**Abstract:** Ru /TiO<sub>2</sub> catalysts are highly active and selective in the selective methanation of CO in the presence of large amounts of CO<sub>2</sub>, but suffer from a considerable deactivation and loss of selectivity during time on stream. Aiming at a fundamental understanding of these processes, we have systematically investigated the physical reasons responsible for these effects, using catalysts with different surface areas and combining time resolved kinetic and *in situ / operando* spectroscopy measurements as well as *ex situ* catalyst characterization. This allowed us to identify and disentangle contributions from different effects such as structural effects, adlayer effects such as site blocking effects and changes in the chemical (surface) composition of the catalysts. *Operando* XANES / EXAFS measurements revealed that an initial activation phase is largely due to the reduction of oxidized Ru species, together with a distinct change in the Ru particle shape, until reaching a state dominated by metallic Ru species (fraction RuO<sub>2</sub> <5%) with the highest Ru mass normalized activity. The loss of activity and also of selectivity during the subsequent deactivation phase are mainly due to slow Ru particle growth (EXAFS, TEM). Surface blocking by adsorbed species such as surface formate / carbonate or surface carbon species, which are formed during the reaction, contributes little, as concluded from *in situ* IR, TPO and XPS data. Consequences on the selectivity for CO methanation, which decreases with time on stream for catalysts with larger surface area and for the distinct loss of adsorbed CO and surface formate species, as well as the role of the catalyst surface area in the reaction are discussed.

Key words: CO methanation, deactivation, selectivity, particle size effect, Ru/TiO<sub>2</sub>, XANES, EXAFS, DRIFTS

## 1 Introduction

The selective methanation of CO in H<sub>2</sub>-rich gas mixtures (SelMeth reaction) has emerged as an interesting alternative to the commonly used preferential oxidation of CO (PROX reaction) to selectively remove small amounts of CO from H<sub>2</sub>-rich feed gases for low-temperature polymer electrolyte fuel cells (PEFCs). Since these feed gases are often prepared by reforming of hydrocarbons or biomass, they also contain significant amounts of CO<sub>2</sub>, typically around 20%, in addition to CO. Therefore, the reaction has to be highly selective for the methanation of CO, as the methanation of CO<sub>2</sub> would lead to intolerable losses of H<sub>2</sub>. The SelMeth reaction is particularly attractive for decentralized, small scale applications, e.g., for house (domestic) heating, where the less complicated and hence economically more feasible technology makes the SelMeth reaction an economic choice.<sup>1;2</sup>

Supported Ru catalysts have turned out as the by far most active and selective catalysts for this reaction.<sup>3-8</sup> In a series of studies we have investigated this reaction on different supported Ru catalysts such as Ru/zeolite,<sup>6;9</sup> Ru/Al<sub>2</sub>O<sub>3</sub><sup>5;10;11</sup> and recently on Ru/TiO<sub>2</sub>.<sup>12</sup> In these studies we addressed mainly the interplay between the structure of these catalysts, in particular the Ru particle size, and their catalytic performance, both in idealized<sup>6;9</sup> and in realistic reformat gases (structure – reactivity correlations).<sup>10;11;13</sup> The previous findings led to the following main conclusions: i) The inherent selectivity for CO methanation, at CO levels where the surface would be accessible also to CO<sub>2</sub> adsorption and not blocked by CO<sub>ad</sub>, is basically controlled by the size of the Ru nanoparticles (NPs), with very small Ru NPs (< 1.2 nm  $\varnothing$ ) being highly selective, while for larger particle size the selectivity decays quickly. This trend applies for both reducible and non-reducible supports. ii) The nature of the oxide support has a pronounced impact on the catalytic activity, with Ru/zeolite and Ru/TiO<sub>2</sub> being 5-8 times more active than Ru/Al<sub>2</sub>O<sub>3</sub>. iii) The presence of realistic amounts of water in the feed gas improves the selectivity for CO methanation by a water-assisted disruption of Ru NPs, while

1  
2  
3  
4 the activity decreases with increasing amount of water in the feed.<sup>14</sup> iv) Finally, for Ru/TiO<sub>2</sub>  
5 catalysts also the support surface area was found to strongly affect the (inherent) selectivity,  
6 with the highest selectivity observed for high-surface area Ru/TiO<sub>2</sub> catalysts.<sup>12</sup> This was  
7 attributed to increasing metal – support interactions (MSI). This effect, which was tentatively  
8 proposed to be valid also for other Ru catalysts supported on reducible oxide supports,  
9 provides additional opportunities for controlling the catalytic performance and in particular  
10 the selectivity for CO methanation of supported Ru catalysts.<sup>12</sup>  
11  
12  
13  
14  
15  
16  
17  
18

19 Ru/TiO<sub>2</sub> catalysts were found to be much more active than other structurally similar Ru  
20 catalysts (e.g., similar Ru wt.%, Ru particle size, porosity and surface area), especially at  
21 lower methanation temperatures.<sup>3;10;12;15</sup> They suffer, however, from a substantial deactivation  
22 and loss of selectivity during reaction, which hinders their commercial use in the SelMeth  
23 reaction and other potential reactions. It should be underlined, however, that even after  
24 deactivation these catalysts are still significantly more active than their counterparts.  
25  
26

28  
29  
30  
31  
32

33 Despite of the numerous studies on the SelMeth reaction on supported Ru  
34 catalysts,<sup>1;3;5;6;10;11;16-23</sup> the activation and the deactivation of the catalyst during reaction has  
35 attracted little attention. This is even true for Ru/TiO<sub>2</sub>,<sup>7</sup> where in contrast to Ru/zeolite  
36 catalysts<sup>5;6;9;14</sup> deactivation was significant. For the closely related Fischer-Tropsch reaction,  
37 the observed deactivation is mainly attributed to the blocking of active sites by deposition of  
38 carbon containing species.<sup>24-26</sup> Note that the buildup of these carbon containing species was  
39 also detected at ambient pressure, not only at elevated pressures,<sup>27;28</sup> accordingly it may also  
40 be assumed as a possible reason for the deactivation of Ru catalysts in the SelMeth reaction,  
41 especially in the presence of large amounts of CO<sub>2</sub> as additional carbon source.<sup>9</sup> Nevertheless,  
42 also other effects such as structural modifications or overreduction of the catalyst cannot be  
43 excluded as physical reasons responsible for deactivation.

1  
2  
3  
4 In the present contribution we present results of a systematic study on the physical origin of  
5  
6 the observed activation and deactivation of Ru/TiO<sub>2</sub> catalysts in the SelMeth reaction, which  
7  
8 includes both losses in activity and in selectivity. This may also be helpful for a better  
9  
10 understanding of the high catalytic activity of these catalysts and its physical origin. Studying  
11  
12 the deactivation behavior of a set of 4 Ru/TiO<sub>2</sub> catalysts with different support surface areas,  
13  
14 but otherwise similar characteristics (same Ru loading and Ru particle sizes), and employing a  
15  
16 multi-technique approach, we will i) try to correlate changes in the catalytic performance with  
17  
18 dynamic changes in the catalyst structure and/or in the catalyst (surface) composition during  
19  
20 different stages of the reaction and ii) derive systematic trends with increasing catalyst surface  
21  
22 area. After a brief description of the experimental instrumentation and procedures (section 2),  
23  
24 we will first focus on the activation / deactivation behavior of a specific Ru/TiO<sub>2</sub> catalyst  
25  
26 (Ru/TiO<sub>2</sub>-1). Kinetic measurements of the (de-)activation with time on stream, and in different  
27  
28 reaction atmospheres are combined with *in situ* IR spectroscopic measurements (diffuse  
29  
30 reflection FTIR spectroscopy – DRIFTS) and *operando* as well as *in situ* (temperature  
31  
32 programmed oxidation - TPO) and *ex situ* measurements for probing the chemical/electronic  
33  
34 (by X-ray photoelectron spectroscopy - XPS and X-ray absorption near edge spectroscopy -  
35  
36 XANES) and structural (by extended X-ray absorption fine structure analysis - EXAFS, high  
37  
38 resolution transmission electron microscopy - HR-TEM and X-ray diffraction - XRD)  
39  
40 properties of the catalyst at different stages of the reaction, to gain information on reaction  
41  
42 induced modifications in the catalyst structure (Ru, TiO<sub>2</sub> particle size) and in the chemical  
43  
44 (surface) composition of the catalysts (TiO<sub>2</sub> phase composition, Ru oxidation state, TiO<sub>2</sub>  
45  
46 support reduction) and on the evolution of adsorbed species during reaction, especially the  
47  
48 deposition of carbon containing species (surface formates and bicarbonates as well as surface  
49  
50 carbon or CH<sub>x</sub> species) on the catalysts (sections 3.1 - 3.3). Afterwards we will discuss the  
51  
52 impact of support surface area on the activation and deactivation behavior on the basis of  
53  
54  
55  
56  
57  
58  
59  
60

similar measurements on the other 3 catalysts (section 3.4). For a more comprehensive view on the origin of catalyst activation / deactivation under realistic reaction conditions we also investigated the effect of adding substantial amounts of water in the feed gas on the (de-)activation behavior (section 3.5). Finally we summarize the main results and the resulting conclusions in section 4.

## 2 Experimental Section

### 2.1 Catalysts preparation and pretreatment

The catalysts used in this study were prepared by incipient wetness impregnation, using TiO<sub>2</sub> materials with different surface areas (see Table 1). Their preparation and details of their characterization were described elsewhere.<sup>12</sup> Prior to the reaction, the diluted Ru/TiO<sub>2</sub> catalysts (see section 2.2) were activated in the following way: i) heating up to 150°C in a flow of N<sub>2</sub> (40 Nml min<sup>-1</sup>), ii) calcination for 30 min in 10% O<sub>2</sub>/N<sub>2</sub> at this temperature, iii) purging in N<sub>2</sub> for 15 min at the same temperature, and finally iv) reduction in the respective reaction gas mixture (see Table 2) by heating up to 190°C in 10 min.

**Table 1:** Specific surface areas and Ru loading of the Ru/TiO<sub>2</sub> catalysts Ru/TiO<sub>2</sub>-1 - Ru/TiO<sub>2</sub>-2.

Catalyst	TiO <sub>2</sub> source	$S_{\text{BET}} / \text{m}^2 \text{g}^{-1}$	Ru wt.%
Ru/TiO <sub>2</sub> -1	Degussa - Evonik	121	2.24
Ru/TiO <sub>2</sub> -2	Sigma Aldrich	20	2.08
Ru/TiO <sub>2</sub> -3	Degussa - Evonik	64	2.17
Ru/TiO <sub>2</sub> -4	Sachtleben	235	2.76

According to previous XPS and energy dispersive X-ray (EDAX) characterization the calcination procedure is sufficient to minimize the residual Cl from the sample after

preparation to very low and similar concentration on all prepared samples, while keeping the thermal load of the catalyst at a minimum (see ref. <sup>12</sup>).

## 2.2 Kinetic measurements

The kinetic measurements were carried out in a fixed bed micro-reactor at atmospheric pressure using high purity gases (99.999%) supplied by Westfalen AG. The gas mixtures indicated in Table 2 were prepared using mass flow controllers from Hastings (HFC-202) with a total gas flow of 41.6 Nml min<sup>-1</sup>. Influent and effluent gases were analyzed by on-line gas chromatography (GC) with a CO detection limit of ca. 10 ppm (DANI 86.10), where H<sub>2</sub> is used as carrier gas. All results were obtained under differential reaction conditions (CO conversion ≤ 20%) by diluting the catalysts with thermally stable and catalytically inactive  $\alpha$ -Al<sub>2</sub>O<sub>3</sub> (calcined at 1200°C for 24 hours) to form a catalyst bed of ~1.2 cm length (~200 mg). The fixed size of the catalyst bed and the identical gas flow ensured a constant space velocity in all experiments. For the first GC measurement, the reaction gas was sampled after 10 min, to allow for a stabilization of the reaction gas composition, subsequently samples were taken every 15 min.

