# Semi-homomorphic Encryption and Multiparty Computation 

Rikke Bendlin, Ivan Damgård, Claudio Orlandi, and Sarah Zakarias<br>Department of Computer Science, Aarhus University and CFEM ${ }^{\star}$

#### Abstract

An additively-homomorphic encryption scheme enables us to compute linear functions of an encrypted input by manipulating only the ciphertexts. We define the relaxed notion of a semi-homomorphic encryption scheme, where the plaintext can be recovered as long as the computed function does not increase the size of the input "too much". We show that a number of existing cryptosystems are captured by our relaxed notion. In particular, we give examples of semi-homomorphic encryption schemes based on lattices, subset sum and factoring. We then demonstrate how semi-homomorphic encryption schemes allow us to construct an efficient multiparty computation protocol for arithmetic circuits, UC-secure against a dishonest majority. The protocol consists of a preprocessing phase and an online phase. Neither the inputs nor the function to be computed have to be known during preprocessing. Moreover, the online phase is extremely efficient as it requires no cryptographic operations: the parties only need to exchange additive shares and verify information theoretic MACs. Our contribution is therefore twofold: from a theoretical point of view, we can base multiparty computation on a variety of different assumptions, while on the practical side we offer a protocol with better efficiency than any previous solution.

## 1 Introduction

The fascinating idea of computing on encrypted data can be traced back at least to a seminal paper by Rivest, Adleman and Dertouzos RAD78 under the name of privacy homomorphism. A privacy homomorphism, or homomorphic encryption scheme in more modern terminology, is a public-key encryption scheme ( $\mathrm{G}, \mathrm{E}, \mathrm{D}$ ) for which it holds that $\mathrm{D}(\mathrm{E}(a) \otimes \mathrm{E}(b))=a \oplus b$, where $(\otimes, \oplus)$ are some group operation in the ciphertext and plaintext space respectively. For instance, if $\oplus$ represents modular addition in some ring, we call such a scheme additively-homomorphic. Intuitively a homomorphic encryption scheme enables two parties, say Alice and Bob, to perform secure computation: as an example, Alice could encrypt her input $a$ under her public key, send the ciphertext $\mathrm{E}(a)$ to Bob; now by the homomorphic property, Bob can compute a ciphertext containing, e.g., $\mathrm{E}(a \cdot b+c)$ and send it back to Alice, who can decrypt and learn the

[^0]result. Thus, Bob has computed a non trivial function of the input $a$. However, Bob only sees an encryption of $a$ which leaks no information on $a$ itself, assuming that the encryption scheme is secure. Informally we will say that a set of parties $P_{1}, \ldots, P_{n}$ holding private inputs $x_{1}, \ldots, x_{n}$ securely compute a function of their inputs $y=f\left(x_{1}, \ldots, x_{n}\right)$ if, by running some cryptographic protocol, the honest parties learn the correct output of the function $y$. In addition, even if (up to) $n-1$ parties are corrupt and cooperate, they are not able to learn any information about the honest parties' inputs, no matter how they deviate from the specifications of the protocol.

Building secure multiparty computation (MPC) protocols for this case of dishonest majority is essential for several reasons: First, it is notoriously hard to handle dishonest majority efficiently and it is well known that unconditionally secure solutions do not exist. Therefore, we cannot avoid using some form of public-key technology which is typically much more expensive than the standard primitives used for honest majority (such as secret sharing). Secondly, security against dishonest majority is often the most natural to shoot for in applications, and is of course the only meaningful goal in the significant 2-party case. Thus, finding practical solutions for dishonest majority under reasonable assumptions is arguably the most important research goal with respect to applications of multiparty computation.

While fully-homomorphic encryption Gen09 allows for significant improvement in communication complexity, it would incur a huge computational overhead with current state of the art. In this paper we take a different road: in a nutshell, we relax the requirements of homomorphic encryption so that we can implement it under a variety of assumptions, and we show how this weaker primitive is sufficient for efficient MPC. Our main contributions are:

A framework for semi-homomorphic encryption: we define the notion of a semihomomorphic encryption modulo $p$, for a modulus $p$ that is input to the key generation. Abstracting from the details, the encryption function is additively homomorphic and will accept any integer $x$ as input plaintext. However, in contrast to what we usually require from a homomorphic cryptosystem, decryption returns the correct result modulo $p$ only if $x$ is numerically small enough. We demonstrate the generality of the framework by giving several examples of known cryptosystems that are semi-homomorphic or can be modified to be so by trivial adjustments. These include: the Okamoto-Uchiyama cryptosystem OU98; Paillier cryptosystem [Pai99] and its generalization by Damgård and Jurik [DJ01]; Regev's LWE based cryptosystem Reg05; the scheme of Damgård, Geisler and Krøigaard [DGK09] based on a subgroup-decision problem; the subset-sum based scheme by Lyubashevsky, Palacio and Segev LPS10; Gentry, Halevi and Vaikuntanathan's scheme GHV10 based on LWE, and van Dijk, Gentry, Halevi and Vaikuntanathan's scheme DGHV10 based on the approximate gcd problem. We also show a zero-knowledge protocol for any semi-homomorphic cryptosystem, where a prover, given ciphertext $C$ and public key $p k$, demonstrates that he knows plaintext $x$ and randomness $r$ such that $C=\mathrm{E}_{p k}(x, r)$, and that $x$ furthermore is numerically less than a given bound. We show that using a twist
of the amortization technique of Cramer and Damgård CD09, one can give $u$ such proofs in parallel where the soundness error is $2^{-u}$ and the cost per instance proved is essentially 2 encryption operations for both parties. The application of the technique from CD09] to prove that a plaintext is bounded in size is new and of independent interest.

Information-theoretic "online" MPC: we propose a UC secure Can01 protocol for arithmetic multiparty computation that, in the presence of a trusted dealer who does not know the inputs, offers information-theoretic security against an adaptive, malicious adversary that corrupts any dishonest majority of the parties. The main idea of the protocol is that the parties will be given additive sharing of multiplicative triples Bea91, together with information theoretic MACs of their shares - forcing the parties to use the correct shares during the protocol. This online phase is essentially optimal, as no symmetric or public-key cryptography is used, matching the efficiency of passive protocols for honest majority like BOGW88, CCD88. Concretely, each party performs $O\left(n^{2}\right)$ multiplications modulo $p$ to evaluate a secure multiplication. This improves on the previous protocol of Damgård and Orlandi (DO) DO10 where a Pedersen commitment was published for every shared value. Getting rid of the commitments we improve on efficiency (a factor of $\Omega(\kappa)$, where $\kappa$ is the security parameter) and security (information theoretic against computational). Implementation results for the two-party case indicate about 6 msec per multiplication (see the full version [BDOZ10]), at least an order of magnitude faster than that of DO on the same platform. Moreover, in DO the modulus $p$ of the computation had to match the prime order of the group where the commitments live. Here, we can, however, choose $p$ freely to match the application which typically allows much smaller values of $p$.

An efficient implementation of the offline phase: we show how to replace the share dealer for the online phase by a protocol based solely on semi-homomorphic encryption. Our offline phase is UC-secure against any dishonest majority, and it matches the lower bound for secure computation with dishonest majority of $O\left(n^{2}\right)$ public-key operations per multiplication gate HIK07. In the most efficient instantiation, the offline phase of DO requires security of Paillier encryption and hardness of discrete logarithms. Our offline phase only has to assume security of Paillier cryptosystem and achieves similar efficiency: A count of operations suggests that our offline phase is as efficient as DO up to a small constant factor (about 2-3). Preliminary implementation results indicate about $2-3 \mathrm{sec}$ to prepare a multiplication. Since we generalize to any semi-homomorphic scheme including Regev's scheme, we get the first potentially practical solution for dishonest majority that is believed to withstand a quantum attack. It is not possible to achieve UC security for dishonest majority without set-up assumptions, and our protocol works in the registered public-key model of [BCNP04] where we

[^1]assume that public keys for all parties are known, and corrupted parties know their own secret keys.

