EventList* and *QueueFacility* for Profile1 than the case for Profiles2, Profile3, and Profile4 (Figure 7-a, 7-b). On the contrary, the application reliability becomes less sensitive to the reliability of the component *ServiceFacility* for Profile1 than it is for Profiles2, Profile3, and Profile4 (Figure 7-c)

6 Related Work

Several reliability models and estimation techniques have been proposed to assess the reliability of software-intensive systems. In the sequel we are concerned with those addressing component-based applications[3].

Gokhale et.al. [Gokhale+98b] discussed the flexibility offered by discrete-event simulation to analyze component-based applications. Their approach relies on random generation of faults in components using a programmatic procedure that returns the inter-failure arrival time of a given component. Total number of failures is calculated for the application under simulation and its reliability is estimated. This approach assumes the existence of control flow graph (component reliability and transitions) of a program, and did not specify the basis for calculating transition probabilities. The simulation approach assumes failure and repair rates for components and uses them to generate failures in executing the application. It also assumes constant execution time per component interaction and ignores failures in component interface and links (transition

[3] Discussion on the applicability of traditional reliability estimation techniques to component-based software and their limitations is beyond the scope of this paper.

reliabilities). Our proposed technique is analytical, not simulation based. We develop a probabilistic model (component dependency graphs) using execution scenarios. We use scenarios to drive the average execution times of applications and components. Our CDG also incorporates execution times, interface and link reliabilities. Our implementation of SBRE algorithm takes a CDG as an input and doesnot require simulation to study the effect of component reliability growth.

The work in [Sanyal+97] introduces the usage of Program Dependency Graphs (PDG) and Fault Propagation Analysis (PGA) [Shah+97, Voas97] for analytical reliability estimation of component based-applications. Their approach is a code-based (reverse-engineering) approach, in which dependency graphs are generated from source code; this is not usually available for components and component-based systems. The authors did not emphasize on how to evaluate the parameters used in their graph (the event and branch probabilities). Their approach is applicable at lower development level, here we propose an approach applicable at higher development level. Their approach also suggests a random mechanism for solving deadlocks due to loops, our algorithm doesn't suffer from loop problems.

The approach in [Krishnamurthy+97] assesses the reliability of component-based applications using reliability of their components, they proposed a technique called *Component Based Reliability Estimation* (CBRE). Their approach is based on test information and test cases. For each test case, the execution path is identified, the path reliability is calculated using the reliability of the components assuming a series connection (using the independent failure assumption and perfect interfaces between components). The reliability of the application is the average estimate of the reliability of each test path. This approach does not consider component interface-errors although they are considerable factors in reliability analysis of component based software. Estimating reliability based on test cases is not the same as using analysis scenarios. Test cases don't take into consideration the frequency of interaction between components. Our approach doesn't use test cases. Instead, we use analysis scenarios to derive a probabilistic dependency graph which is used to analyze the sensitivity of application reliability to component reliabilities, transitions reliabilities, and usage scenarios. We take into account the component interface reliabilities and link reliabilities to incorporate the case of distributed components.

To apply models used in hardware reliability analysis to component-based software, the research group at university of Toronto [Mason+98, Woit+98] proposed following certain discipline in software component development and a set of design and interaction rules to minimize the interaction and dependability issues between component. The proposed rules would facilitate modeling the component based system in Markov chains and hence can apply the same reliability analysis techniques as in hardware cases. However, such disciplines are difficult to impose and practice by the component developer and vendors.

Most of these approaches can be considered as path-based approach to reliability estimation of component based software. The work in [Gokhale+98] proposed a solution to dependencies among components in path-based techniques, which usually gives a pessimistic evaluation of the system reliability. The solution takes

into account time-dependent representation of the reliability of a component and a fixed execution time per interaction. Our approach solves the dependency in a more simplistic way using the average execution time of the application, and that of a component, based on analysis scenarios.

Everett [Everett99] described an approach to analyzing software reliability using component analysis. The approach uses the Extended Execution Time (EET) reliability growth model and uses test cases to arrive at a composite reliability growth model for the testing period. Our approach shares the same benefits of early reliability analysis of component-based applications prior to detailed implementation. Our CDG model and SBRE algorithm integrates into the "*superimpose component reliability*" step in Everett framework. Our approach is scenario-based and incorporate interface and link reliabilities which were not considered by Everett.