**Table 2:** Composition of the different reaction gas mixtures used in the kinetic and spectroscopic measurements.

Reaction reformat	Reaction gas composition		
	CO /ppm	CO <sub>2</sub> /%	N <sub>2</sub> /%
ID-ref 6000	6000	0.0	3.0, balance H <sub>2</sub>
SR-ref 6000	6000	15.5	3.0, balance H <sub>2</sub>
SR-ref 100	100	15.5	3.0, balance H <sub>2</sub>

The Ru mass-normalized reaction rate  $r_{CO}$  for CO methanation was calculated according to equation (1), using the CO conversion ( $X_{CO}$ ) under differential reaction conditions ( $X_{CO} <$

20%, see above), the molar flow rate of CO into the reactor ( $\dot{n}_{CO,in}$ ), and the absolute mass of Ru metal ( $m_{Ru}$ ). The Ru mass-normalized CH<sub>4</sub> formation rate, in contrast, was calculated from the effluent molar flow rate of CH<sub>4</sub> formed ( $\dot{n}_{CH_4,out}$ ), which is produced from CO and CO<sub>2</sub> (equation (2)). From these Ru mass-normalized reaction rates, the turnover frequencies (TOFs) were calculated, using the molar mass of Ru ( $M_{Ru}$ ) and the Ru dispersion ( $D_{Ru}$ ) obtained from the EXAFS measurements, according to equation (3). The selectivity towards CO methanation ( $S_{CO}$ ) is given by the ratio of the CO methanation rate divided by the overall methane formation rate (from CO and CO<sub>2</sub>, see equation 4). The deactivation (De.%) of the catalyst for CO methanation was calculated as the difference between the highest reaction rate ( $r_{max}$ ) during the measurement and the reaction rate at the respective reaction times ( $r_t$ ), normalized by the maximum rate ( $r_{max}$ ).

$$r_{CO} = \frac{X_{CO} \times \dot{n}_{CO,in}}{m_{Ru}} \quad (1)$$

$$r_{CH_4} = \frac{\dot{n}_{CH_4,out}}{m_{Ru}} \quad (2)$$

$$TOF_{CO} = \frac{r_{CO} \times M_{Ru}}{D_{Ru}} \quad (3)$$

$$S_{CO} = \frac{r_{CO}}{r_{CH_4}} = \frac{r_{CO}}{r_{CO} + r_{CO_2}} \times 100 \quad (4)$$

$$De. \% = \frac{r_{max} - r_t}{r_{max}} \times 100 \quad (5)$$

**2.3 *In situ* IR spectroscopy measurements:** *In situ* diffuse reflectance Fourier transform infrared spectroscopy (DRIFTS) measurements were carried out using a commercial *in situ* reaction cell (Harricks, HV-DR2). The spectra were recorded using a Magna 6700 spectrometer (Thermo-Fischer) equipped with a MCT narrow-band gap detector. Background spectra were recorded in a flow of N<sub>2</sub> at 150°C directly after the pretreatment. Afterwards, the catalysts were heated up in the respective reaction gas mixture as described for the kinetic measurements. After starting the reaction, spectra with a high time resolution, with 20 scans

1  
2  
3  
4 per spectrum (data acquisition: 15 sec, one spectrum every 15 sec), were recorded during the  
5  
6 first 10 min in order to follow rapid changes in the catalyst surface (first spectrum started 5 s  
7  
8 after starting the reaction). After 15 min, we changed to a lower time resolution with better  
9  
10 signal-to-noise, averaging over 400 scans per spectrum (data acquisition 200 sec, one  
11  
12 spectrum every 250 sec). All DRIFTS spectra are presented in Kubelka-Munk units (KMU),  
13  
14 whose intensities are generally considered to be proportional to the coverage of the respective  
15  
16 surface species.  
17  
18  
19

## 20 **2.4 Chemical and structural characterization**

21  
22 **2.4.1 X-ray photoelectron spectroscopy (XPS):** XP spectra were recorded on a PHI 5800  
23  
24 ESCA system (Physical Electronics), using monochromatized Al-K $\alpha$  radiation (1486 eV) and a  
25  
26 detection angle of 45° with respect to the surface normal. Spectra were recorded after reaction  
27  
28 in a SR-ref 6000 gas mixture at 190 °C for 10 and 1000 min respectively. The binding energies  
29  
30 (BEs) were calibrated using the C(1s) peak of adventitious carbon at 284.4 eV as reference.  
31  
32 The Ru:Ti surface ratios were calculated from the measured intensities of the Ru(3d) and  
33  
34 Ti(2p) signals, using tabulated atomic sensitivity factors.  
35  
36  
37

38  
39 **2.4.2 X-ray diffraction (XRD):** XRD measurements were performed on a Siemens D5000  
40  
41 diffractometer after 10 and 1000 min of reaction in ID-ref 6000 reformat, using Cu K $\alpha$   
42  
43 radiation ( $\lambda = 0.154$  nm). The average TiO $_2$  crystallite sizes in the respective catalysts were  
44  
45 calculated from the width of the diffraction peak of anatase at  $2\Theta = 25.373^\circ$  via the Scherrer  
46  
47 equation. The ratio of anatase / rutile was also estimated from the diffractograms, taking the  
48  
49 relative intensities of the diffraction peaks at  $25.373^\circ \langle 101 \rangle$  for anatase, and  $27.522^\circ \langle 110 \rangle$  for  
50  
51 rutile.  
52  
53

54  
55 **2.4.3 Transmission electron microscopy (TEM):** The sizes, size distributions and shapes of  
56  
57 the Ru NPs were determined from HR-TEM micrographs taken after reaction in SR-ref 6000  
58  
59  
60

1  
2  
3  
4 reformate for different times on stream (10, 590 and 1000 min) at 190 °C. The catalyst  
5  
6 particles were deposited by drop coating onto carbon grids. The TEM measurements were  
7  
8 performed on a Philips CM 20 instrument operated at 200 kV. For detailed information on the  
9  
10 Ru particle size distribution, at least 600 particles were evaluated for each sample.  
11

12  
13 **2.4.4 X-ray absorption spectroscopy (XAS):** Time resolved *operando* XANES and EXAFS  
14  
15 measurements were performed in the transmission mode at the XAFS beamline of the Elettra  
16  
17 synchrotron, using a Si-311 double crystal monochromator. The spot size illuminated by the  
18  
19 X-ray beam was roughly 6 mm vertical and 2 mm horizontal. A specially designed reaction  
20  
21 cell was used for the *in situ* XAS measurements.<sup>6;9</sup> A catalyst bed of 50 mg of Ru/TiO<sub>2</sub>  
22  
23 diluted with SiO<sub>2</sub> (2:1 - roughly 33 mg Ru/TiO<sub>2</sub>) was loaded in the reaction cell. Note that the  
24  
25 amount of catalyst is roughly 2 times larger than the amount used in kinetic measurements to  
26  
27 allow for reasonable signal-to-noise ratio (for conversions see Fig. S1 in the Supporting  
28  
29 Information). The spectra were collected in transmission mode at the Ru K-edge (22117 eV),  
30  
31 using two Ar / N<sub>2</sub> filled ionization chambers for detection. A ruthenium metal foil placed in  
32  
33 between the second and an additional ionization chamber allowed for simultaneous internal  
34  
35 calibration during all experiments. The pre-edge region was measured from 21867 to 22087  
36  
37 eV with a step size of 10 eV. For the XANES region (22087 - 22157 eV) and for the  
38  
39 EXAFS region (22157 - 23317 eV) we used step widths of 0.5 and 0.98 eV. The data  
40  
41 acquisition in the XANES region took 5 min per spectrum, while for the EXAFS spectra this  
42  
43 took about 30 min. A Ru foil and a pellet of Ru (IV) oxide, which were measured in  
44  
45 transmission, were used as reference materials for the data evaluation. Background  
46  
47 subtraction and spectra normalization as well as the linear combination analysis (LCA) of the  
48  
49 XANES spectra were performed using the Athena software from the IFEFFIT program  
50  
51 package.<sup>29;30</sup> Based on the linear combination analysis of the XANES spectra the fraction of  
52  
53 oxidized / reduced Ru nanoparticles was obtained by determining the contribution of the  
54  
55  
56  
57  
58  
59  
60

1  
2  
3  
4 respective reference spectra to the catalyst / reaction spectra.<sup>29;31</sup> The data reduction and  
5  
6 subsequent fits of EXAFS spectra were carried out using the XDAP software package with  
7  
8 standard procedures, as described elsewhere.<sup>32</sup> Assuming a hcp structure, theoretical  
9  
10 references were calculated by FEFF 8.0, and calibrated with experimental references of Ru  
11  
12 foil and RuO<sub>2</sub> powder.<sup>33;34</sup> All XANES / EXAFS measurements were performed in ID-ref  
13  
14 6000 reaction gas mixture (see Table 2).

15  
16  
17 The EXAFS data were evaluated in the R-space (R: 0.0 – 4.5 Å), using the k-range from 3.2 -  
18  
19 11.8 Å<sup>-1</sup>. In the EXAFS data fit we allowed the coordination number (CN), the Debye-Waller  
20  
21 factor (DWF), the Ru-Ru bond length (R), and the energy shift (E<sub>0</sub>) to change freely.  
22  
23

24  
25 **2.4.5 Temperature programmed oxidation (TPO):** To detect the amount of oxidizable  
26  
27 carbon on the catalyst surface at different stages of the reaction, TPO measurements were  
28  
29 performed directly after reaction in the same reactor. After purging for 1000 min in a stream  
30  
31 of N<sub>2</sub> at 190°C, we first performed an additional temperature programmed desorption (TPD)  
32  
33 run (in N<sub>2</sub>, from 190°C to 450°C: 9°C min<sup>-1</sup>) to remove surface carbonates and formate.  
34  
35 Subsequently, the gas flow was switched to 10% O<sub>2</sub>/N<sub>2</sub> (35 NmL min<sup>-1</sup>) and the temperature  
36  
37 was continuously increased from 190°C min<sup>-1</sup> to 450°C (9°C min<sup>-1</sup>). The resulting CO<sub>2</sub> and  
38  
39 CO concentrations in the effluent gas were monitored continuously by IR transmission  
40  
41 spectroscopy, using an analyzer set-up combining a shoe-box sized Bruker Alpha FTIR  
42  
43 spectrometer (Bruker Optics Inc., Germany) and a customized integrated hollow-waveguide  
44  
45 (iHWG).<sup>35</sup> All TPO measurement were performed in ID-ref 6000 reaction gas mixture (see  
46  
47 Table 2).  
48  
49  
50

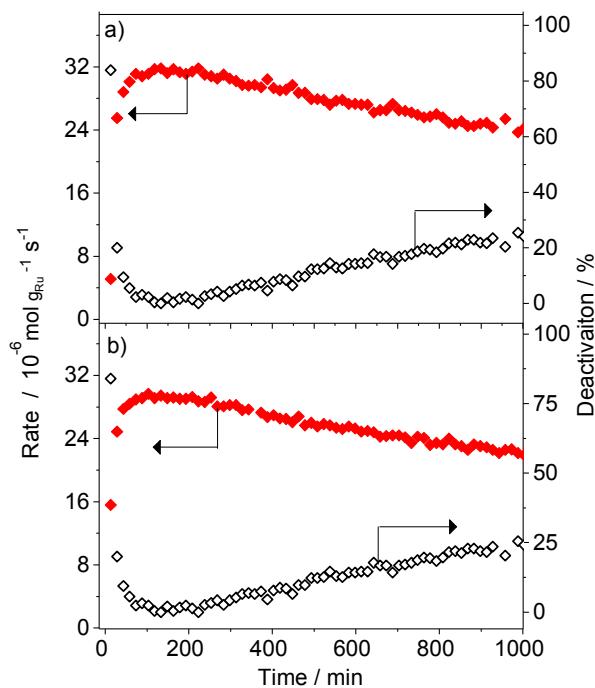

## 51 52 53 **3 Results and discussion**

56  
57  
58  
59  
60

We first followed the catalytic activity of the Ru/TiO<sub>2</sub>-1 catalyst in reformat gases with medium CO concentrations (6000 ppm), both in the presence (SR-ref 6000) and in the absence (ID-ref 6000) of CO<sub>2</sub> (see Table 2). In the latter case, interaction of CO<sub>2</sub> with the support is avoided as well. In SR-ref 6000, the selectivity for CO methanation was found to be always 100%. By comparing with findings for a Ru/zeolite catalyst, we attribute this to site blocking for CO<sub>2</sub> adsorption by adsorbed CO, which completely covers the Ru NPs.<sup>6</sup>

Fig. 1a illustrates the temporal evolution of the Ru mass normalized CH<sub>4</sub> formation rate during the reaction in SR-ref 6000 gas mixture, which at 100% selectivity (see above) is equal to the CO methanation rate, and the corresponding deactivation. In the initial phase, the activity increased continuously from  $5.2 \times 10^{-6} \text{ mol}_{\text{CH}_4} \text{ g}_{\text{Ru}}^{-1} \text{ s}^{-1}$  after 10 min, until it reached its maximum value of  $31.8 \times 10^{-6} \text{ mol}_{\text{CH}_4} \text{ g}_{\text{Ru}}^{-1} \text{ s}^{-1}$  after 120 min. After this activation phase, the

**Figure 1** Ru mass normalized CO methanation rates (♦) and corresponding deactivation (◇) for the Ru/TiO<sub>2</sub>-1 catalyst in SR-ref 6000 (a) and in ID-ref 6000 (b) during reaction at 190°C.