Related Work: It was shown by Canetti, Lindell, Ostrovsky and Sahai CLOS02 that secure computation is possible under general assumptions even when considering any corrupted number of parties in a concurrent setting (the UC framework). Their solution is, however, very far from being practical. For computation over Boolean circuits efficient solutions can be constructed from Yao's garbled circuit technique, see e.g. Pinkas, Schneider, Smart and Williams PSSW09. However, our main interest here is arithmetic computation over larger fields or rings, which is a much more efficient approach for applications such as benchmarking or some auction variants. A more efficient solution for the arithmetic case was shown by Cramer, Damgård and Nielsen CDN01, based on threshold homomorphic encryption. However, it requires distributed key generation and uses heavy public-key machinery throughout the protocol. More recently, Ishai, Prabhakaran and Sahai IPS09 and the aforementioned DO protocol show more efficient solutions. Although the techniques used are completely different, the asymptotic complexities are similar, but the constants are significantly smaller in the DO solution, which was the most practical protocol proposed so far.

Notation: We let $U_{S}$ denote the uniform distribution over the set $S$. We use $x \leftarrow X$ to denote the process of sampling $x$ from the distribution $X$ or, if $X$ is a set, a uniform choice from it.

We say that a function $f: \mathbb{N} \rightarrow \mathbb{R}$ is negligible if $\forall c, \exists n_{c}$ s.t. if $n>n_{c}$ then $f(n)<n^{-c}$. We will use $\varepsilon(\cdot)$ to denote an unspecified negligible function.

For $p \in \mathbb{N}$, we represent $\mathbb{Z}_{p}$ by the numbers $\{-\lfloor(p-1) / 2\rfloor, \ldots,\lceil(p-1) / 2\rceil\}$. If $\mathbf{x}$ is an $m$-dimensional vector, $\|\mathbf{x}\|_{\infty}:=\max \left(\left|x_{1}\right|, \ldots,\left|x_{m}\right|\right)$. Unless differently specified, all the logarithms are in base 2.

As a general convention: lowercase letters $a, b, c, \ldots$ represent integers and capital letters $A, B, C, \ldots$ ciphertexts. Bold lowercase letters $\mathbf{r}, \mathbf{s}, \ldots$ are vectors and bold capitals $\mathbf{M}, \mathbf{A}, \ldots$ are matrices. We call $\kappa$ the computational security parameter and $u$ the statistical security parameter. In practice $u$ can be set to be much smaller than $\kappa$, as it does not depend on the computing power of the adversary.

## 2 The Framework for Semi-homomorphic Encryption

In this section we introduce a framework for public-key cryptosystems, that satisfy a relaxed version of the additive homomorphic property. Let $\mathrm{PKE}=(\mathrm{G}, \mathrm{E}, \mathrm{D})$ be a tuple of algorithms where:
$\mathrm{G}\left(1^{\kappa}, p\right)$ is a randomized algorithm that takes as input a security parameter $\kappa$ and a modulus $\eta^{2}$; It outputs a public/secret key pair $(p k, s k)$ and a set of parameters $\mathbb{P}=\left(p, M, R, \mathcal{D}_{\sigma}^{d}, \mathbb{G}\right)$. Here, $M, R$ are integers, $\mathcal{D}_{\sigma}^{d}$ is the description

[^2]of a randomized algorithm producing as output $d$-vectors with integer entries (to be used as randomness for encryption). We require that except with negligible probability, $\mathcal{D}_{\sigma}^{d}$ will always output $\mathbf{r}$ with $\|\mathbf{r}\|_{\infty} \leq \sigma$, for some $\sigma<R$ that may depend on $\kappa$. Finally, $\mathbb{G}$ is the abelian group where the ciphertexts belong (written in additive notation). For practical purposes one can think of $M$ and $R$ to be of size super-polynomial in $\kappa$, and $p$ and $\sigma$ as being much smaller than $M$ and $R$ respectively. We will assume that every other algorithm takes as input the parameters $\mathbb{P}$, without specifying this explicitly.
$\mathrm{E}_{p k}(x, \mathbf{r})$ is a deterministic algorithm that takes as input an integer $x \in \mathbb{Z}$ and a vector $\mathbf{r} \in \mathbb{Z}^{d}$ and outputs a ciphertext $C \in \mathbb{G}$. We sometimes write $\mathrm{E}_{p k}(x)$ when it is not important to specify the randomness explicitly. Given $C_{1}=\mathrm{E}_{p k}\left(x_{1}, \mathbf{r}_{1}\right), C_{2}=\mathrm{E}_{p k}\left(x_{2}, \mathbf{r}_{2}\right)$ in $\mathbb{G}$, we have $C_{1}+C_{2}=\mathrm{E}_{p k}\left(x_{1}+x_{2}, \mathbf{r}_{1}+\mathbf{r}_{2}\right)$. In other words, $\mathrm{E}_{p k}(\cdot, \cdot)$ is a homomorphism from $\left(\mathbb{Z}^{d+1},+\right)$ to $\left.(\mathbb{G},+)\right)$. Given some $\tau$ and $\rho$ we call $C$ a $(\tau, \rho)$-ciphertext if there exists $x, \mathbf{r}$ with $|x| \leq \tau$ and $\|\mathbf{r}\|_{\infty} \leq \rho$ such that $C=\mathrm{E}_{p k}(x, \mathbf{r})$. Note that given a ciphertext $\tau$ and $\rho$ are not unique. When we refer to a $(\tau, \rho)$-ciphertext, $\tau$ and $\rho$ should be interpreted as an upper limit to the size of the message and randomness contained in the ciphertext.
$\mathrm{D}_{s k}(C)$ is a deterministic algorithm that takes as input a ciphertext $C \in \mathbb{G}$ and outputs $x^{\prime} \in \mathbb{Z}_{p} \cup\{\perp\}$.

We say that a semi-homomorphic encryption scheme PKE is correct if, $\forall p$ :

$$
\begin{aligned}
\operatorname{Pr}\left[(p k, s k, \mathbb{P}) \leftarrow \mathrm{G}\left(1^{\kappa}, p\right), x \in \mathbb{Z},|x| \leq M ; \mathbf{r} \in \mathbb{Z}^{d},\|\mathbf{r}\|_{\infty} \leq R:\right. & \\
\left.\mathrm{D}_{s k}\left(\mathrm{E}_{p k}(x, \mathbf{r})\right) \neq x \bmod p\right] & <\varepsilon(\kappa)
\end{aligned}
$$

where the probabilities are taken over the random coins of $G$ and $E$.
We now define the IND-CPA security game for a semi-homomorphic cryptosystem. Let $\mathcal{A}=\left(\mathcal{A}_{1}, \mathcal{A}_{2}\right)$ be a PPT TM, then we run the following experiment:

$$
\begin{aligned}
(p k, s k, \mathbb{P}) & \leftarrow \mathrm{G}\left(1^{\kappa}, p\right) \\
\left(m_{0}, m_{1}, \text { state }\right) & \leftarrow \mathcal{A}_{1}\left(1^{\kappa}, p k\right) \text { with } m_{0}, m_{1} \in \mathbb{Z}_{p} \\
b \leftarrow\{0,1\}, C & \leftarrow \mathrm{E}_{p k}\left(m_{b}\right), b^{\prime} \leftarrow \mathcal{A}_{2}\left(1^{\kappa}, \text { state }, C\right)
\end{aligned}
$$

We define the advantage of $\mathcal{A}$ as $\operatorname{Adv}{ }^{\text {cPA }}(\mathcal{A}, \kappa)=\left|\operatorname{Pr}\left[b=b^{\prime}\right]-1 / 2\right|$, where the probabilities are taken over the random choices of $\mathrm{G}, \mathrm{E}, \mathcal{A}$ in the above experiment. We say that PKE is IND-CPA secure if $\forall \operatorname{PPT} \mathcal{A}, \operatorname{Adv}^{\mathrm{CPA}}(\mathcal{A}, \kappa)<\varepsilon(\kappa)$.

Next, we discuss the motivation for the way this framework is put together: when in the following, honest players encrypt data, plaintext $x$ will be chosen in $\mathbb{Z}_{p}$ and the randomness $\mathbf{r}$ according to $\mathcal{D}_{\sigma}^{d}$. This ensures IND-CPA security and also that such data can be decrypted correctly, since by assumption on $\mathcal{D}_{\sigma}^{d}$, $\|\mathbf{r}\|_{\infty} \leq \sigma \leq R$. However, we also want that a (possibly dishonest) player $P_{i}$ is committed to $x$ by publishing $C=\mathrm{E}_{p k}(x, \mathbf{r})$. We are not able to force a player to choose $x$ in $\mathbb{Z}_{p}$, nor that $\mathbf{r}$ is sampled with the correct distribution. But our zero-knowledge protocols can ensure that $C$ is a $(\tau, \rho)$-ciphertext, for concrete values of $\tau, \rho$. If $\tau<M, \rho<R$, then correctness implies that $C$ commits $P_{i}$ to $x \bmod p$, even if $x, \mathbf{r}$ may not be uniquely determined from $C$.