7 Conclusion

This paper presents a new technique to analyze the reliability of component-based applications. The algorithm is named *Scenario-Based Reliability Estimation* (SBRE). The technique is suitable for applications whose analysis is based on valid scenarios with timed sequence diagrams and the execution profile of those scenarios are available. *Component Dependency Graphs* (CDG) are derived to establish a probabilistic model on which the reliability estimation technique is based. A stack-based algorithm is discussed to analyze the reliability of component-based applications. A simple case study for "*simulation of waiting queues*" is used to illustrate the applicability of the approach. This case study, being simple enough for illustration purposes, clearly shows that SBRE algorithm can be used to discuss the sensitivity of the application reliability to component reliabilities, interface reliabilities, and usage scenarios. Results of applying the algorithm can clearly identify critical component and critical component interfaces and links that would require intensive testing and validation. We can summarize the benefits and limitations of the approach as follows:

Benefits

- The approach is based on scenarios, execution times, and components usage. A fault in a frequently executed component would easily manifest itself into a failure. Using our CDG model, we incorporate the effect of frequently executed components, interfaces, and links and hence we can dedicate more testing and development effort to those critical artifacts.
- The algorithm is applicable early at the development phase of a component-based software because they are based in scenarios between reusable components.
- The SBRE algorithm is automatable. We have implemented the algorithm and used the implementation in our case study. Automating the calculation of the parameters from a sequence diagrams is a straightforward task.

- Using scenarios to derive the model allows us to incorporate differences in the usage of a component in reliability analysis of component-based software. Applications using the same component, but with different usage scenarios, will have different sensitivity to the reliability of that particular component.

Limitations

- The nature of the application: The approach is applicable to component-based application which are analyzed using execution scenarios.
- The algorithm does not consider failure dependencies between components.
- The algorithm is applicable for sensitivity analysis of application reliability to component and interface reliability in a given period of execution, a scenario average execution time. Currently, the algorithm does not consider the overall application reliability growth as function of time. However, using the reliability growth of individual components, we can periodically conduct sensitivity analysis for the application reliability.

Future work

- Extend the applicability the algorithm and the CDG model to complex systems which are hierarchical in nature. The extension will incorporate subsystem concepts and hence the CDG will have to be extended to include root and leaf nodes.
- Extend the model to consider the effect of intra-component dependency.
- Extend the model to account for the criticality and complexity of a component or a scenario. Some scenarios could be more critical than others but they are seldomely executed. The model should be able to consider the reliability sensitivity to those particular scenarios.

Appendix B Fault Propagation Analysis (FPA)

The probabilistic model constructed in Section 3 as a component dependency graph establishes the basis of probabilistic study of fault propagation in an application developed from components. Fault propagation analysis is useful in component based applications because:

- It facilitates studying the effect of a defective component on other components in the application and possible on the output of the application as a whole.
- The study of adding, replacing, or modifying a component becomes more feasible from a single model (the component dependency graph).

The algorithm of Section 4.3 is modified to allow fault propagation analysis from a source node to a destination. The objective of the modified algorithm is to estimate the probability that a destination component "D" is affected by a fault in the source component "S". The probability of fault propagation is called *Fault Propagation Probability* (FPP). The algorithm is named *Scenario Based Fault Propagation Analysis* (SB_FPA). The algorithm is limited to single failure propagation and no loops include the source node.

Procedure SB_FPA
Parameters
    consumes CDG, AE_{appl}, S, D
    produces FPP
Initialization:
    $FPP = 0$, $Time = 0$, $FPP_{temp} = (1-R_s)$
Algorithm
    push tuple $<S, R_s, AE_s>$, Time, FPP_{temp}
    while Stack not EMPTY do
        pop $< C_i, RC_i , AEc_i >$, Time, FPP_{temp}
        if $Time < AE_{appl}$
            if $C_j = D$
                $FPP += FPP_{temp}$
            else
                $\forall < C_j ,RC_j , AEc_j > \in children(C_i)$
                $FPP_{temp} = FPP_{temp} * PTi_j * RC_j * RT_{ij}$ ###
                push ($<C_j, RC_j ,AEc_j>$, $Time += AEc_i$, FPP_{temp})
            end
        end
    end while

The algorithm assumes a single fault at a time.