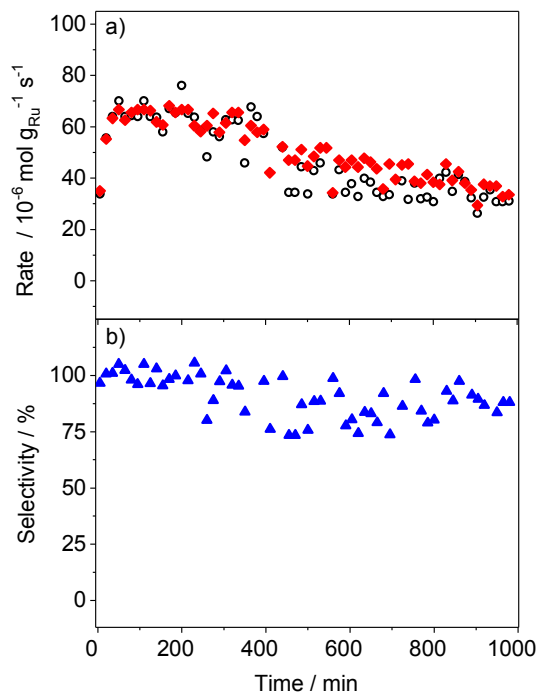

rate started to decrease continuously, reaching a value of  $24.0 \times 10^{-6} \text{ mol}_{\text{CH}_4} \text{ g}_{\text{Ru}}^{-1} \text{ s}^{-1}$  after 1000 min. This represents a deactivation of 24% over 1000 min relative to the maximum activity, which was reached at 120 min (see Table 3). It should be noted that in both gas mixtures the  $\text{CH}_4$  methane formation rate is identical to the CO methanation rate under these conditions. In ID-ref 6000 reformat, in the absence of  $\text{CO}_2$  (Fig. 1b), the reaction behavior was rather similar, with only small differences in the absolute values of the Ru mass normalized activity. After 10 min the rate was  $15.6 \times 10^{-6} \text{ mol}_{\text{CH}_4} \text{ g}_{\text{Ru}}^{-1} \text{ s}^{-1}$  and reached its maximum value ( $30.5 \times 10^{-6} \text{ mol}_{\text{CH}_4} \text{ g}_{\text{Ru}}^{-1} \text{ s}^{-1}$ ) also after  $\sim 120$  min. Intuitively, one would expect a lower deactivation in the absence of  $\text{CO}_2$  compared to that measured in SR-ref 6000 (Fig. 1a), since  $\text{CO}_2$  is known to be one of the main sources of deactivation during hydrogenation reactions, due to the formation of surface formates and / or bi-carbonates.<sup>9;36;37</sup> In the present case, however, the magnitude of the deactivation was almost identical in both reformat gas mixtures (see Table 3), indicating that under present reaction conditions, the interaction of  $\text{CO}_2$  with the Ru/ $\text{TiO}_2$  catalyst cannot be responsible for the observed deactivation. This will be investigated in more detail later (see section 3.2).

**Table 3** Maximum and final CO methanation rates after 1000 min ( $r_{800}$ ) and after deactivation in SR-ref 6000 and ID-ref 6000 reformat gas mixtures, respectively, for different Ru/ $\text{TiO}_2$  catalysts.

Catalyst	CO methanation / $10^{-6} \text{ mol g}_{\text{Ru}}^{-1} \text{ s}^{-1}$ (SR-ref 6000)			CO methanation / $10^{-6} \text{ mol g}_{\text{Ru}}^{-1} \text{ s}^{-1}$ (ID-ref 6000)		
	$r_{\text{max}}$	$r_{1000}$	Deactivation / %	$r_{\text{max}}$	$r_{\text{d}}$	Deactivation / %
Ru/ $\text{TiO}_2$ -1	31.8	24.2	23.9	30.5	26.4	23
Ru/ $\text{TiO}_2$ -2	4.10	2.30	43.9	5.90	3.30	44.1
Ru/ $\text{TiO}_2$ -3	26.0	19.8	23.8	19.6	13.2	32.7
Ru/ $\text{TiO}_2$ -4	12.5	10.2	18.4	10.6	8.30	21.7

\*  $R_{\text{max}}$  Maximum activity attained during reaction

For comparison, we furthermore investigated the reaction behavior of a reaction gas mixture with a much lower CO concentration (100 ppm, SR-ref 100 reformat). Based on previous work on Ru/zeolite catalysts performed under identical conditions, the  $\text{CO}_{\text{ad}}$  coverage is far below saturation under these conditions,<sup>5</sup> which allows for testing the intrinsic activity of the Ru NP catalyst for the  $\text{CO}_2$  methanation, in the absence of a  $\text{CO}_{\text{ad}}$  blocking layer. Fig. 2 shows the time evolution of the activity / deactivation and the selectivity for CO methanation. Similar to reaction in the 6000 ppm CO gas mixtures, the activity for CO methanation passed through an initial activation phase, before it decreased again. The maximum activity was reached, however, significantly earlier and the rate was much higher, increasing from  $31.0 \times 10^{-6} \text{ mol}_{\text{CH}_4} \text{ g}_{\text{Ru}}^{-1} \text{ s}^{-1}$  after 10 min to  $65.0 \times 10^{-6} \text{ mol}_{\text{CH}_4} \text{ g}_{\text{Ru}}^{-1} \text{ s}^{-1}$  at 75 min, pointing to a negative reaction order for CO at higher CO concentrations, as it was also reported for Ru/zeolite and Ru/ $\text{Al}_2\text{O}_3$  catalysts.<sup>5</sup> The earlier reaching of the maximum may be related to the fact that the catalyst dilution was significantly higher in this gas mixture. After 1000 min

**Figure 2** a) Activity ( $\blacklozenge$ :  $\text{CH}_4$  formation;  $\circ$ : CO methanation) and b) selectivity ( $\blacktriangle$ ) during the selective CO methanation in SR-ref 100 at  $190^\circ\text{C}$  over the Ru/ $\text{TiO}_2$ -1 catalyst.

1  
2  
3  
4 on stream, the rate had decreased to  $24.2 \times 10^{-6} \text{ mol}_{\text{CH}_4} \text{ g}_{\text{Ru}}^{-1} \text{ s}^{-1}$  (see table 3). The selectivity for  
5  
6 CO methanation remained stable at 100% during the first 400 min, while for longer reaction  
7  
8 times it decreased slowly, but continuously, to reach ~89% after 1000 min on stream.  
9

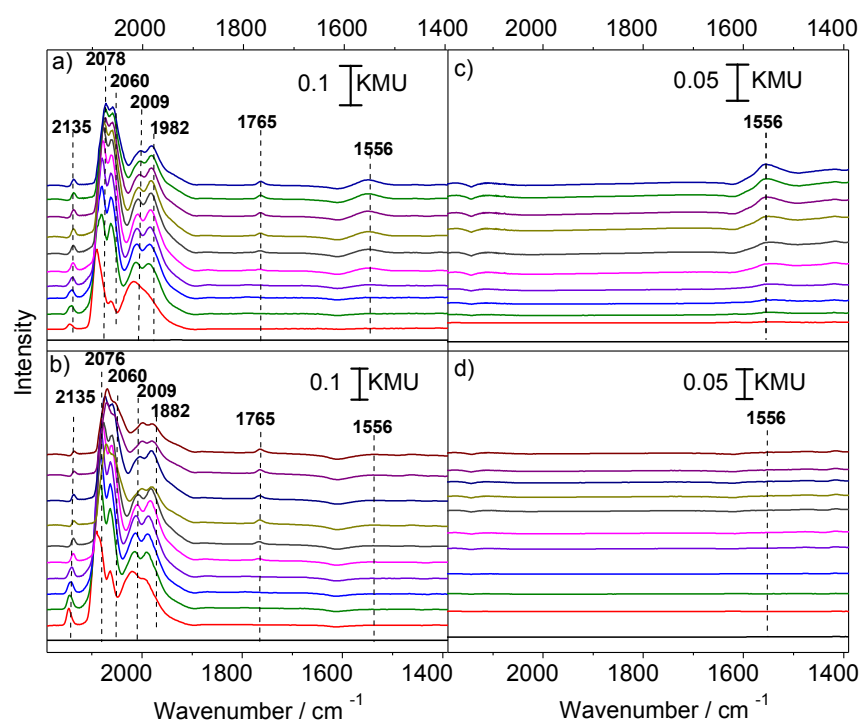

### 11 **3.2 Adlayer formation and changes during selective CO methanation**

12  
13  
14 In Fig. 3 we present DRIFTS spectra recorded during CO methanation at 190°C in a SR-ref  
15  
16 6000 gas mixture on the Ru/TiO<sub>2</sub>-1 catalyst (left panels; Fig. 3a) and on the pure TiO<sub>2</sub>-1  
17  
18 support, respectively (right panels; Fig. 3c). On the catalyst the spectra resolve a number of  
19  
20 different modes related to CO adsorbed on the surface of the Ru NPs (see also <sup>12</sup>). Bands at  
21  
22 2135 and 2078 cm<sup>-1</sup> were previously attributed to CO coadsorbed with O<sub>ad</sub> or to CO<sub>ad</sub> at the  
23  
24 Ru-oxide interface, possibly with multiply bonded carbonyl species, respectively.<sup>38-40</sup> The  
25  
26 band at around 2060 cm<sup>-1</sup> was associated with CO adsorbed on top sites of the Ru NPs.  
27  
28 Finally, the bands at 2009 cm<sup>-1</sup> and 1982 cm<sup>-1</sup> were likely also due to on top adsorbed CO<sub>ad</sub>  
29  
30 species at different sites of the Ru NPs or on very small Ru NPs.<sup>41</sup> Leaving the CO<sub>ad</sub> regime, a  
31  
32 weak band at 1765 cm<sup>-1</sup> is attributed to formyl surface species (HCO<sub>ad</sub>),<sup>18</sup> and the band at  
33  
34 1556 cm<sup>-1</sup> is associated with either surface formate or surface bicarbonate (HOCO<sub>2,ad</sub>)  
35  
36 species.<sup>40;42</sup> Comparison with the bare TiO<sub>2</sub>-1 support shows that there are no peaks in the  
37  
38 CO<sub>ad</sub> region, while the formate / bicarbonate related band at 1556 cm<sup>-1</sup> was present also on the  
39  
40 bare support material (see Fig. 3a). Interestingly, in both cases the initial and the final  
41  
42 intensity of this band were essentially identical (Fig. 3c). Evidently, these species are formed  
43  
44 on the TiO<sub>2</sub> surface rather than on the Ru NPs, and the formation rate is not enhanced by the  
45  
46 presence of the Ru NPs.  
47  
48  
49

50  
51 Similar measurements were performed in an ID-ref 6000 reformat gas mixture. In this case  
52  
53 we particularly wanted to evaluate the extent of carbon-containing surface species formed  
54  
55 upon the interaction of the catalyst / catalyst support with the CO / H<sub>2</sub> mixture in the absence  
56  
57  
58  
59  
60

of CO<sub>2</sub>. The spectra collected on the Ru/TiO<sub>2</sub>-1 catalyst (see Fig. 3b) showed similar features in the CO stretch region as in the SR-ref 6000 gas mixture, while the weak formate (bicarbonate) related band at 1556 cm<sup>-1</sup> is much lower than in the latter case, with intensities close to noise level, both on the catalyst (Fig. 3b) and on the TiO<sub>2</sub>-1 support (Fig. 3d).

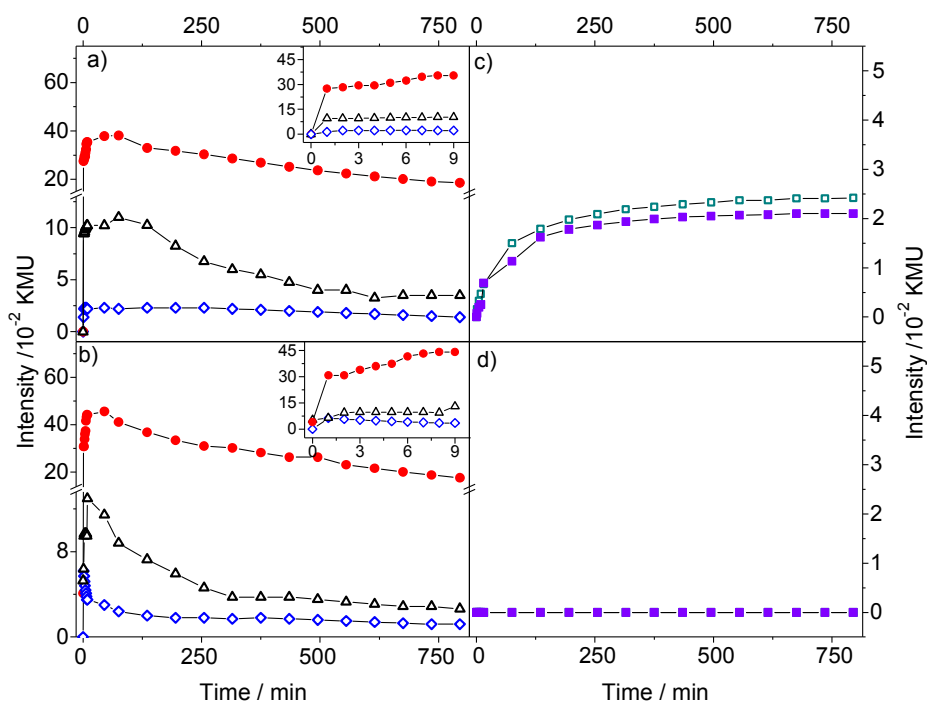

**Figure 3** Series of *in situ* time-resolved DRIFTS spectra measured on the Ru/TiO<sub>2</sub>-1 catalyst (left panels: a,b) and on the bare TiO<sub>2</sub>-1 support (right panels: c,d) in SR-ref 6000 (a,c) and in ID-ref 6000 (b,d) reformate gas mixtures (from bottom to top: 0, 1, 5, 7, 15, 35, 105, 195, 495, 645, and 795 min, reaction temperature 190°C).