### 2.1 Examples of Semi-homomorphic Encryption

Regev's cryptosystem Reg05 is parametrized by $p, q, m$ and $\alpha$, and is given by (G, E, D). A variant of the system was also given in BD10, where parameters are chosen slightly differently than in the original. In both Reg05] and BD10 only a single bit was encrypted, it is quite easy, though, to extend it to elements of a bigger ring. It is this generalized version of the variant in BD10 that we describe here. All calculations are done in $\mathbb{Z}_{q}$. Key generation $G\left(1^{\kappa}\right)$ is done by sampling $\mathbf{s} \in \mathbb{Z}_{q}^{n}$ and $\mathbf{A} \in \mathbb{Z}_{q}^{m \times n}$ uniformly at random and $\mathbf{x} \in \mathbb{Z}_{q}^{m}$ from a discrete Gaussian distribution with mean 0 and standard deviation $\frac{q \alpha}{\sqrt{2 \pi}}$. We then have the key pair $(p k, s k)=((\mathbf{A}, \mathbf{A s}+\mathbf{x}), \mathbf{s})$. Encryption of a message $\gamma \in \mathbb{Z}_{p}$ is done by sampling a uniformly random vector $\mathbf{r} \in\{-1,0,1\}^{m}$. A ciphertext $C$ is then given by $C=\mathbf{E}_{p k}(\gamma, \mathbf{r})=(\mathbf{a}, b)=\left(\mathbf{A}^{T} \mathbf{r},(\mathbf{A} \mathbf{s}+\mathbf{x})^{T} \mathbf{r}+\gamma\lfloor q / p\rceil\right)$. Decryption is given by $\mathrm{D}_{s k}(C)=\left\lfloor\left(b-\mathbf{s}^{T} \mathbf{a}\right) \cdot p / q\right\rceil$. Regev's cryptosystem works with a decryption error, which can, however, be made negligibly small when choosing the parameters.

Fitting the cryptosystem to the framework is quite straight forward. The group $\mathbb{G}=\mathbb{Z}_{q}^{n} \times \mathbb{Z}_{q}$ and $p$ is just the same. The distribution $\mathcal{D}_{\sigma}^{d}$ from which the randomness $\mathbf{r}$ is taken is the uniform distribution over $\{-1,0,1\}^{m}$, that is $d=m$ and $\sigma=1$. Given two ciphertexts ( $\mathbf{a}, b$ ) and ( $\left.\mathbf{a}^{\prime}, b^{\prime}\right)$ we define addition to be $\left(\mathbf{a}+\mathbf{a}^{\prime}, b+b^{\prime}\right)$. With this definition it follows quite easily that the homomorphic property holds. Due to the choices of message space and randomness distribution in Regev's cryptosystem, we will always have that the relation $M=R p / 2$ should hold. How $M$ can be chosen, and thereby also $R$, depends on all the original parameters of the cryptosystem. First assume that $q \cdot \alpha=\sqrt[d]{q}$ with $d>1$. Furthermore we will need that $p \leq q /(4 \sqrt[c]{q})$ for some constant $c<d$. Then to bound $M$ we should have first that $M<q /(4 p)$ and secondly that $M<$ $p \sqrt[s]{q} /(2 m)$ for some $s>c d /(d-c)$. Obtaining these bounds requires some tedious computation which we leave out here.

In Paillier's cryptosystem [Pai99] the secret key is two large primes $p_{1}, p_{2}$, the public key is $N=p_{1} p_{2}$, and the encryption function is $\mathrm{E}_{p k}(x, r)=(N+$ 1) ${ }^{x} r^{N} \bmod N^{2}$ where $x \in Z_{N}$ and $r$ is random in $\mathbb{Z}_{N^{2}}^{*}$. The decryption function $\mathrm{D}_{s k}^{\prime}$ reconstructs correctly any plaintext in $\mathbb{Z}_{N}$, and to get a semi-homomorphic scheme modulo $p$, we simply redefine the decryption as $\mathrm{D}(c)=\mathrm{D}^{\prime}(c) \bmod p$. It is not hard to see that we get a semi-homomorphic scheme with $M=(N-$ 1) $/ 2, R=\infty, d=1, \mathcal{D}_{\sigma}^{d}=U_{\mathbb{Z}_{N^{2}}}, \sigma=\infty$ and $\mathbb{G}=\mathbb{Z}_{N^{2}}^{*}$. In particular, note that we do not need to bound the size of the randomness, hence we set $\sigma=R=\infty$.

The cryptosystem looks syntactically a bit different from our definition which writes $\mathbb{G}$ additively, while $Z_{N^{2}}^{*}$ is usually written with multiplicative notation; also for Paillier we have $\mathrm{E}_{p k}(x, r)+\mathrm{E}_{p k}\left(x^{\prime}, r\right)=\mathrm{E}_{p k}\left(x+x^{\prime}, r \cdot r^{\prime}\right)$ and not $\mathrm{E}_{p k}(x+$ $\left.x^{\prime}, r+r^{\prime}\right)$. However, this makes no difference in the following, except that it actually makes some of the zero-knowledge protocols simpler (more details in Section (2.2). It is easy to see that the generalization of Paillier in DJ01 can be modified in a similar way to be semi-homomorphic.

In the full paper BDOZ10 we show how several other cryptosystems are semi-homomorphic.

### 2.2 Zero-Knowledge Proofs

We present two zero-knowledge protocols, $\Pi_{\mathrm{PoPK}}, \Pi_{\mathrm{PoCM}}$ where a prover $P$ proves to a verifier $V$ that some ciphertexts are correctly computed and that some ciphertexts satisfy a multiplicative relation respectively. $\Pi_{\text {PoPK }}$ has (amortized) complexity $O(\kappa+u)$ bits per instance proved, where the soundness error is $2^{-u}$. $\Pi_{\mathrm{PoCM}}$ has complexity $O(\kappa u)$. We also show a more efficient version of $\Pi_{\mathrm{PoCM}}$ that works only for Paillier encryption, with complexity $O(\kappa+u)$. Finally, in the full paper BDOZ10, we define the multiplication security property that we conjecture is satisfied for all our example cryptosystems after applying a simple modification. We show that assuming this property, $\Pi_{\text {PoCM }}$ can be replaced by a different check that has complexity $O(\kappa+u)$.
$\Pi_{\text {PoPK }}$ and $\Pi_{\text {PoCM }}$ will both be of the standard 3-move form with a random $u$-bit challenge, and so they are honest verifier zero-knowledge. To achieve zero-knowledge against an arbitrary verifier standard techniques can be used. In particular, in our MPC protocol we will assume - only for the sake of simplicity - a functionality $\mathcal{F}_{\text {Rand }}$ that generates random challenges on demand. The $\mathcal{F}_{\text {Rand }}$ functionality is specified in detail in the full paper BDOZ10 and can be implemented in our key registration model using only semi-homomorphic encryption. In the protocols both prover and verifier will have public keys $p k_{P}$ and $p k_{V}$. By $\mathrm{E}_{P}(a, \mathbf{r})$ we denote an encryption under $p k_{P}$, similarly for $\mathrm{E}_{V}(a, \mathbf{r})$.

We emphasize that the zero-knowledge property of our protocols does not depend on IND-CPA security of the cryptosystem, instead it follows from the homomorphic property and the fact that the honest prover creates, for the purpose of the protocol, some auxiliary ciphertexts containing enough randomness to hide the prover's secrets.

Proof of Plaintext Knowledge. $\Pi_{\text {PoPK }}$ takes as common input $u$ ciphertexts $C_{k}, k=1, \ldots, u$. If these are ( $\tau, \rho$ )-ciphertexts, the protocol is complete and statistical zero-knowledge. The protocol is sound in the following sense: assuming that $p k_{P}$ is well-formed, if $P$ is corrupt and can make $V$ accept with probability larger than $2^{-u}$, then all the $C_{k}$ are $\left(2^{2 u+\log u} \tau, 2^{2 u+\log u} \rho\right)$-ciphertexts. The protocol is also a proof of knowledge with knowledge error $2^{-u}$ that $P$ knows correctly formed plaintexts and randomness for all the $C_{k}$ 's.

In other words, $\Pi_{\text {PoPk }}$ is a ZKPoK for the following relation, except that zeroknowledge and completeness only hold if the $C_{k}$ 's satisfy the stronger condition of being $(\tau, \rho)$-ciphertexts. However, this is no problem in the following: the prover will always create the $C_{k}$ 's himself and can therefore ensure that they are correctly formed if he is honest.

$$
\begin{array}{ll}
R_{\mathrm{PoPK}}^{(u, \tau, \rho)}=\{(x, w) \mid \quad & x=\left(p k_{P}, C_{1}, \ldots, C_{u}\right) ; \\
w & =\left(\left(x_{1}, \mathbf{r}_{1}\right), \ldots,\left(x_{u}, \mathbf{r}_{u}\right)\right): C_{k}=\mathrm{E}_{P}\left(x_{k}, \mathbf{r}_{k}\right), \\
& \left.\left|x_{k}\right| \leq 2^{2 u+\log u} \tau,\left\|\mathbf{r}_{k}\right\|_{\infty} \leq 2^{2 u+\log u} \rho\right\}
\end{array}
$$

We use the approach of [CD09] to get small amortized complexity of the zeroknowledge proofs, and thereby gaining efficiency by performing the proofs on $u$
simultaneous instances. In the following we define $m=2 u-1$, furthermore $\mathbf{M}_{\mathbf{e}}$ is an $m \times u$ matrix constructed given a uniformly random vector $\mathbf{e}=\left(e_{1}, \ldots, e_{u}\right) \in$ $\{0,1\}^{u}$. Specifically the $(i, k)$-th entry $\mathbf{M}_{\mathbf{e}, i, k}$ is given by $\mathbf{M}_{\mathbf{e}, i, k}=\mathbf{e}_{i-k+1}$ for $1 \leq i-k+1 \leq u$ and 0 otherwise. By $\mathbf{M}_{\mathbf{e}, i}$ we denote the $i$-th row of $\mathbf{M}_{\mathbf{e}}$. The protocol can be seen in Figure 1 Completeness and zero-knowledge follow by standard arguments that can be found in the full paper BDOZ10]. Here we argue soundness which is the more interesting case: Assume we are given any prover $P^{*}$, and consider the case where $P^{*}$ can make V accept for both $\mathbf{e}$ and $\mathbf{e}^{\prime}, \mathbf{e} \neq \mathbf{e}^{\prime}$, by sending $\mathbf{z}, \mathbf{z}^{\prime}, \mathbf{T}$ and $\mathbf{T}^{\prime}$ respectively. We now have the following equation:

$$
\begin{equation*}
\left(\mathbf{M}_{\mathbf{e}}-\mathbf{M}_{\mathbf{e}^{\prime}}\right) \mathbf{c}=\left(\mathbf{d}-\mathbf{d}^{\prime}\right) \tag{1}
\end{equation*}
$$

What we would like is to find $\mathbf{x}=\left(x_{1}, \ldots, x_{u}\right)$ and $\mathbf{R}=\left(\mathbf{r}_{1}, \ldots, \mathbf{r}_{u}\right)$ such that $C_{k}=\mathrm{E}_{P}\left(x_{k}, \mathbf{r}_{k}\right)$. We can do this by viewing (1) as a system of linear equations. First let $j$ be the biggest index such that $\mathbf{e}_{j} \neq \mathbf{e}_{j}^{\prime}$. Now look at the $u \times u$ submatrix of $\mathbf{M}_{\mathbf{e}}-\mathbf{M}_{\mathbf{e}}$, given by the rows $j$ through $j+u$ both included. This is an upper triangular matrix with entries in $\{-1,0,1\}$ and $\mathbf{e}_{j}-\mathbf{e}_{j}^{\prime} \neq 0$ on a diagonal. Now remember the form of the entries in the vectors $\mathbf{c}, \mathbf{d}$ and $\mathbf{d}^{\prime}$, we have $C_{k}=\mathrm{E}_{P}\left(x_{k}, \mathbf{r}_{k}\right), D_{k}=\mathrm{E}_{P}\left(z_{k}, \mathbf{t}_{k}\right), D_{k}^{\prime}=\mathrm{E}_{P}\left(z_{k}^{\prime}, \mathbf{t}_{k}^{\prime}\right)$. We can now directly solve the equations for the $x_{k}$ 's and the $\mathbf{r}_{k}$ 's by starting with $C_{u}$ and going up. We give examples of the first few equations (remember we are going bottom up). For simplicity we will assume that all entries in $\mathbf{M}_{\mathbf{e}}-\mathbf{M}_{\mathbf{e}^{\prime}}$ will be 1 .

$$
\begin{aligned}
\mathrm{E}_{P}\left(x_{u}, \mathbf{r}_{u}\right) & =\mathrm{E}_{P}\left(z_{u+j}-z_{u+j}^{\prime}, \mathbf{t}_{u+j}-\mathbf{t}_{u+j}^{\prime}\right) \\
\mathrm{E}_{P}\left(x_{u-1}, \mathbf{r}_{u-1}\right)+\mathrm{E}_{P}\left(x_{u}, \mathbf{r}_{u}\right) & =\mathrm{E}_{P}\left(z_{u+j-1}-z_{u+j-1}^{\prime}, \mathbf{t}_{u+j-1}-\mathbf{t}_{u+j-1}^{\prime}\right)
\end{aligned}
$$

Since we know all values used on the right hand sides and since the cryptosystem used is additively homomorphic, it should now be clear that we can find $x_{k}$ and $\mathbf{r}_{k}$ such that $C_{k}=\mathrm{E}_{P}\left(x_{k}, \mathbf{r}_{k}\right)$. A final note should be said about what we can guarantee about the sizes of $x_{k}$ and $\mathbf{r}_{k}$. Knowing that $\left|z_{i}\right| \leq 2^{u-1+\log u} \tau$, $\left|z_{i}^{\prime}\right| \leq 2^{u-1+\log u} \tau,\left\|\mathbf{t}_{i}\right\|_{\infty} \leq 2^{u-1+\log u} \rho$ and $\left\|\mathbf{t}_{i}^{\prime}\right\|_{\infty} \leq 2^{u-1+\log u} \rho$ we could potentially have that $C_{1}$ would become a $\left(2^{2 u+\log u} \tau, 2^{2 u+\log u} \rho\right)$ ciphertext. Thus this is what we can guarantee.

Proof of Correct Multiplication. $\Pi_{\mathrm{PoCM}}(u, \tau, \rho)$ takes as common input $u$ triples of ciphertexts $\left(A_{k}, B_{k}, C_{k}\right)$ for $k=1, \ldots, u$, where $A_{k}$ is under $p k_{P}$ and $B_{k}$ and $C_{k}$ are under $p k_{V}$ (and so are in the group $\mathbb{G}_{V}$ ). If $P$ is honest, he will know $a_{k}$ and $a_{k} \leq \tau$. Furthermore $P$ has created $C_{k}$ as $C_{k}=a_{k} B_{k}+\mathrm{E}_{V}\left(r_{k}, \mathbf{t}_{k}\right)$, where $\mathrm{E}_{V}\left(r_{k}, \mathbf{t}_{k}\right)$ is a random $\left(2^{3 u+\log u} \tau^{2}, 2^{3 u+\log u} \tau \rho\right)$-ciphertext. Under these assumptions the protocol is zero-knowledge.

Jumping ahead, we note that in the context where the protocol will be used, it will always be known that $B_{k}$ in every triple is a $\left(2^{2 u+\log u} \tau, 2^{2 u+\log u} \rho\right)$ ciphertext, as a result of executing $\Pi_{\mathrm{PoPK}}$. The choice of sizes for $\mathrm{E}_{V}\left(r_{k}, \mathbf{t}_{k}\right)$ then ensures that $C_{k}$ is statistically close to a random $\left(2^{3 u+\log u} \tau^{2}, 2^{3 u+\log u} \tau \rho\right)$ ciphertext, and so reveals no information on $a_{k}$ to $V$.