To quantify the changes in the band intensities and thus in the coverages of the respective species during the reaction, we plotted the respective band intensities as a function of time on stream. Fig. 4.a shows the temporal evolution of different CO<sub>ad</sub> bands / Ru-carbonyl species over 800 min in the SR-ref 6000 reformate gas mixture. Similar to the activity behavior in the kinetic measurements the coverage of these species first increases, followed by a continuous decay with time. In some cases, steady-state conditions are reached after between 600 and 800

min, in others not. Interestingly, the initial ‘activation phase’ is much shorter than in the kinetic measurements, ca. 30 min as compared to 120 min, despite the identical reaction conditions.

For a quantitative correlation with the deactivation we calculated the relative decrease of the different band intensities during time on stream relative to the maximum intensity. The result

**Figure 4** a,b) Time evolution of the intensity of different CO<sub>ad</sub> and Ru-carbonyl species ( $\diamond$ : 2135 cm<sup>-1</sup>;  $\bullet$ : 2078 cm<sup>-1</sup>;  $\Delta$ : 2009) during selective methanation on the Ru/TiO<sub>2</sub>-1 catalyst in SR-ref 6000 (a) and in ID-ref 6000 reformate gas mixtures (b). c,d) Time evolution of the intensity of the surface formate related band (1556 cm<sup>-1</sup>) on the bare TiO<sub>2</sub> support (empty symbol) and on the Ru/TiO<sub>2</sub>-1 catalyst (filled symbol) in SR-ref 6000 (c) and in ID-ref 6000 reformate gas mixture (d). Insets (a,b) shows the time evolution of the Ru-carbonyl CO band intensity during the first 10 min.

ting values are around 40% for the Ru-carbonyl at 2078 - 2085 cm<sup>-1</sup>, and 43% for the Ru-carbonyl at 2135 cm<sup>-1</sup>, while it was 39% for on top adsorbed CO<sub>ad</sub> (2009 cm<sup>-1</sup>). Essentially, the decay of the CO<sub>ad</sub> related IR band intensities is around 40%, independent of the type. For

1  
2  
3  
4 comparison, the deactivation after 800 min on stream was about 20%. Possible correlations  
5  
6 between deactivation and decay in the coverage of adsorbed species will be discussed later  
7  
8 (section 3.3).  
9

10  
11 Similar DRIFTS measurements performed in the ID-ref 6000 reformat gas mixture, in the  
12  
13 absence of CO<sub>2</sub>, led to the following results (see Fig. 4b): First of all, essentially the same  
14  
15 species are formed, and also the general accumulation behavior is similar as in SR-ref 6000.  
16  
17 The maximum intensities are generally reached in a shorter time compared to reaction in SR-  
18  
19 ref 6000, within few minutes, and also the loss in relative intensity after 800 min is more  
20  
21 pronounced. The relative intensity loss in this case is 44% and 72% for the two different Ru  
22  
23 carbonyls at 2078 - 2085 cm<sup>-1</sup> and at 2135 cm<sup>-1</sup>, and 66% for on top adsorbed CO<sub>ad</sub> (2009 cm<sup>-1</sup>).  
24  
25  
26  
27

28  
29 Comparing the time evolution of the band intensities of the surface formate species on the  
30  
31 Ru/TiO<sub>2</sub>-1 catalyst and on the pure TiO<sub>2</sub>-1 support in the SR-ref 6000 gas mixture (see Fig.  
32  
33 4), we find that this is almost identical in both cases. The coverage of these species increases  
34  
35 steadily during the first 400 min and then seems to saturate. After 400 min it reached about  
36  
37 95% of the final value obtained after 800 min on stream. In this case, the discrepancy between  
38  
39 decay of the band intensity and deactivation is even more pronounced than for the CO<sub>ad</sub>  
40  
41 coverage. For reaction in ID-ref 6000 the intensities were too low to be evaluated, although  
42  
43 kinetic measurements showed a sizeable deactivation (24%) also in this case.  
44  
45

46  
47 Another side product of methanation reactions often reported in the literature are carbon or  
48  
49 adsorbed CH<sub>x</sub> deposits, that may block the Ru NP surface for reaction. In order to test for the  
50  
51 formation of these species, we performed TPO measurements on the Ru/TiO<sub>2</sub>-2 catalyst with  
52  
53 the lowest surface area (20 m<sup>2</sup> g<sup>-1</sup>), which showed the highest deactivation (see section 3.1).  
54  
55 To determine possible background contributions, we first performed a TPO measurement on a  
56  
57 catalyst sample that after calcination was activated for 10 min at 190°C in ID-ref 6000 gas  
58  
59  
60

1  
2  
3  
4 mixture. In a second measurement, we used a sample after 1000 min on stream. The TPO  
5  
6 spectra (see Fig. S2, Supporting Information) show that in both cases there was very little  
7  
8 CO<sub>2</sub> evolution and no measurable CO formation during the TPO measurement. After  
9  
10 background subtraction, the total amount of oxidizable carbon on the surface after 1000 min  
11  
12 on stream corresponds to about 2.5% of a monolayer, assuming a dispersion of 48% for the  
13  
14 Ru NPs (see section 3.4) and that all of this carbon is adsorbed on the surface of the Ru NPs.  
15  
16 The extent of surface site blocking by adsorbed carbon species is far below the deactivation  
17  
18 over 1000 min on stream of 44% measured for this catalyst (section 3.1).  
19  
20

21  
22 These findings in total indicate that under present reaction conditions site blocking by CO<sub>ad</sub> or  
23  
24 by reaction intermediates / reaction side products is not mainly responsible for the observed  
25  
26 deactivation, but at most a minor contribution. Other possible reasons could be structural or  
27  
28 chemical modifications such as a change of Ru NPs dispersion or of the catalyst surface  
29  
30 composition with time, which would fit to the decaying intensity of adsorbed CO. This will be  
31  
32 explored in the next section.  
33  
34  
35

### 36 **3.3 Reaction induced changes of Ru/TiO<sub>2</sub> catalyst**

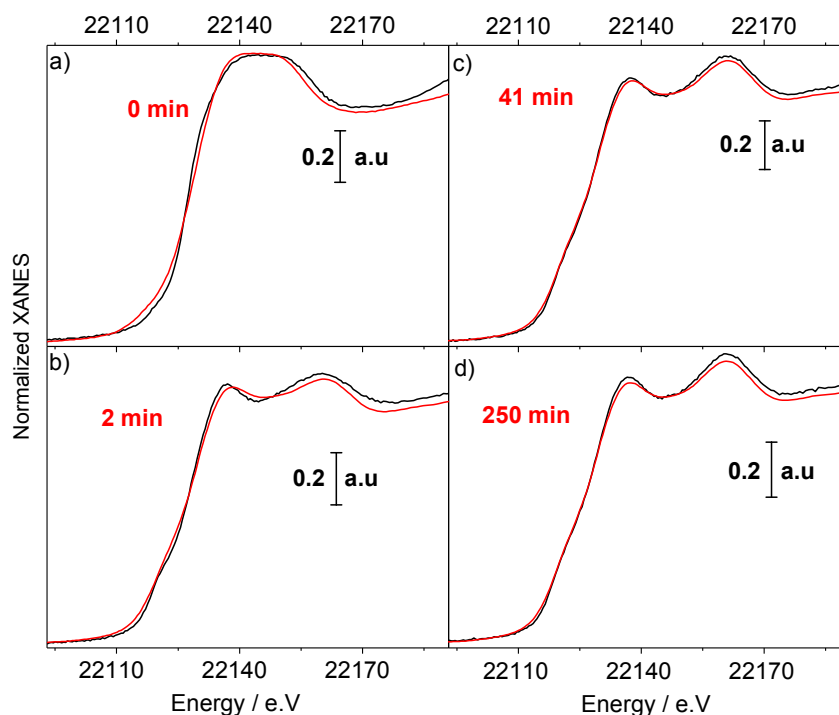

37  
38 In this part we focus on reaction induced changes in the chemical / electronic and structural  
39  
40 properties of the Ru/TiO<sub>2</sub>-1 catalyst due to the interaction with the reaction gas mixture. We  
41  
42 will first characterize changes in the chemical / electronic properties of the Ru NPs and the  
43  
44 TiO<sub>2</sub> crystallites during the reaction employing XANES and XPS measurements.  
45  
46 Subsequently, structural modifications will be evaluated based on time resolved *operando*  
47  
48 EXAFS and *ex situ* HR-TEM and XRD measurements.  
49  
50

#### 51 **3.3.1 Reaction induced chemical modifications - Reduction of Ru and TiO<sub>2</sub> particles**

52  
53 Time resolved *operando* XANES measurements were performed after pretreatment and  
54  
55 subsequent heat-up in ID-ref 6000 reaction gas, while CO methanation was simultaneously  
56  
57  
58  
59  
60

1  
2  
3  
4 followed by GC (see Fig. S1, Supporting Information). The spectra were evaluated by  
5  
6 applying a linear combination analysis (LCA) in order to quantify the contribution of oxidized  
7  
8 and metallic Ru species in the catalyst (see Fig. S3, Supporting Information), using  
9  
10 additionally measured spectra of RuO<sub>2</sub> and of a Ru foil as references.<sup>31;43;44</sup>

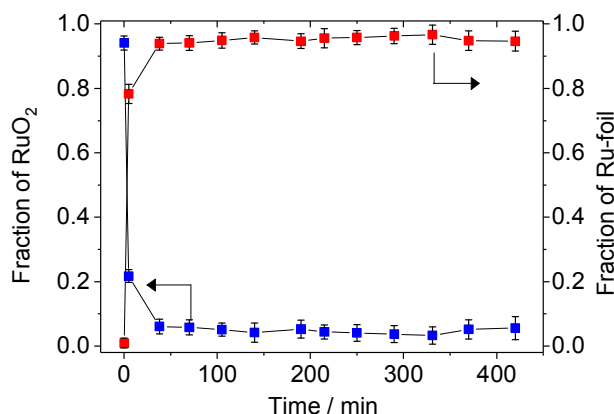

11  
12  
13 The general appearance of the spectrum in Fig. 5 with its characteristic broad peak in the  
14  
15 range of 22115 eV – 22140 eV closely resembles that of RuO<sub>2</sub> (see spectrum for RuO<sub>2</sub> in Fig.  
16  
17 S3, Supporting Information), indicating that after calcination in 10% O<sub>2</sub>/N<sub>2</sub> at 150°C the  
18  
19 catalyst is in an almost fully oxidized state. This is confirmed by the LCA analysis, which  
20  
21 reveals a dominant oxidic contribution (96±1%) with a very small fraction of metallic Ru  
22

56  
57  
58  
59  
60

(4±1%). Upon switching to the reaction gas, the XANES spectrum recorded after 2 min (2 - 7 min) showed that the strong white line, which is characteristic for the excitation of Ru(1s) electrons into unoccupied d-states and thus directly proportional to the oxidation state of Ru, has decreased to less than 25% of its original intensity (see Fig. 6). On a quantitative scale, the LCA indicates a decay of the contribution of RuO<sub>2</sub> in the sample from 0.96 (after calcination, 0 min) to 0.25 after 2-7 min on stream.

After 41 min on stream, the contribution of oxidized Ru in the spectra (RuO<sub>2</sub>) decreased to 0.06 (i.e., metallic Ru = 0.94). Also after longer reaction times the contribution of RuO<sub>2</sub> to the XANES spectra remained stable at ≤ 0.05 (see Table S1, Supporting Information). The small contribution of oxidic Ru may result from the interaction of the metal Ru NPs with lattice oxygen of TiO<sub>2</sub> at the contact area.<sup>45</sup> Hence, the fraction of oxidic Ru species decreases rapidly during time on stream, reaching a steady-state situation with a contribution of metallic Ru of ≥ 0.95 after at most 50 min. This is significantly shorter than the time required for reaching the maximum activity under identical reaction conditions (Fig. 1b), it fits better to

**Figure 6** Time evolution of the contributions from oxidized and reduced Ru species to the Ru K-edge XANES spectrum during the selective CO methanation on the Ru/TiO<sub>2</sub>-1 catalyst, as obtained from a linear combination analysis of the XANES spectra using RuO<sub>2</sub> and a Ru foil as references.