## Subprotocol $\Pi_{\text {РоРк }}$ : Proof of Plaintext Knowledge

$\operatorname{PoPK}(u, \tau, \rho)$ :

1. The input is $u$ ciphertexts $\left\{C_{k}=\mathrm{E}_{P}\left(x_{k}, \mathbf{r}_{k}\right)\right\}_{k=1}^{u}$. We define the vectors $\mathbf{c}=\left(C_{1}, \ldots, C_{u}\right)$ and $\mathbf{x}=\left(x_{1}, \ldots, x_{u}\right)$ and the matrix $\mathbf{R}=\left(\mathbf{r}_{1}, \ldots, \mathbf{r}_{u}\right)$, where the $\mathbf{r}_{k}$ 's are rows.
2. $P$ constructs $m\left(2^{u-1+\log u} \tau, 2^{u-1+\log u} \rho\right)$-ciphertexts $\left\{A_{i}=\mathrm{E}_{P}\left(y_{i}, \mathbf{s}_{i}\right)\right\}_{i=1}^{m}$, and sends them to $V$. We define vectors a and $\mathbf{y}$ and matrix $\mathbf{S}$ as above.
3. $V$ chooses a uniformly random vector $\mathbf{e}=\left(e_{1}, \ldots, e_{u}\right) \in\{0,1\}^{u}$, and sends it to $P$.
4. Finally $P$ computes and sends $\mathbf{z}=\mathbf{y}+\mathbf{M}_{\mathbf{e}} \cdot \mathbf{x}$ and $\mathbf{T}=\mathbf{S}+\mathbf{M}_{\mathbf{e}} \cdot \mathbf{R}$ to $V$.
5. $V$ checks that $\mathbf{d}=\mathbf{a}+\mathbf{M}_{\mathbf{e}} \cdot \mathbf{c}$ where $\mathbf{d}=\left(\mathrm{E}_{P}\left(z_{1}, \mathbf{t}_{1}\right), \ldots, \mathrm{E}_{P}\left(z_{m}, \mathbf{t}_{m}\right)\right)$. Furthermore, $V$ checks that $\left|z_{i}\right| \leq 2^{u-1+\log u} \tau$ and $\left\|\mathbf{t}_{i}\right\|_{\infty} \leq 2^{u-1+\log u} \rho$.

Fig. 1. Proof of Plaintext Knowledge

## Subprotocol $\Pi_{\text {PoCM }}$ : Proof of Correct Multiplication

$\operatorname{PoCM}(u, \tau, \rho)$ :

1. The input is $u$ triples of ciphertexts $\left\{\left(A_{k}, B_{k}, C_{k}\right)\right\}_{k=1}^{u}$, where $A_{k}=$ $\mathrm{E}_{P}\left(a_{k}, \mathbf{h}_{k}\right)$ and $C_{k}=a_{k} B_{k}+\mathrm{E}_{V}\left(r_{k}, \mathbf{t}_{k}\right)$.
2. $P$ constructs $u$ uniformly random $\left(2^{3 u-1+\log u} \tau, 2^{3 u-1+\log u} \rho\right)$-ciphertexts $D_{k}=\mathrm{E}_{P}\left(d_{k}, \mathbf{s}_{k}\right)$ and $u$ ciphertexts $F_{k}=d_{k} B_{k}+\mathrm{E}_{V}\left(f_{k}, \mathbf{y}_{k}\right)$, where $\mathrm{E}_{V}\left(f_{k}, \mathbf{y}_{k}\right)$ are uniformly random $\left(2^{4 u-1+\log u} \tau^{2}, 2^{4 u-1+\log u} \tau \rho\right)$ ciphertexts.
3. $V$ chooses $u$ uniformly random bits $e_{k}$ and sends them to $P$.
4. $P$ returns $\left\{\left(z_{k}, \mathbf{v}_{k}\right)\right\}_{k=1}^{u}$ and $\left\{\left(x_{k}, \mathbf{w}_{k}\right)\right\}_{k=1}^{u}$ to $V$. Here $z_{k}=d_{k}+e_{k} a_{k}$, $\mathbf{v}_{k}=\mathbf{s}_{k}+e_{k} \mathbf{h}_{k}, x_{k}=f_{k}+e_{k} r_{k}$ and $\mathbf{w}_{k}=\mathbf{y}_{k}+e_{k} \mathbf{t}_{k}$.
5. $V$ checks that $D_{k}+e_{k} A_{k}=\mathrm{E}_{P}\left(z_{k}, \mathbf{v}_{k}\right)$ and that $F_{k}+e_{k} C_{k}=z_{k} B_{k}+$ $\mathrm{E}_{V}\left(x_{k}, \mathbf{w}_{k}\right)$. Furthermore, he checks that $\left|z_{k}\right| \leq 2^{3 u-1+\log u} \tau,\left\|\mathbf{v}_{k}\right\|_{\infty} \leq$ $2^{3 u-1+\log u} \rho,\left|x_{k}\right| \leq 2^{4 u-1+\log u} \tau^{2}$ and $\left\|\mathbf{w}_{k}\right\|_{\infty} \leq 2^{4 u-1+\log u} \tau \rho$.
6. Step 2-5 is repeated in parallel $u$ times.

Fig. 2. Proof of Correct Multiplication

Summarizing, $\Pi_{\mathrm{PoCM}}$ is a ZKPoK for the relation (under the assumption that $p k_{P}, p k_{V}$ are well-formed):

$$
\begin{aligned}
R_{\mathrm{PoCM}}^{(u, \tau, \rho)}=\{(x, w) \mid \quad & x=\left(p k_{P}, p k_{V},\left(A_{1}, B_{1}, C_{1}\right), \ldots,\left(A_{u}, B_{u}, C_{u}\right)\right) ; \\
& w=\left(\left(a_{1}, \mathbf{h}_{1}, r_{1}, \mathbf{t}_{1}\right), \ldots,\left(a_{u}, \mathbf{h}_{u}, r_{u}, \mathbf{t}_{u}\right)\right): \\
& A_{k}=\mathrm{E}_{P}\left(a_{k}, \mathbf{h}_{k}\right), B_{k} \in \mathbb{G}_{V}, C_{k}=a_{k} B_{k}+\mathrm{E}_{V}\left(r_{k}, \mathbf{t}_{k}\right), \\
& \left|a_{k}\right| \leq 2^{3 u+\log u} \tau,\left\|\mathbf{h}_{k}\right\|_{\infty} \leq 2^{3 u+\log u} \rho, \\
& \left.\left.\left|r_{k}\right| \leq 2^{4 u+\log u} \tau^{2},\left\|\mathbf{t}_{k}\right\|_{\infty} \leq 2^{4 u+\log u} \tau \rho\right)\right\}
\end{aligned}
$$

The protocol can be seen in Figure 2. Note that Step 6 could also be interpreted as choosing $e_{k}$ as a $u$-bit vector instead, thereby only calling $\mathcal{F}_{\text {Rand }}$ once. Completeness, soundness and zero-knowledge follow by standard arguments that can be found in the full paper [BDOZ10].

Zero-Knowledge Protocols for Paillier. For the particular case of Paillier encryption, $\Pi_{\text {PoPK }}$ can be used as it is, except that there is no bound required on the randomness, instead all random values used in encryptions are expected to be in $\mathbb{Z}_{N^{2}}^{*}$. Thus, the relations to prove will only require that the random values are in $\mathbb{Z}_{N^{2}}^{*}$ and this is also what the verifier should check in the protocol.

For $\Pi_{\mathrm{PoCm}}$ we sketch a version that is more efficient than the above, using special properties of Paillier encryption. In order to improve readability, we depart here from the additive notation for operations on ciphertexts, since multiplicative notation is usually used for Paillier. In the following, let $p k_{V}=N$. Note first that based on such a public key, one can define an unconditionally hiding commitment scheme with public key $g=\mathrm{E}_{V}(0)$. To commit to $a \in \mathbb{Z}_{N}$, one sends $\operatorname{com}(a, r)=g^{a} r^{N} \bmod N$, for random $r \in \mathbb{Z}_{N^{2}}^{*}$. One can show that the scheme is binding assuming it is hard to extract $N$-th roots modulo $N^{2}$ (which must be the case if Paillier encryption is secure).

We restate the relation $R_{\text {PoCM }}^{(u, \tau, \rho)}$ from above as it will look for the Paillier case, in multiplicative notation and without bounds on the randomness:

$$
\begin{aligned}
R_{\mathrm{PoCM}, \text { Paillier }}^{(\tau, \rho)}=\{(x, w) \mid \quad & x=\left(p k_{P}, p k_{V},\left(A_{1}, B_{1}, C_{1}\right), \ldots,\left(A_{u}, B_{u}, C_{u}\right)\right) ; \\
& w=\left(\left(a_{1}, h_{1}, r_{1}, t_{1}\right), \ldots,\left(a_{u}, h_{u}, r_{u}, t_{u}\right)\right): \\
& A_{k}=\mathrm{E}_{P}\left(a_{k}, h_{k}\right), B_{k} \in \mathbb{Z}_{N^{2}}, C_{k}=B_{k}^{a_{k}} \cdot \mathrm{E}_{V}\left(r_{k}, t_{k}\right), \\
& \left.\left|a_{k}\right| \leq 2^{2 u+\log u} \tau,\left|r_{k}\right| \leq 2^{5 u+2 \log u} \tau^{2}\right\}
\end{aligned}
$$

The idea for the proof of knowledge for this relation is now to ask the prover to also send commitments $\Psi_{k}=\operatorname{com}\left(a_{k}, \alpha_{k}\right), \Phi_{k}=\operatorname{com}\left(r_{k}, \beta_{k}\right), k=1 \ldots u$ to the $r_{k}$ 's and $a_{k}$ 's. Now, the prover must first provide a proof of knowledge that for each $k: 1$ ) the same bounded size value is contained in both $A_{k}$ and $\Psi_{k}$, and that $2)$ a bounded size value is contained in $\Phi_{k}$. The proof for $\left\{\Phi_{k}\right\}$ is simply $\Pi_{\mathrm{PoPK}}$ since a commitment has the same form as an encryption (with $(N+1)$ replaced by $g$ ). The proof for $\left\{\Psi_{k}, A_{k}\right\}$ is made of two instances of $\Pi_{\mathrm{PoPK}}$ run in parallel, using the same challenge $e$ and responses $z_{i}$ in both instances. Finally, the prover must show that $C_{k}$ can be written as $C_{k}=B_{k}^{a_{k}} \cdot \mathrm{E}_{V}\left(r_{k}, t_{k}\right)$, where $a_{k}$ is the value contained in $\Psi_{k}$ and $r_{k}$ is the value in $\Phi_{k}$. Since all commitments and ciphertexts live in the same group $\mathbb{Z}_{N^{2}}^{*}$, where $p k_{V}=N$, we can do this efficiently using a variant of a protocol from CDN01. The resulting protocol is shown in Figure 3 .

Completeness of the protocol in steps 1-4 of Figure 3 is straightforward by inspection. Honest verifier zero-knowledge follows by the standard argument: choose $e$ and the prover's responses uniformly in their respective domains and use the equations checked by the verifier to compute a matching first message $D, X, Y$. This implies completeness and honest verifier zero-knowledge for the overall protocol, since the subprotocols in steps 2 and 3 have these properties as well.

Subprotocol $\Pi_{\mathrm{PoCM}}$ : Proof of Correct Multiplication (only for Paillier)

1. $P$ sends $\Psi_{k}=\operatorname{com}\left(a_{k}, \alpha_{k}\right), \Phi_{k}=\operatorname{com}\left(r_{k}, \beta_{k}\right), k=1, \ldots, u$ to the verifier.
2. $P$ uses $\Pi_{\text {PoPK }}$ on $\Phi_{k}$ to prove that, even if $P$ is corrupted, each $\Phi_{k}$ contains a value $r_{k}$ with $\left|r_{k}\right| \leq 2^{5 u+2 \log u} \tau^{2}$.
3. $P$ uses $\Pi_{\text {PoРк }}$ in parallel on $\left(A_{k}, \Psi_{k}\right)$ (where $V$ uses the same $\mathbf{e}$ in both runs) to prove that, even if $P$ is corrupted, $\Psi_{k}$ and $A_{k}$ contains the same value $a_{k}$ and $\left|a_{k}\right| \leq 2^{2 u+\log u} \tau$.
4. To show that the $C_{k}$ 's are well-formed, we do the following for each $k$ :
(a) $P$ picks random $x, y, v, \gamma, \delta \leftarrow \mathbb{Z}_{N^{2}}^{*}$ and sends $D=B_{k}^{x} \mathrm{E}_{V}(y, v), X=$ $\operatorname{com}\left(x, \gamma_{x}\right), Y=\operatorname{com}\left(y, \gamma_{y}\right)$ to $V$.
(b) $V$ sends a random $u$-bit challenge $e$.
(c) $P$ computes $z_{a}=x+e a_{k} \bmod N, z_{r}=y+e r_{k} \bmod N$.

He also computes $q_{a}, q_{r}$, where $x+e a=q_{a} N+z_{a}, y+e r_{k}=q_{r} N+z_{r} \sqrt{a}$.
$P$ sends $z_{a}, z_{r}, w=v s_{k}^{e} B_{k}^{q_{a}} \bmod N^{2}, \delta_{a}=\gamma_{x} \alpha_{k}^{e} g^{q_{a}} \bmod N^{2}$, and $\delta_{r}=$ $\gamma_{y} \beta_{k}^{e} g^{q_{r}} \bmod N^{2}$ to $V$.
(d) $V$ accepts if $D C_{k}^{e}=B_{k}^{z_{a}} \mathrm{E}_{V}\left(z_{r}, w\right) \bmod N^{2} \wedge X \Psi_{k}^{e}=\operatorname{com}\left(z_{a}, \delta_{a}\right) \bmod N^{2} \wedge$ $Y \Phi_{k}^{e}=\operatorname{com}\left(z_{r}, \delta_{r}\right) \bmod N^{2}$.
${ }^{a}$ Since $g$ and $B_{k}$ do not have order $N$, we need to explicitly handle the quotients $q_{a}$ and $q_{r}$, in order to move the "excess multiples" of $N$ into the randomness parts of the commitments and ciphertext.

Fig. 3. Proof of Correct Multiplication for Paillier encryption
Finally, soundness follows by assuming we are given correct responses in step 7 to two different challenges. From the equations checked by the verifier, we can then easily compute $a_{k}, \alpha_{k}, r_{k}, \beta_{k}, s_{k}$ such that $\Psi_{k}=\operatorname{com}\left(a_{k}, \alpha_{k}\right), \Phi_{k}\left(r_{k}, \beta_{k}\right), C_{k}=$ $B_{k}^{a_{k}} \mathrm{E}_{V}\left(r_{k}, s_{k}\right)$. Now, by soundness of the protocols in steps 2 and 3 , we can also compute bounded size values $a_{k}^{\prime}, r_{k}^{\prime}$ that are contained in $\Psi_{k}, \Phi_{k}$. By the binding property of the commitment scheme, we have $r_{k}^{\prime}=r_{k}, a_{k}^{\prime}=a_{k}$ except with negligible probability, so we have a witness as required in the specification of the relation.

## 3 The Online Phase

Our goal is to implement reactive arithmetic multiparty computation over $\mathbb{Z}_{p}$ for a prime $p$ of size super-polynomial in the statistical security parameter $u$. The (standard) ideal functionality $\mathcal{F}_{\mathrm{AMPC}}$ that we implement can be seen in Figure 6 , We assume here that the parties already have a functionality for synchronous ${ }^{3}$, secure communication and broadcast.
${ }^{3}$ A malicious adversary can always stop sending messages and, in any protocol for dishonest majority, all parties are required for the computation to terminate. Without synchronous channels the honest parties might wait forever for the adversary to send his messages. Synchronous channels guarantee that the honest parties can detect that the adversary is not participating anymore and therefore they can abort the protocol. If termination is not required, the protocol can be implemented over an asynchronous network instead.

We first present a protocol for an online phase that assumes access to a functionality $\mathcal{F}_{\text {TRIP }}$ which we later show how to implement using an offline protocol. The online phase is based on a representation of values in $\mathbb{Z}_{p}$ that are shared additively where shares are authenticated using information theoretic message authentication codes (MACs). Before presenting the protocol we introduce how the MACs work and how they are included in the representation of a value in $\mathbb{Z}_{p}$. Furthermore, we argue how one can compute with these representations as we do with simple values, and in particular how the relation to the MACs are maintained.