1  
2  
3  
4 the time required to reach the maximum  $\text{CO}_{\text{ad}}$  coverages (see Fig. 4). Therefore, the reaction  
5  
6 is dominated by metallic Ru NPs. We expect that the initial reduction of the catalyst will  
7  
8 result in a significant increase in CO methanation activity in the first few minutes. Even after  
9  
10 this reduction process, however, the activity increases, though this increase becomes rather  
11  
12 slow after 50 – 60 min. Hence, there must be another process contributing to the catalyst  
13  
14 activation in this period, most likely structural modification of the Ru nanoparticles. Finally,  
15  
16 the data clearly demonstrate that the deactivation of the catalyst cannot be related to a  
17  
18 reduction or oxidation of the Ru NP surface.  
19  
20

21  
22 These findings were supported by the results of *ex situ* XPS measurements, performed after  
23  
24 reaction for 10 and 1000 min in ID-ref 6000 reformat gas at 190°C (spectra see Fig. S4a and  
25  
26 Table S2, Supporting Information). Here we have to keep in mind that these measurements  
27  
28 require transfer of the Ru NP catalyst through air, which is likely to cause some surface  
29  
30 oxidation. Comparing the binding energy (BE) of the Ru(3d<sub>5/2</sub>) state of a catalyst operated for  
31  
32 1000 min with that after reaction for 10 min, we find a down-shift of the BE by 0.8 eV, from  
33  
34 280.1 to 279.3 eV. For comparison, reference values for surface oxidized Ru and for metallic  
35  
36 Ru are 280.3 and 279.2 eV.<sup>46</sup> Hence, these spectra also indicate that the Ru NPs are reduced  
37  
38 during reaction, in good agreement with the results of the *operando* XANES measurements.  
39  
40

41  
42 The BEs of the Ti (2p<sub>3/2</sub>) signals of the different Ru/TiO<sub>2</sub> catalysts are located in the range  
43  
44 from 458.0 eV and 458.6 eV, which is typical for Ti<sup>4+</sup>.<sup>47,48</sup> For all catalysts, we found a slight  
45  
46 down-shift in the BE of the Ti (2p<sub>3/2</sub>) state by around 0.3 eV during the reaction, e.g., from  
47  
48 458.5 (after 10 min) to 458.2 eV (after 1000 min) for the Ru/TiO<sub>2</sub>-1 catalyst (see Fig. S4a and  
49  
50 Table S2, Supporting Information). Apparently, the reaction leads to a slight reduction of the  
51  
52 TiO<sub>2</sub> support, which often is accompanied by a partial overgrowth of the metal NPs by a thin  
53  
54 TiO<sub>x</sub> (x<2) layer, which would reduce the number of accessible Ru sites.<sup>49-52</sup>  
55  
56  
57

59  
60

### 3.3.2 Reaction induced structural changes of Ru/TiO<sub>2</sub> catalysts

**TiO<sub>2</sub> structure:** We first evaluated XRD measurements to see whether there is a change in the TiO<sub>2</sub> crystallite size or phase composition (ratio anatase: rutile) during reaction, which could be a reason for the observed deactivation. Comparing the size of the TiO<sub>2</sub> crystallites in the Ru/TiO<sub>2</sub>-1 catalyst before and after 1000 min reaction indicated negligible change of the crystallite size (see Table S3 and Fig. S5, Supporting Information). Before reaction, the catalyst showed strong reflections at 25.3°, and 48.1°, which are related to the (101) and (200) planes of anatase,<sup>53-55</sup> and reflections at 27.4°, 36°, and 55°, which are assigned to the (110), (101), and (211) planes of rutile. After 1000 min on stream the diffraction pattern did not change much. Quantitative evaluation of the anatase : rutile intensity ratio, using the reflections at  $2\theta = 25.373^\circ$  (anatase) and  $27.52^\circ$  (rutile), yielded a constant ratio before and after 1000 min on stream (see Table S3, Supporting Information). Hence, a structural modification of the support can be excluded as a potential reason for the observed deactivation of the catalyst.

**Ru dispersion / particle size and shape:** Changes in the average Ru particle size /dispersion as well as in the particle shape during reaction were followed by *ex situ* (HR-TEM / XPS) and by time resolved *operando* EXAFS measurements during reaction in ID-ref 6000 reformat.

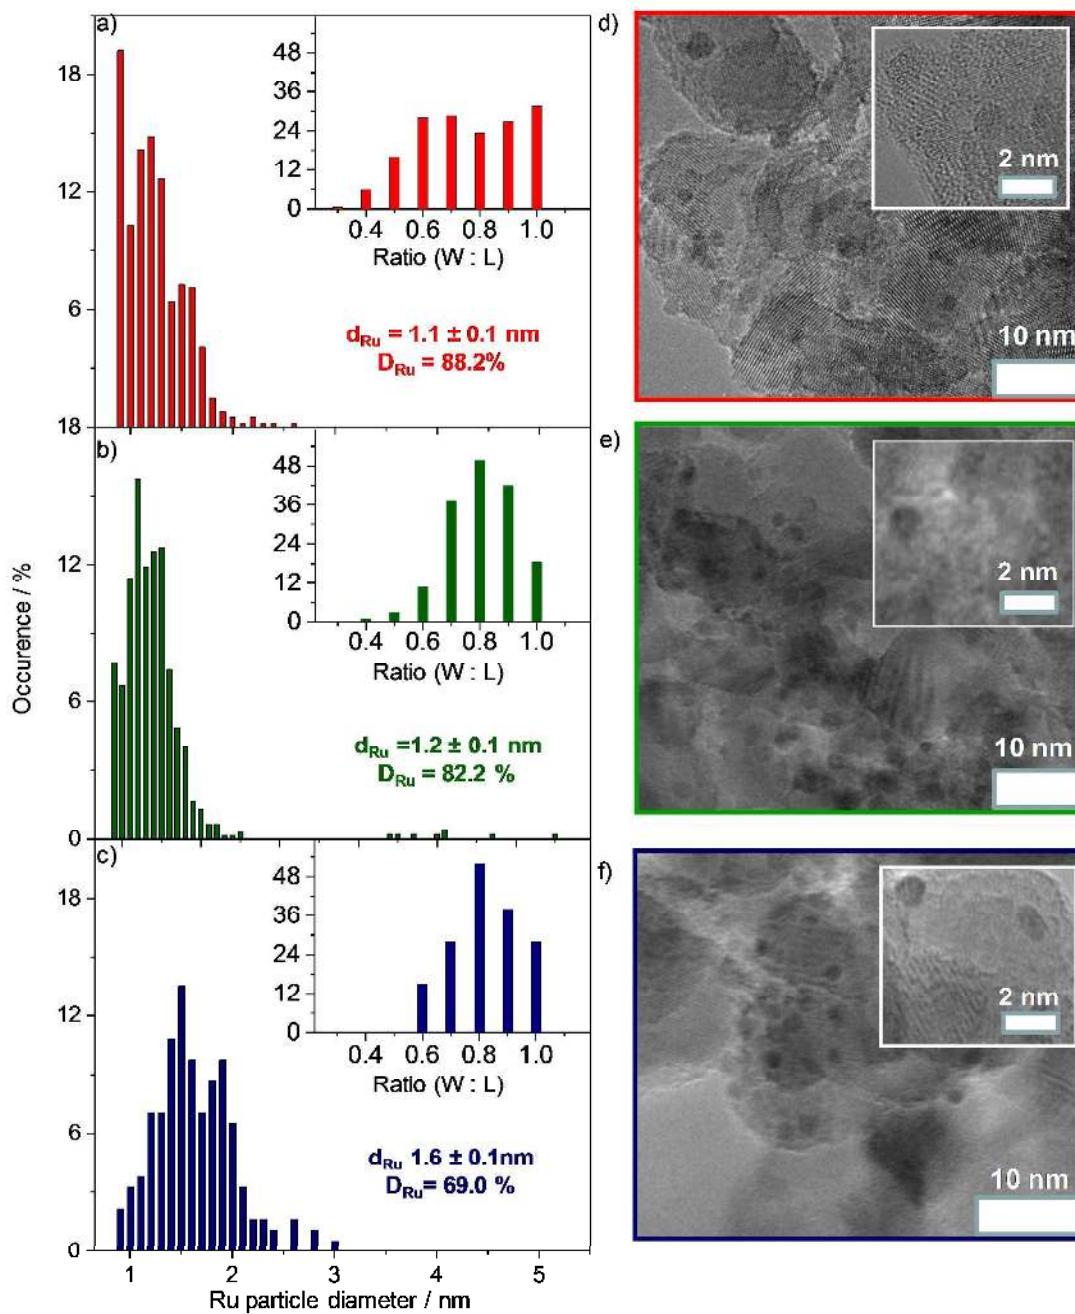

First we calculated the change in the atomic ratio of Ru : Ti in the surface of the Ru/TiO<sub>2</sub>-1 catalyst from the intensities of the Ru (3d<sub>5/2</sub>) and Ti (2p<sub>3/2</sub>) peaks in the XPS data discussed in the previous section, after correction by the atomic sensitivity factors (see Fig. S6, Supporting Information).<sup>46</sup> Comparing the ratio after 10 min to that after reaction for 1000 min indicated a significant decrease by a factor of about 1.9 (Table S2 and Fig. S6, Supporting Information). Obviously, the concentration of surface Ru decreases during reaction. Considering the constant overall concentrations in the catalyst, such behavior can result either from Ru particle size growth or from an overgrowth of the metal particles by TiO<sub>x</sub>.

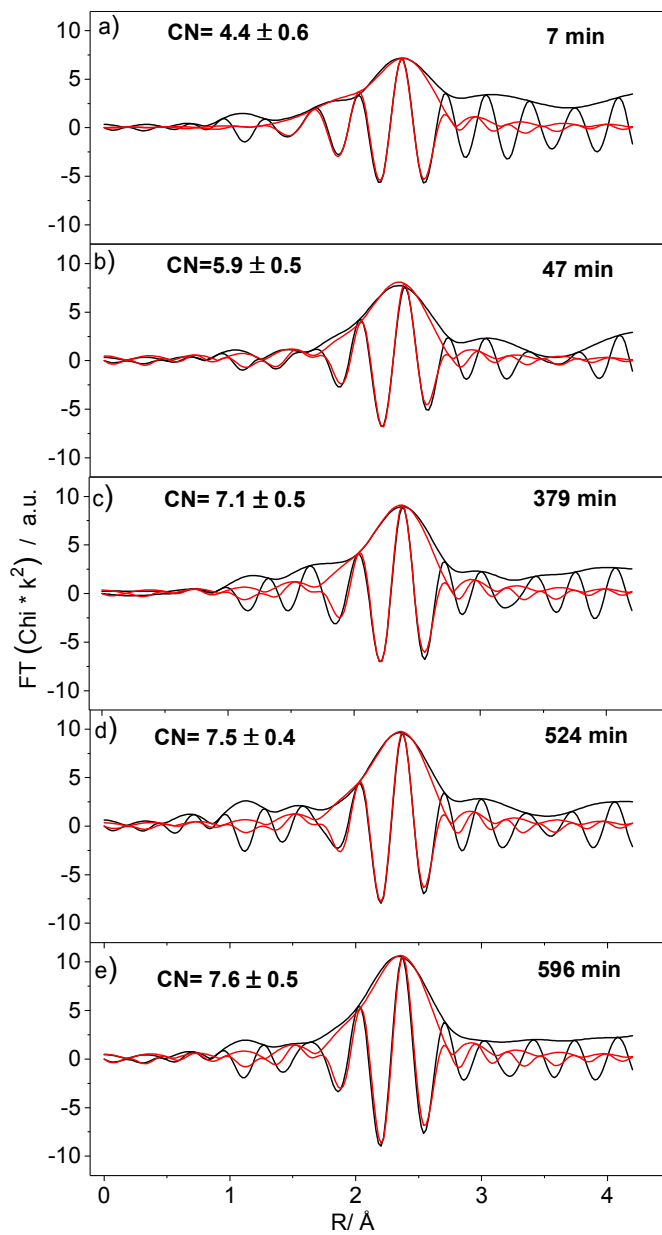

1  
2  
3  
4 Using HR-TEM imaging, the particle size distribution of the Ru NPs of Ru/TiO<sub>2</sub>-1 catalyst  
5 was measured after reaction in ID-ref 6000 reformat gas for 10, 590 and 1000 min,  
6  
7 respectively. The resulting data indicate a rather slow, gradual increase of the Ru particle size  
8  
9 with increasing reaction time, from 1.1 nm ( $D_{\text{Ru}} = 88.5\%$ ) after 10 min to 1.3 nm ( $D_{\text{Ru}} =$   
10  
11 82.5%) and 1.6 nm ( $D_{\text{Ru}} = 69.0\%$ ) after reaction in ID-ref 6000 for 590 and 1000 min,  
12  
13 respectively (see Fig. 7).  
14  
15

16  
17 To gain more information on the particle shape, we determined the ratio of the smaller  
18 diameter (width) vs. the longer diameter (length) for each particle and plotted the frequency of  
19 different particle diameter ratios (Insets in Figs. 7a, b, c). Looking at a flat, disk-like particle  
20 from the side one would obtain a rather low value for the diameter ratio, whereas in a top  
21 view this would yield a ratio of 1. For a spherical particle, in contrast, one would always  
22 obtain a ratio of 1, independent of the angle of view. While a quantitative evaluation of the  
23 particle shape from a statistical analysis of the distributions is beyond the present data and  
24 also beyond the scope of the present data, the plots nevertheless provide valuable qualitative  
25 information. Both after 590 and 1000 min on stream the data reveal a rather narrow  
26 distribution, ranging from a diameter ratio of about 0.5 to 1.0 with a shape that resembles a  
27 Gauss distribution and a maximum around 0.8. For the fresh particles, after 10 min initial  
28 reaction, the center of mass is also at about 0.8, but in this case the distribution has a different  
29 shape, with significantly higher frequencies at lower diameter ratios, down to 0.3, and also  
30 much higher frequencies at 0.9 and in particular at 1.0. Qualitatively, this means that there  
31 was not only a measurable change in particle size in the later phases of the reaction, between  
32 590 and 1000 min, but there is also a significant change in particle shape in the initial phase,  
33 with flat particles significantly more abundant initially than in the later phases of the reaction,  
34 while in later stages hemispherical particles seem to dominate.