In the rest of this section, all additions and multiplications are to be read modulo $p$, even if not specified. The number of parties is denoted by $n$, and we call the parties $P_{1}, \ldots, P_{n}$.

### 3.1 The MACs

A key $K$ in this system is a random pair $K=(\alpha, \beta) \in \mathbb{Z}_{p}^{2}$, and the authentication code for a value $a \in \mathbb{Z}_{p}$ is $\operatorname{MAC}_{K}(a)=\alpha a+\beta \bmod p$.

We will apply the MACs by having one party $P_{i}$ hold $a, \mathrm{MAC}_{K}(a)$ and another party $P_{j}$ holding $K$. The idea is to use the MAC to prevent $P_{i}$ from lying about $a$ when he is supposed to reveal it to $P_{j}$. It will be very important in the following that if we keep $\alpha$ constant over several different MAC keys, then one can add two MACs and get a valid authentication code for the sum of the two corresponding messages. More concretely, two keys $K=(\alpha, \beta), K^{\prime}=\left(\alpha^{\prime}, \beta^{\prime}\right)$ are said to be consistent if $\alpha=\alpha^{\prime}$. For consistent keys, we define $K+K^{\prime}=\left(\alpha, \beta+\beta^{\prime}\right)$ so that it holds that $\operatorname{MAC}_{K}(a)+\operatorname{MAC}_{K^{\prime}}\left(a^{\prime}\right)=\operatorname{MAC}_{K+K^{\prime}}\left(a+a^{\prime}\right)$.

The MACs will be used as follows: we give to $P_{i}$ several different values $m_{1}, m_{2}, \ldots$ with corresponding MACs $\gamma_{1}, \gamma_{2}, \ldots$ computed using keys $K_{i}=$ $\left(\alpha, \beta_{i}\right)$ that are random but consistent. It is then easy to see that if $P_{i}$ claims a false value for any of the $m_{i}$ 's (or a linear combination of them) he can guess an acceptable MAC for such a value with probability at most $1 / p$.

### 3.2 The Representation and Linear Computation

To represent a value $a \in \mathbb{Z}_{p}$, we will give a share $a_{i}$ to each party $P_{i}$. In addition, $P_{i}$ will hold MAC keys $K_{a_{1}}^{i}, \ldots, K_{a_{n}}^{i}$. He will use key $K_{a_{j}}^{i}$ to check the share of $P_{j}$, if we decide to make $a$ public. Finally, $P_{i}$ also holds a set of authentication codes $\mathrm{MAC}_{K_{a_{i}}^{j}}\left(a_{i}\right)$. We will denote $\mathrm{MAC}_{K_{a_{i}}^{j}}\left(a_{i}\right)$ by $m_{j}\left(a_{i}\right)$ from now on. Party $P_{i}$ will use $m_{j}\left(a_{i}\right)$ to convince $P_{j}$ that $a_{i}$ is correct, if we decide to make $a$ public. Summing up, we have the following way of representing $a$ :

$$
[a]=\left[\left\{a_{i},\left\{K_{a_{j}}^{i}, m_{j}\left(a_{i}\right)\right\}_{j=1}^{n}\right\}_{i=1}^{n}\right]
$$

where $\left\{a_{i},\left\{K_{a_{j}}^{i}, m_{j}\left(a_{i}\right)\right\}_{j=1}^{n}\right\}$ is the information held privately by $P_{i}$, and where we use $[a]$ as shorthand when it is not needed to explicitly talk about the shares and MACs. We say that $[a]=\left[\left\{a_{i},\left\{K_{a_{j}}^{i}, m_{j}\left(a_{i}\right)\right\}_{j=1}^{n}\right\}_{i=1}^{n}\right]$ is consistent, with $a=\sum_{i} a_{i}$, if $m_{j}\left(a_{i}\right)=\operatorname{MAC}_{K_{a_{i}}^{j}}\left(a_{i}\right)$ for all $i, j$. Two representations

$$
[a]=\left[\left\{a_{i},\left\{K_{a_{j}}^{i}, m_{j}\left(a_{i}\right)\right\}_{j=1}^{n}\right\}_{i=1}^{n}\right], \quad\left[a^{\prime}\right]=\left[\left\{a_{i}^{\prime},\left\{K_{a_{j}^{\prime}}^{i}, m_{j}\left(a_{i}^{\prime}\right)\right\}_{j=1}^{n}\right\}_{i=1}^{n}\right]
$$

Opening: We can reliably open a consistent representation to $P_{j}$ : each $P_{i}$ sends $a_{i}, m_{j}\left(a_{i}\right)$ to $P_{j} . P_{j}$ checks that $m_{j}\left(a_{i}\right)=\operatorname{MAC}_{K_{a_{i}}^{j}}\left(a_{i}\right)$ and broadcasts $O K$ or fail accordingly. If all is OK, $P_{j}$ computes $a=\sum_{i} a_{i}$, else we abort. We can modify this to opening a value $[a]$ to all parties, by opening as above to every $P_{j}$.
Addition: Given two key-consistent representations as above we get that

$$
\left[a+a^{\prime}\right]=\left[\left\{a_{i}+a_{i}^{\prime},\left\{K_{a_{j}}^{i}+K_{a_{j}^{\prime}}^{i}, m_{j}\left(a_{i}\right)+m_{j}\left(a_{i}^{\prime}\right)\right\}_{j=1}^{n}\right\}_{i=1}^{n}\right]
$$

is a consistent representation of $a+a^{\prime}$. This new representation can be computed only by local operations.
Multiplication by constants: In a similar way, we can multiply a public constant $\delta$ "into" a representation. This is written $\delta[a]$ and is taken to mean that all parties multiply their shares, keys and MACs by $\delta$. This gives a consistent representation $[\delta a]$.
Addition of constants: We can add a public constant $\delta$ into a representation. This is written $\delta+[a]$ and is taken to mean that $P_{1}$ will add $\delta$ to his share $a_{1}$. Also, each $P_{j}$ will replace his key $K_{a_{1}}^{j}=\left(\alpha_{1}^{j}, \beta_{a_{1}}^{j}\right)$ by $K_{a_{1}+\delta}^{j}=\left(\alpha_{1}^{j}, \beta_{a_{1}}^{j}-\delta \alpha_{1}^{j}\right)$. This will ensure that the MACs held by $P_{1}$ will now be valid for the new share $a_{1}+\delta$, so we now have a consistent representation $[a+\delta]$.

Fig. 4. Operations on [•]-representations
are said to be key-consistent if they are both consistent, and if for all $i, j$ the keys $K_{a_{j}}^{i}, K_{a_{j}^{\prime}}^{i}$ are consistent. We will want all representations in the following to be key-consistent: this is ensured by letting $P_{i}$ use the same $\alpha_{j}$-value in keys towards $P_{j}$ throughout. Therefore the notation $K_{a_{j}}^{i}=\left(\alpha_{j}^{i}, \beta_{a_{j}}^{i}\right)$ makes sense and we can compute with the representations, as detailed in Figure 4.

### 3.3 Triples and Multiplication

For multiplication and input sharing we will need both random single values $[a]$ and triples $[a],[b],[c]$ where $a, b$ are random and $c=a b \bmod p$. Also, we assume that all singles and triples we ever produce are key consistent, so that we can freely add them together. More precisely, we assume we have access to an ideal functionality $\mathcal{F}_{\text {TRIP }}$ providing us with the above. This is presented in Figure 5 ,

The principle in the specification of the functionality is that the environment is allowed to specify all the data that the corrupted parties should hold, including all shares of secrets, keys and MACs. Then, the functionality chooses the secrets to be shared and constructs the data for honest parties so it is consistent with the secrets and the data specified by the environment.

Thanks to this functionality we are also able to compute multiplications in the following way: If the parties hold two key-consistent representations $[x],[y]$, we can use one precomputed key-consistent triple $[a],[b],[c]$ (with $c=a b$ ) to compute a new representation of $[x y]$.