60

**Figure 7** High resolution TEM micrographs of the Ru/TiO<sub>2</sub>-1 catalyst and the corresponding Ru particle size distributions after reaction in ID-ref 6000 for 10 min (a, d), 590 min (b, e) and for 1000 min (c, f). Insets in layers (a,b,c) show distribution of width-to-length ratios in Ru nanoparticles.

**Figure 8** Fourier transformed EXAFS data collected at the Ru K-edge during reaction on the Ru/TiO<sub>2</sub>-1 catalyst in ID-ref 6000 at different reaction times (data acquisition started after a) 7 min, b) 47 min, c) 379 min, d) 524 min and e) 595 min).

extracted from the EXAFS data at the Ru K-edge. The first EXAFS spectrum was recorded starting 7 min after switching the reaction gas mixture to the cell, and measuring for 30 min.

Fourier transforms of EXAFS spectra recorded after different reaction times are presented in Fig. 8 (a-e), while the corresponding EXAFS data (fit parameters and the  $k^3$  weighted Chi

1  
2  
3  
4 functions) are presented as supplementary data (Table S4 and Fig. S7, Supporting  
5  
6 Information). The EXAFS data were fitted with a Ru-Ru backscatterer. A contribution from a  
7  
8 Ru-O shell was not detected, although the LCA indicated the presence of an oxidized fraction  
9  
10 of 0.217 in the XANES spectrum taken after 2 min on stream (measurement from 2 – 7 min)  
11  
12 (Table S1, Supporting information). Here we should keep in mind that the data acquisition for  
13  
14 an EXAFS spectrum is 30 min, while the XANES region takes only 5 min. Hence, we can  
15  
16 assume that the remaining fraction of oxidic Ru decreases to almost the steady-state value of  
17  
18 0.04 in the time from 7 - 37 min. The EXAFS result further corroborates the findings derived  
19  
20 from the XANES data, which indicated that the oxidation state of Ru (metallic Ru) is about  
21  
22 constant after 40 min on stream.  
23  
24

25  
26 The CN values for Ru NPs extracted from EXAFS data were found to increase steadily during  
27  
28 reaction on-stream, first rather quickly from  $4.5 \pm 0.6$  at 7 - 37 min to  $6.2 \pm 0.5$  after 121 -151  
29  
30 min and then slower to  $7.5 \pm 0.5$  after 595 - 625 min. Obviously, the dispersion of the Ru NPs  
31  
32 decreases during reaction. Qualitatively, this trend is in good agreement with those derived  
33  
34 from the TEM and XPS measurements, while on a quantitative scale this is different. For  
35  
36 instance, the TEM based mean particle size increases only rather little in the first 590 min,  
37  
38 and more over longer times, up to 1000 min. The CN values, in contrast, exhibit the most  
39  
40 pronounced changes in the initial phase, up to 120 min, while later on the growth is slower.  
41  
42 These discrepancies can at least partly be resolved when considering also the pronounced  
43  
44 changes in particle shape from 10 min to 590 min. As discussed above, the data indicate a  
45  
46 much higher fraction of flatter particles in the beginning, after 10 min on stream, than in the  
47  
48 later stages. Considering that flat particles have lower CN values than hemispherical or even  
49  
50 spherical particles, where the exact amount depends on the aspect ratio, the change in particle  
51  
52 shape could at least partly account for the pronounced initial changes in the CN based particle  
53  
54 size. The same effect explains also at least partly the distinct discrepancy between the initial  
55  
56  
57  
58  
59  
60

1  
2  
3  
4 CN based and TEM based particle sizes on an absolute scale. After 590 min the Ru particle  
5  
6 sizes obtained from  $CN_{Ru-Ru}$  and from HR-TEM measurements are about equal, which is  $1.1 \pm$   
7  
8  $0.3$  nm (based on a hemi-spherical particle shape<sup>13</sup>) and  $1.3 \pm 0.1$  nm, respectively. In total,  
9  
10 we conclude that there is a significant change in Ru particle shape in the first about 120 min  
11  
12 of the reaction.  
13  
14  
15

### 16 **3.3.3 Ru particle size / particle shape effects**

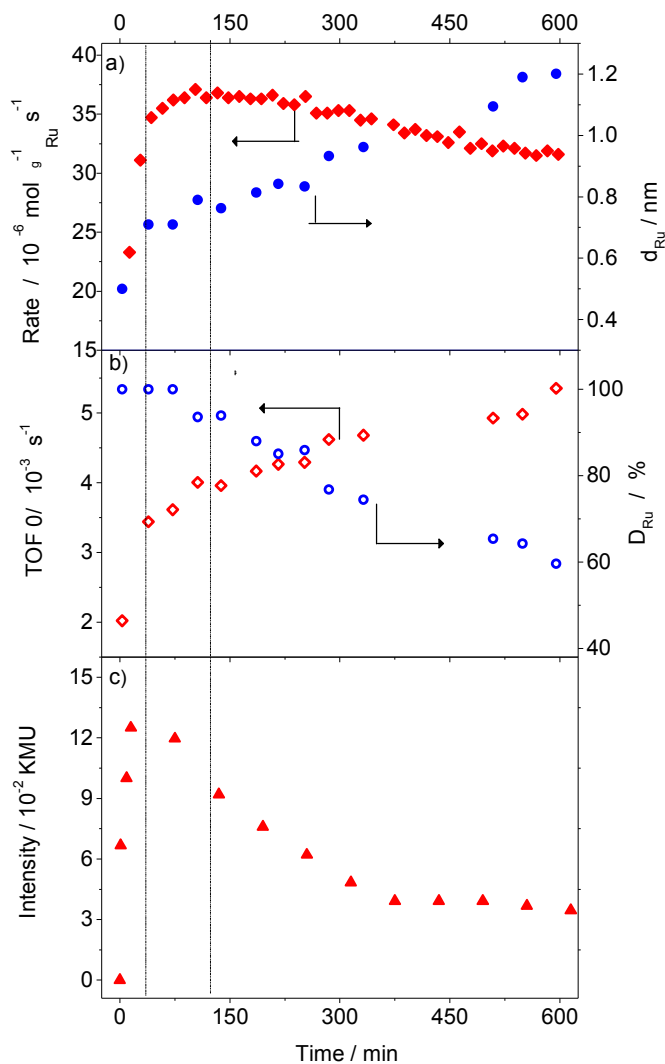

17  
18 Here we will discuss correlations between the changes in activity and selectivity during  
19  
20 reaction of the Ru/TiO<sub>2</sub>-1 catalyst in ID-ref 6000 and particle size related data, including also  
21  
22 the intensity of the CO<sub>ad</sub> related band, which we assume can be considered as a measure of the  
23  
24 Ru surface area available for the reaction. These data and their variation with time are  
25  
26 summarized in Fig. 9.  
27  
28

29  
30 The Ru mass normalized CO methanation rate (data from Fig. 1b) is plotted in Fig. 9a,  
31  
32 together with the Ru particle size derived from the EXAFS spectra, assuming hemispherical  
33  
34 particle size. It is clear from our previous discussion of the particle shape distribution (section  
35  
36 3.3.2) that this assumption is not correct in the initial phase of the reaction (see discussion in  
37  
38 the previous section), but it should be correct for longer reaction times, where TEM data  
39  
40 indicate a constant particle shape. Based on the combined TEM and EXAFS data we assume  
41  
42 that these are about constant after about 120 min, i.e., from the time where the maximum  
43  
44 activity is reached. In that case, particle sizes derived from CN numbers will be reliable from  
45  
46 that point on. This assumption will be justified in the coming discussion. For information, we  
47  
48 also included the mean particle size derived from TEM imaging (Fig. 9a). The intensity of the  
49  
50 band related to on top adsorbed CO<sub>ad</sub> at  $2009\text{ cm}^{-1}$  is plotted in Fig. 9c. In addition to these  
51  
52 data, we plotted the dispersion of the Ru NPs and the turnover frequency (TOF values)  
53  
54 determined from the Ru mass normalized rates and the dispersion in Fig. 9b. This assumes  
55  
56 that the entire accessible surface of the Ru NPs is active for catalyzing the reaction.  
57  
58  
59  
60

1  
2  
3  
4 Looking at the time evolution of these quantities, we can distinguish three different time  
5  
6 periods, as indicated in Fig. 9: In the first one, covering about the first 30 min, the activity  
7  
8 increases rapidly. The CO<sub>ad</sub> band intensity also shows a steep initial increase, mainly for the  
9  
10 first 15 min, and then seems to saturate. Finally, also the (EXAFS based) Ru particle size  
11  
12 seems to increase. As discussed before, however, the increase in CN is at least partly due to a  
13  
14 change in particle shape rather than in particle size. Accordingly, this apparent increase in  
15  
16 particle size has to be taken with caution. The same is true also for the TOF numbers in this  
17  
18 phase. This first phase includes also the reduction of the catalyst, resulting in metallic Ru  
19  
20 NPs. With increasing metallic character of the Ru NPs also the adsorption of CO<sub>ad</sub> increases.  
21  
22 The correlation between these trends indicates that the metallic NPs are the active catalysts.  
23  
24

25  
26 In the second phase, ranging up to about 120 min, the Ru mass normalized activity is still  
27  
28 increasing, but the increase is less steep and levels off in the second part of this phase. The  
29  
30 intensity of the CO<sub>ad</sub> band changes little, and also the apparent (see above) particle size seems  
31  
32 to vary little. Most simply, the trends in this phase can be explained by assuming that the  
33  
34 shape modification of the Ru NPs has largely occurred in the first phase, but was not fully  
35  
36 completed, while reduction was finished in the first phase.  
37  
38

39  
40 Finally, the third phase, starting at 120 min, can be considered as the deactivation phase. The  
41  
42 (Ru mass based) activity of the catalyst decreases continuously, losing about 25% during  
43  
44 that time. At the same time the Ru particle size increases slowly, from about 0.8 nm (EXAFS:  
45  
46 0.8 nm, TEM: 1.1 nm) to about 1.2 nm (EXAFS: 1.2, TEM: 1.2) at about 600 min on stream.  
47  
48 TEM data indicate that this increase in particle size continues also at later stages, reaching 1.6  
49  
50 nm after 1000 min. The more or less continuous increase in particle size (see dashed line)  
51  
52 together with the decrease in Ru mass normalized activity result in a slow increase of the  
53  
54 inherent activity of the Ru NPs, indicated by the TOF numbers. A similar increase of the  
55  
56 intrinsic activity with increasing Ru particle size was already reported previously for CO  
57  
58  
59  
60

**Figure 9** Time evolution of a) the Ru particle size (●), the CO methanation rate (data from Fig. 1b, ◆), b) Ru dispersion (○), turnover frequency (◇), and c) on top  $\text{CO}_{\text{ad}}$  intensity (data from Fig. 4b, ▲: band  $2009 \text{ cm}^{-1}$ ) during CO methanation in a ID-ref 6000 gas mixture. The inset in c) shows the evolution of KMU intensity in the first 10 min. Dashed lines indicate the two activation phases and the deactivation phase ( $>120 \text{ min}$ ).

hydrogenation (methanation and Fischer-Tropsch synthesis) on different Ru catalysts.<sup>6;9;16;56;57</sup>

On a microscopic scale this was attributed by several groups to an increasing fraction of surface sites on smooth terraces, indicating that these act as active sites.<sup>56;58;59</sup> On the other hand, Marini et al. concluded for the CO methanation on a Ru/SiO<sub>2</sub> catalyst with mass

1  
2  
3  
4 selected Ru nanoparticles (particle sizes between 3.7 and 13.5 nm) that terraces were more or  
5 less inactive, and that steps were the origin of all activity.<sup>60</sup> Similar conclusions were derived  
6 also for reaction on Ru single crystal surfaces.<sup>61</sup> The apparent discrepancy with the present  
7 observations may be related to the very small particle sizes in the present study, where other  
8 particle size related effects, such as size dependent changes in the electronic properties, may  
9 also play a role. Alternatively, this may also be related to metal support interactions, which  
10 had been demonstrated for Ru on the reducible TiO<sub>2</sub> support,<sup>11</sup> while it should be absent for  
11 Ru/SiO<sub>2</sub> or Ru single crystal surfaces.  
12  
13  
14  
15  
16  
17  
18  
19  
20

21 The change of selectivity is another aspect of these structural changes of the Ru NPs. Using  
22 the reaction in SR-100 as example, where site blocking by CO<sub>ad</sub> is not dominating the  
23 reaction, the selectivity of the Ru/TiO<sub>2</sub>-1 catalyst for CO methanation decays from initially  
24 100% to 88% after 1000 min (see Fig. 2). Assuming that the trend of a slow, but continuous  
25 particle growth is valid also under these reaction conditions, we obtain a decay in selectivity  
26 with increasing Ru particle size, where the initial mean particle size of 1.1 nm was  
27 sufficiently low to obtain 100% selectivity. This behavior closely resembles previous findings  
28 for Ru/zeolite and Ru/Al<sub>2</sub>O<sub>3</sub> catalysts, which established a clear correlation between the  
29 inherent selectivity for CO methanation and the average Ru particle size,<sup>6;9;23</sup> and similar  
30 particle size effects were reported also for other Ru catalysts,<sup>15;16</sup>. The variation of Ru particle  
31 size of Ru/zeolite, Ru/Al<sub>2</sub>O<sub>3</sub> and Ru/TiO<sub>2</sub> catalysts (e.g., by changing the Ru loading,<sup>6</sup> the  
32 calcination temperature,<sup>9</sup> the support surface area<sup>12</sup> or the water content<sup>13</sup>) resulted in  
33 significant changes of the CO selectivity under reaction conditions identical to those used in  
34 the present study. These results were explained by a reaction model based on the Bronsted-  
35 Evans-Polani principle,<sup>62</sup> where increasing Ru particles seemed to stabilize CO<sub>ad</sub> and thus  
36 stabilize the finale state for CO<sub>2</sub> dissociation. According to the BEP model this stabilization  
37 reduces the barrier for CO<sub>2</sub> dissociation.<sup>6;9</sup> This trend can also explain the increasing activity

5 catalyst during time on stream.  
6  
7

### 8 9 **3.4 Impact of the support surface area on the deactivation behavior of the Ru/TiO<sub>2</sub>** 10 **catalysts**

11  
12  
13 To identify effects of the catalyst surface area on the activation / deactivation behavior we  
14 tested also 3 other catalysts which were based on TiO<sub>2</sub> supports with different surface areas  
15 (see Table 1). We had demonstrated earlier that the support surface area sensitively affects the  
16 catalytic activity of these catalysts by modifying the Ru-TiO<sub>2</sub> metal – support interactions.<sup>10;12</sup>  
17  
18

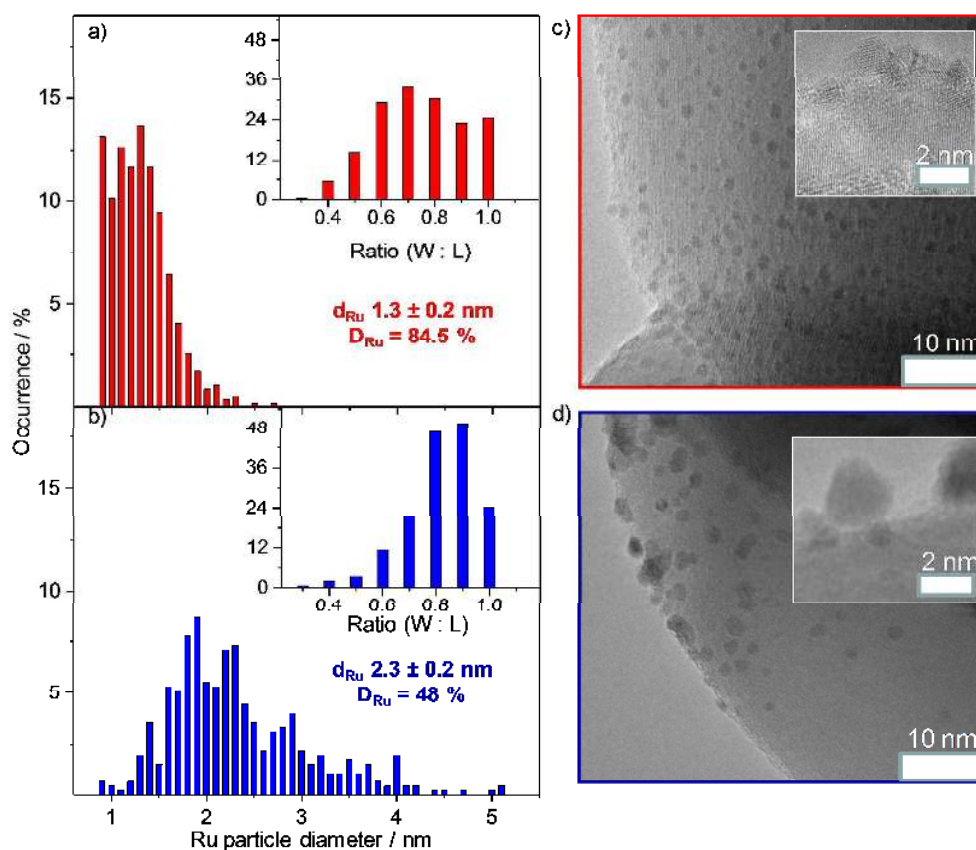

19  
20 Kinetic measurements on the different Ru/TiO<sub>2</sub> catalysts both in the SR-ref 6000 (left panels,  
21 Fig. 10a-c) and in ID-ref 6000 reformates (right panels, Fig. 10d-f) exhibited a deactivation  
22 behavior which closely resembles that observed for the Ru/TiO<sub>2</sub>-1 catalyst with two  
23 differences. First, the initial activation period increases with increasing support surface area  
24 (see Table 3). Second, the relative deactivation, calculated after 1000 min on stream,  
25 decreased with increasing support surface area, from 44% on the Ru/TiO<sub>2</sub>-2 catalysts (20 m<sup>2</sup>g<sup>-1</sup>)  
26 to 18% for the Ru/TiO<sub>2</sub>-4 catalyst (235 m<sup>2</sup>g<sup>-1</sup>).  
27  
28

29  
30 For the Ru/TiO<sub>2</sub>-2 catalyst, which showed the most pronounced activation / deactivation, we  
31 also explored changes in the Ru particle size after operating the catalyst for 10 min and 1000  
32 min and compared these with the changes for the Ru/TiO<sub>2</sub>-1 catalyst discussed before (section  
33 3.3). For the Ru/TiO<sub>2</sub>-2 catalyst, HR-TEM measurements (see Fig. 11) indicated a more  
34 pronounced increase of the mean Ru particle size from 1.2 nm ( $D_{Ru} = 88.5$  from HR-TEM )  
35 after 10 min reaction to 2.3 nm ( $D_{Ru} = 48.0\%$  - HR-TEM) after reaction for 1000 min.  
36  
37 Comparison of micrographs taken after 10 min indicated a homogeneous distribution of Ru  
38 NPs with a rather high density of particles in the beginning of reaction, which after 1000 min  
39 had decreased significantly. It should be noted that in a previous study on these catalysts we  
40  
41  
42  
43  
44  
45

51  
52  
53  
54  
55  
56  
57  
58  
59  
60

**Figure 10** Temporal evolution of the CO methanation rate (filled symbols) and the corresponding deactivation (open symbols) in SR-ref 6000 (left panels) and in ID-ref 6000 (right panels) on Ru/TiO<sub>2</sub> catalysts with different surface areas (reaction temperature 190°C): (a,d) Ru/TiO<sub>2</sub>-2, (b,e) Ru/TiO<sub>2</sub>-3, (c,f) Ru/TiO<sub>2</sub>-4.

had found that the metal-support interactions were much weaker on the Ru/TiO<sub>2</sub>-2 than on the Ru/TiO<sub>2</sub>-1 catalyst,<sup>11</sup> which might explain the increased tendency for Ru particle growth in the Ru/TiO<sub>2</sub>-2 catalyst (Fig. S8, Supporting Information). Similar to the Ru/TiO<sub>2</sub>-1 catalyst we evaluated the changes in the Ru NPs shapes based on the ratio of the short (W) and long diameter (L). Also in this case, the fraction of flat particles (ratios < 0.6) on Ru/TiO<sub>2</sub>-2 after 10 min was found to decrease during the reaction (1000 min on stream, Fig.11 – insets). In this case, however, the center of mass after 1000 min is slightly higher (around 0.85) compared to Ru/TiO<sub>2</sub>-1 (0.8).

**Figure 11** High resolution TEM micrographs of the Ru/TiO<sub>2</sub>-2 catalyst and the corresponding Ru particle size (left panel) and particle shape (left panel, insets) distributions after reaction in ID-ref 6000 for 10 min (a, c) and for 1000 min (b, d).

Similar to the Ru/TiO<sub>2</sub>-1 catalyst, we also tested the deactivation behavior at low CO concentrations, in SR-ref 100 reformat, where Ru site blocking by adsorbed CO is not important. The magnitude of the deactivation was found to increase with decreasing support surface area, similar to the trend for reaction at higher CO concentrations (SR-ref 6000 and ID-ref 6000). Also the CO selectivity, or more specifically, the decay of the selectivity with time on stream, varied with the support surface area (see Table 4), with a more pronounced decay for lower surface areas.

All catalysts were essentially fully selective for CO methanation in the beginning of the reaction, but the selectivity decayed with different amounts during time on stream (Fig. S9, Supporting Information). While for the high surface area catalysts, Ru/TiO<sub>2</sub>-4 and Ru/TiO<sub>2</sub>-1, the decay was negligible or rather low, it became significant or even very pronounced for the lower surface area catalysts Ru/TiO<sub>2</sub>-3 and Ru/TiO<sub>2</sub>-2 (see Table 4). The initial high selectivity is mainly related to the presence of small Ru NPs (1.1 nm on Ru/TiO<sub>2</sub>-1 and 1.3 nm Ru/TiO<sub>2</sub>-2, assuming hemispherical NPs (see discussion in 3.3)). The difference in the final selectivity also correlated with the Ru particle Ru size. Ru/TiO<sub>2</sub>-1 with the higher selectivity (88%) has significantly smaller Ru NPs (TEM:  $d_{\text{Ru}}=1.6$  nm) compared to the

**Table 4:** Initial and final (after 1000 min on stream) rates for CO methanation and CH<sub>4</sub> formation and the corresponding selectivities in SR-ref 100 reformat gas (reaction temperature 190°C).

Catalyst	Reaction rate * 10 <sup>-6</sup> / mol g <sub>Ru</sub> <sup>-1</sup> s <sup>-1</sup>		Selectivity / %	
	Initial (CO / CH <sub>4</sub> )	Final (CO / CH <sub>4</sub> )	Initial	Final
Ru/TiO <sub>2</sub> -1	65.6 / 65.6	34.8 / 39.1	100	89
Ru/TiO <sub>2</sub> -2	6.8 / 7.0	2.10 / 3.70	97	57
Ru/TiO <sub>2</sub> -3	34.5 / 33.5	18.5 / 24.6	100	75
Ru/TiO <sub>2</sub> -4	31.6 / 31.5	26.5 / 27.1	100	97

\* Selectivity is the ratio of the CO methanation rate to the total CH<sub>4</sub> formation rate (from CO and CO<sub>2</sub>).

Ru/TiO<sub>2</sub>-2 catalyst (TEM:  $d_{\text{Ru}}=2.3$  nm) with its much lower selectivity of 57%.

These findings further support our previous proposal that the inherent selectivity of supported Ru catalysts is sensitively controlled by the Ru particle size.<sup>6;9-12;14</sup> A high inherent selectivity, in the absence of Ru site blocking by CO<sub>ad</sub>, is reached only for very small Ru NPs.<sup>6;9</sup>

Finally, we used both XPS and XRD to characterize reaction induced changes in the surface composition of the Ru/TiO<sub>2</sub> catalysts and in the size and phase composition of the TiO<sub>2</sub> support particles for the different catalysts.

1  
2  
3  
4 XPS measurements performed after reaction for 10 and 1000 min, respectively, showed a  
5  
6 similar trend for all other catalysts as observed for the Ru/TiO<sub>2</sub>-1 catalyst, with the Ru  
7  
8 concentration in the catalyst surface decreasing with time on stream (Fig. S5 and Fig. S6,  
9  
10 Supporting Information). Comparing the intensities of the Ru 3d<sub>5/2</sub> and of the Ti 2p<sub>3/2</sub> peak,  
11  
12 the Ru: Ti atomic ratio of the catalyst with the highest surface area (Ru/TiO<sub>2</sub>-4) decreased by  
13  
14 a factor of 1.6 after reaction for 1000 min, while this decrease was more pronounced for the  
15  
16 other three catalysts. Most simply this can be explained by a less significant loss of Ru  
17  
18 dispersion (growth of the Ru NPs) on the latter catalyst. This explanation would also fit with  
19  
20 the lower deactivation observed on that catalyst. The Ru (3d) and Ti (2p) binding energies  
21  
22 showed similar changes as described before for Ru/TiO<sub>2</sub>-1, with both shifting to slightly  
23  
24 lower values after reaction for 1000 min (Table S2, Supporting Information). A decrease of  
25  
26 the BEs by 0.3- 0.4 eV after 1000 min reaction was observed for all catalysts. Hence, the  
27  
28 reduction of the support is not affected much by the surface area. Furthermore, for the  
29  
30 Ru/TiO<sub>2</sub>-2 catalyst with the lowest surface area, the Ru(3d) BE (279.0 eV ± 0.1 eV) was  
31  
32 measurably lower than that of the other catalysts (279.3 ± 0.1 eV), which we attribute to a  
33  
34 particle size effect, resulting from the significantly bigger Ru particles on the Ru/TiO<sub>2</sub>-2  
35  
36 catalyst compared to the other catalysts.  
37  
38  
39

40  
41 In principle, one could also determine the accumulation of deposited carbon species from  
42  
43 these XPS data. Here it has to be kept in mind, however, that there is a considerable uptake of  
44  
45 hydrocarbon species during sample transport through air, which precludes a quantitative  
46  
47 evaluation of such data. As expected for such contamination effects, the C1s intensity in the  
48  
49 spectra in Fig. S4 (Supporting Information) increases with surface area of the catalyst.  
50

51  
52 XRD analysis of the catalysts after reaction for 10 and 1000 min revealed that differences in  
53  
54 size and phase composition of the TiO<sub>2</sub> crystallites are insignificant, which further supported  
55  
56 our previous conclusion that such changes in the support can essentially be ruled out as  
57  
58  
59  
60

1  
2  
3  
4 significant contributions to the deactivation of these catalysts in the CO methanation reaction  
5  
6 under present reaction conditions (see Fig. S5 and Table S3, Supporting Information).  
7

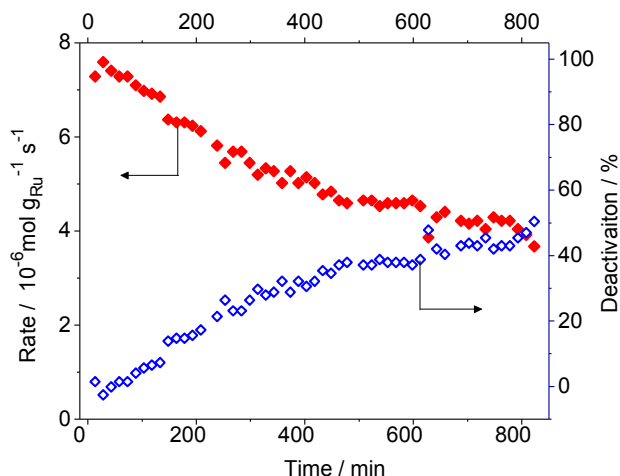

8  
9 The growth of the small metal nanoparticles during reaction can proceed via different  
10 mechanisms, such as Ostwald ripening, or particle coalescence.<sup>63;64</sup> From the present data it is  
11 not possible to identify the exact growth mechanism. Considering the constant metal loading,  
12 the increasing spacing between Ru NPs with increasing support surface area is also expected  
13 to lower the tendency for Ru particle growth.<sup>65</sup> Furthermore, we previously demonstrated for  
14 the same group of catalysts that the increasing surface area goes along with an increase of  
15 metal-support interactions,<sup>11</sup> which can also effect the tendency for particle growth.<sup>63</sup>  
16  
17 Stronger metal-support interactions due to an increasing tendency for O vacancy formation  
18 with varying support particle size (= varying support surface area) had been detected  
19 theoretically for ceria recently.<sup>66</sup>  
20  
21  
22  
23  
24  
25  
26  
27  
28  
29

30  
31 Finally it should be noted that in previous studies residual Cl had been reported to affect the  
32 selectivity of supported Ru catalysts for CO methanation.<sup>67;68</sup>, shifting the onset of CO<sub>2</sub>  
33 methanation to higher temperatures. This results in a wider temperature range with high  
34 selectivities for CO methanation. Therefore, we quantified the amounts of residual Cl on the  
35 four samples by EDX as well as by XPS measurements, once after calcination and 10 min  
36 reaction and once after additional 1000 min on stream. In the EDX analysis, a bulk sensitive  
37 technique, we did not detect any measurable signal for Cl, indicating that the bulk Cl content  
38 is below 0.1 at.%. XPS analysis, on the other hand, which is sensitive to the topmost few  
39 layers of the catalyst only, detected residual Cl contents in the range 0.4 to 1 at.% after  
40 calcination and 10 min reaction. After another 1000 min reaction, the surface contents were in  
41 the range 0.3 - 0.5 at.%. While we cannot rule out that the presence of Cl surface trace  
42 impurities in the fresh samples may contribute to the high selectivity (100%) observed during  
43 the first few minutes of the reaction, this is different for the performance after longer reaction  
44

3  
4 times (see Figure S10 - Supporting Information). The trend of increasing selectivity after  
5  
6 1000 min on stream with increasing surface area (which corresponds also to decreasing Ru  
7  
8 particle size) is not correlated with a similar trend in increasing levels of Cl surface  
9  
10 impurities, instead these are low and about similar for all catalysts. Hence, under these  
11  
12 conditions this represents a genuine effect of the catalysts, caused by the increasing surface  
13  
14 area of the support together with the decreasing particle size and decreasing tendency for  
15  
16 particle growth during time on stream.  
17  
18

### 20 **3.5 Effect of water on the catalyst deactivation**

21  
22 Since water is a byproduct of this reaction, we finally studied the impact of water on the  
23  
24 activation and deactivation behavior of the Ru/TiO<sub>2</sub>-2 catalyst, which showed the shortest  
25  
26 activation period and the highest tendency for deactivation in the absence of water (44%). We  
27  
28 followed the changes in the catalytic activity for 800 min in SR-ref 6000 in the presence of  
29  
30 15% water vapor at 190°C. Water was added by bubbling the dry gas mixture through a water  
31  
32 bath at fixed temperature (for more information see ref. <sup>13</sup>). We observed an almost similar  
33  
34 reaction behavior in the presence of water as in the absence of water (see Fig. 10a). In the  
35  
36 presence of water methane formation reached its highest rate of  $7.2 \times 10^{-6} \text{ mol g}_{\text{Ru}}^{-1} \text{ s}^{-1}$  in  
37  
38 25min (see Fig. 12), similar to the time this took in the absence of water. Afterwards, the  
39  
40 activity decayed with time on stream at a similar rate as in the absence of water (see Fig. 10a)  
41  
42 reaching  $3.7 \times 10^{-6} \text{ mol g}_{\text{Ru}}^{-1} \text{ s}^{-1}$  after 800 min on stream, equivalent to a total deactivation of  
43  
44 47%, which is of similar order of magnitude as in the absence of water (44%).

**Figure 12** Temporal evolution of the CO methanation rate ( $\blacklozenge$ ) and the corresponding deactivation ( $\blacklozenge$ ) in SR-ref 6000 gas mixture saturated with 15% water over the Ru/TiO<sub>2</sub>-2 catalyst (reaction temperature 190° C).

In previous studies on Ru/Al<sub>2</sub>O<sub>3</sub> and Ru/zeolite catalysts we had observed that the addition of up to 15% water vapor to the reaction gas mixture, using an identical feed gas, resulted in a slight decrease in the catalytic activity, both for the initial and final activity for CO methanation, while CO<sub>2</sub> methanation was fully suppressed<sup>13</sup>. Using a low-CO reformat (SR-ref 100), the selectivity was below 100%, except for very small Ru NPs. In those cases the selectivity was found to increase, reflecting a decreasing CO<sub>2</sub> methanation rate, upon addition of water to the gas mixture. This was explained by the simultaneous decrease of the mean Ru particle size determined by *operando* EXAFS measurements.<sup>10;12;13</sup> The selectivity remained at 100%, as expected for the higher CO concentration (see section 3.1).

Based on these observations and earlier findings we can largely exclude the possibility of deactivation due to the formation of water during the reaction.

#### 4 Summary and main conclusions

Aiming at a fundamental understanding of the physical origin of the observed activation and deactivation of Ru/TiO<sub>2</sub> catalysts during the selective methanation of CO, we have systemati-

1  
2  
3  
4 cally studied this reaction in different reformat gas mixtures by a combination of kinetic  
5  
6 measurements, time resolved *operando* XAS and *in situ* infrared spectroscopy measurements  
7  
8 as well as *ex situ* characterization by XPS, XRD and TEM. This led to the following main  
9  
10 results and conclusions:

- 11  
12  
13 i) Fully oxidized Ru/TiO<sub>2</sub> catalysts, obtained after pretreatment in an oxidative atmosphere,  
14  
15 show an initial activation phase, followed by a continuous deactivation. This goes along  
16  
17 with a rapid reduction of the Ru NPs, whose oxide content decreases by ~90% in the first  
18  
19 10 min and reaches a steady-state content of oxidized Ru species of < 5% at extended  
20  
21 reaction time ≥ 40 min. In addition to this reduction process, which dominates the  
22  
23 catalyst activation in the first 30 min, also the shape of the Ru NPs changes distinctly,  
24  
25 towards more hemispherical particles. Based on a combination of EXAFS and TEM  
26  
27 data this proceeds up to the observed activity maximum at about 120 min, indicating that  
28  
29 this also contribute to the activation, in particular in the second phase of the activation  
30  
31 phase, from 30 to 120 min. Neither changes in the oxidation state nor changes in particle  
32  
33 shape correlate with the catalyst deactivation, which occurs at later times and on a  
34  
35 different time scale.  
36  
37  
38  
39 ii) This activation period gets longer with increasing support surface area, while the rate of  
40  
41 the relative deactivation decreases with increasing surface area. The latter is attributed to  
42  
43 the slower growth of the Ru particles with increasing support surface area, as indicated  
44  
45 from the different increase in Ru particle size between 10 min and 1000 min on stream  
46  
47 (Ru/TiO<sub>2</sub>-2 (SA = 20 m<sup>2</sup>g<sup>-1</sup>) d<sub>Ru</sub>: 1.2 nm@10 min to 2.3 nm@1000 min compared to  
48  
49 Ru/TiO<sub>2</sub>-1 (SA = 121 m<sup>2</sup>g<sup>-1</sup>) d<sub>Ru</sub>: 1.1 nm@10 min to 1.6 nm@1000 min). The slower  
50  
51 increase in the size of Ru NPs on larger surface area was attributed previously <sup>11</sup> to a  
52  
53 significant increase in the MSI interaction with increasing surface area, which can  
54  
55 presumably be responsible for stabilizing the metal nanoparticles.  
56  
57  
58  
59  
60

- 1  
2  
3  
4 iii) The deactivation, starting after ~120 min in reformat gases with medium CO content  
5 (0.6% CO), is mainly attributed to a structural effect, to slow growth of the Ru NPs  
6 during time on stream.  
7  
8  
9  
10  
11 iv) During the deactivation phase the TOF based activity increases, while the Ru mass  
12 normalized activity decreases concurrently, which implies that the deactivation is  
13 attributed in part to the decrease of the overall number of active sites.  
14  
15  
16  
17 v) All catalysts were ~100% selective for CO methanation (0% CO<sub>2</sub> methanation) at the  
18 beginning of the reaction both in SR-ref 6000 and in SR-ref 100 gas mixtures,  
19 independent of their surface area. In agreement with previous findings for Ru/zeolite  
20 catalysts,<sup>6;9;10</sup> this is attributed to the high dispersion (small size) of the Ru NPs in the  
21 beginning of the reaction. Very small Ru NPs prevail at this stage (0.8 to 1.1 nm), which  
22 are stable for a certain period (roughly 100 min), and then grow with different rates  
23 during the reaction, depending on the surface area of the TiO<sub>2</sub> support (faster growth for  
24 lower specific surface areas). Since this particle size effect was reported on different  
25 catalyst supports,<sup>6;10;11;15;16</sup> the correlation between Ru particle size and selectivity for CO  
26 methanation is considered to be of general validity, independent of the support.  
27  
28  
29  
30  
31  
32  
33  
34  
35  
36  
37  
38  
39  
40 vi) The accumulation of surface formate / bicarbonate species, which form mainly from the  
41 interaction of CO<sub>2</sub> with the TiO<sub>2</sub> support, does not seem to contribute significantly to the  
42 long-term deactivation of the catalysts, since it saturates already after 280 min, while  
43 deactivation continues over the entire time on stream (1000 min). Furthermore, the build-  
44 up of formate / bicarbonate species in the absence of CO<sub>2</sub> was at least 20 times less than  
45 in the presence of CO<sub>2</sub>, although the catalyst showed similar deactivation in both cases.  
46  
47  
48  
49  
50  
51  
52  
53 vii) Similarly, deposition of surface carbon or adsorbed CH<sub>x</sub> species is found to be  
54 insignificant under present reaction conditions, and can at most be a minor contribution to  
55 the observed deactivation.  
56  
57  
58  
59  
60

viii) The addition of 5% water in the reaction gas during reaction did not result in any significant changes in the activation or deactivation process of the most strongly deactivating Ru/TiO<sub>2</sub>-2 catalyst, indicating that site blocking by adsorption of water or Ru particle restructuring by interaction with water, where the water may either be present in the feed gas or formed in the reaction, does not play a major role for the (de-)activation processes.

Based on these results the deactivation behavior observed during the selective methanation of CO at 190°C on Ru/TiO<sub>2</sub> catalysts, including losses in activity and inherent selectivity for CO methanation, is mainly caused by structural effects, by slow growth of the initially very small Ru NPs. The tendency for particle growth decreases with higher surface area of the TiO<sub>2</sub> support, which is ascribed to increasing metal support interactions. In contrast, activation of oxidatively pretreated catalysts is mainly related to reduction of the catalysts, together with changes in the particle shape, from higher fractions of flat particles in the initial phase to hemispherical particles in later stages of the activation phase. Poisoning of active sites by building of carbon containing species can be excluded as possible reason for the catalyst deactivation, and accumulation of these species occurs dominantly on the TiO<sub>2</sub> support.