## Functionality $\mathcal{F}_{\text {TRIP }}$

Initialize: On input ( init, $p$ ) from all parties the functionality stores the modulus $p$. For each corrupted party $P_{i}$ the environment specifies values $\alpha_{j}^{i}, j=1, \ldots, n$, except those $\alpha_{j}^{i}$ where both $P_{i}$ and $P_{j}$ are corrupt. For each honest $P_{i}$, it chooses $\alpha_{j}^{i}, j=1, \ldots, n$ at random.
Singles: On input (singles, $u$ ) from all parties $P_{i}$, the functionality does the following, for $v=1, \ldots, u$ :

1. It waits to get from the environment either "stop", or some data as specified below. In the first case it sends "fail" to all honest parties and stops. In the second case, the environment specifies for each corrupt party $P_{i}$, a share $a_{i}$ and $n$ pairs of values $\left(m_{j}\left(a_{i}\right), \beta_{a_{j}}^{i}\right), j=1, \ldots, n$, except those $\left(m_{j}\left(a_{i}\right), \beta_{a_{j}}^{i}\right)$ where both $P_{i}$ and $P_{j}$ are corrupt.
2. The functionality chooses $a \in \mathbb{Z}_{p}$ at random and creates the representation [a] as follows:
(a) First it chooses random shares for the honest parties such that the sum of these and those specified by the environment is correct: Let $C$ be the set of corrupt parties, then $a_{i}$ is chosen at random for $P_{i} \notin \mathrm{C}$, subject to $a=\sum_{i} a_{i}$.
(b) For each honest $P_{i}$, and $j=1, \ldots, n, \beta_{a_{j}}^{i}$ is chosen as follows: if $P_{j}$ is honest, $\beta_{a_{j}}^{i}$ is chosen at random, otherwise it sets $\beta_{a_{j}}^{i}=m_{i}\left(a_{j}\right)-\alpha_{j}^{i} a_{j}$. Note that the environment already specified $m_{i}\left(a_{j}\right), a_{j}$, so what is done here is to construct the key to be held by $P_{i}$ to be consistent with the share and MAC chosen by the environment.
(c) For all $i=1, \ldots, n, j=1, \ldots, n$ it sets $K_{a_{j}}^{i}=\left(\alpha_{j}^{i}, \beta_{a_{j}}^{i}\right)$, and computes $m_{j}\left(a_{i}\right)=\operatorname{MAC}_{K_{a_{i}}^{j}}\left(a_{i}\right)$.
(d) Now all data for $[a]$ is created. The functionality sends $\left\{a_{i},\left\{K_{a_{j}}^{i}, m_{j}\left(a_{i}\right)\right\}_{j=1, \ldots, n}\right\}$ to each honest $P_{i}$ (no need to send anything to corrupt parties, the environment already has the data).
Triples: On input (triples, $u$ ) from all parties $P_{i}$, the functionality does the following, for $v=1, \ldots, u$ :
3. Step 1 is done as in "Singles".
4. For each triple to create it chooses $a, b$ at random and sets $c=a b$. Now it creates representations $[a],[b],[c]$, each as in Step 2 in "Singles".

Fig. 5. The ideal functionality for making singles $[a]$ and triples $[a],[b],[c]$

To compute $[\mathrm{xy}]$ we first open $[x]-[a]$ to get a value $\varepsilon$, and $[y]-[b]$ to get $\delta$. Then, we have $x y=(a+\varepsilon)(b+\delta)=c+\varepsilon b+\delta a+\varepsilon \delta$. Therefore, we get a new representation of $x y$ as follows:

$$
[x y]=[c]+\varepsilon[b]+\delta[a]+\varepsilon \delta .
$$

Using the tools from the previous sections we can now construct a protocol $\Pi_{\text {AMPC }}$ that securely implements the MPC functionality $\mathcal{F}_{\text {AMPC }}$ in the UC security framework. $\mathcal{F}_{\mathrm{AMPC}}$ and $\Pi_{\mathrm{AMPC}}$ are presented in Figure 6 and Figure 7 respectively. The proof of Theorem 1 can be found in the full paper [BDOZ10].

## Functionality $\mathcal{F}_{\text {AMPC }}$

Initialize: On input (init, $p$ ) from all parties, the functionality activates and stores the modulus $p$.
Rand: On input (rand, $P_{i}$, varid) from all parties $P_{i}$, with varid a fresh identifier, the functionality picks $r \leftarrow \mathbb{Z}_{p}$ and stores (varid, $r$ ).
Input: On input (input, $P_{i}$, varid, $x$ ) from $P_{i}$ and (input, $P_{i}$, varid,?) from all other parties, with varid a fresh identifier, the functionality stores (varid, $x$ ).
Add: On command ( $a d d$, varid $_{1}$, varid $_{2}$, varid $_{3}$ ) from all parties (if varid 1, varid $_{2}$ are present in memory and varid $_{3}$ is not), the functionality retrieves (varid $\left.{ }_{1}, x\right)$, $\left(\right.$ varid $\left._{2}, y\right)$ and stores $\left(\right.$ varid $\left._{3}, x+y \bmod p\right)$.
Multiply: On input (multiply, varid $_{1}$, varid $_{2}$, varid $_{3}$ ) from all parties (if varid $_{1}$, varid $_{2}$ are present in memory and varid $_{3}$ is not), the functionality retrieves $\left(\right.$ varid $\left._{1}, x\right),\left(\right.$ varid $\left._{2}, y\right)$ and stores $\left(\right.$ varid $\left._{3}, x \cdot y \bmod p\right)$.
Output: On input (output, $P_{i}$, varid) from all parties (if varid is present in memory), the functionality retrieves (varid, $x$ ) and outputs it to $P_{i}$.

Fig. 6. The ideal functionality for arithmetic MPC

## Protocol $\Pi_{\mathrm{AMPC}}$

Initialize: The parties first invoke $\mathcal{F}_{\text {TRIP }}($ init,$p)$. Then, they invoke $\mathcal{F}_{\text {TRIP }}($ triples,$u)$ and $\mathcal{F}_{\text {TRIP }}($ singles,$u)$ a sufficient number of times to create enough singles and triples.
Input: To share $P_{i}$ 's input $\left[x_{i}\right]$ with identifier varid, $P_{i}$ takes a single $[a]$ from the set of available ones. Then, the following is performed:

1. $[a]$ is opened to $P_{i}$.
2. $P_{i}$ broadcasts $\delta=x_{i}-a$.
3. The parties compute $\left[x_{i}\right]=[a]+\delta$.

Rand: The parties take an available single $[a]$ and store with identifier varid.
Add: To add $[x],[y]$ with identifiers varid $_{1}$, varid $_{2}$ the parties compute $[z]=[x]+[y]$ and assign $[z]$ the identifier varid $_{3}$.
Multiply: To multiply $[x],[y]$ with identifiers varid $_{1}$, varid $_{2}$ the parties do the following:

1. They take a triple $([a],[b],[c])$ from the set of the available ones.
2. $[x]-[a]=\varepsilon$ and $[y]-[b]=\delta$ are opened.
3. They compute $[z]=[c]+\varepsilon[b]+\delta[a]+\varepsilon \delta$
4. They assign $[z]$ the identifier varid $_{3}$ and remove $([a],[b],[c])$ from the set of the available triples.
Output: To output $[x]$ with identifier varid to $P_{i}$ the parties do an opening of $[x]$ to $P_{i}$.

Fig. 7. The protocol for arithmetic MPC

Theorem 1. In the $\mathcal{F}_{\text {TRIP }}-$ hybrid model, the protocol $\Pi_{\mathrm{AMPC}}$ implements $\mathcal{F}_{\mathrm{AMPC}}$ with statistical security against any statid , active adversary corrupting up to $n-1$ parties.

## 4 The Offline Phase

In this section we describe the protocol $\Pi_{\text {TRIP }}$ which securely implements the functionality $\mathcal{F}_{\text {TRIP }}$ described in Section 3 in the presence of two standard functionalities: a key registration functionality $\mathcal{F}_{\text {KeyReg }}$ and a functionality that generates random challenges $\mathcal{F}_{\text {Rand }}[5$. Detailed specifications of these functionalities can be found in the full paper [BDOZ10].

## $4.1\langle\cdot\rangle$-Representation

Throughout the description of the offline phase, $\mathrm{E}_{i}$ will denote $\mathrm{E}_{p k_{i}}$ where $p k_{i}$ is the public key of party $P_{i}$, as established by $\mathcal{F}_{\text {KeyReg }}$. We assume the cryptosystem used is semi-homomorphic modulo $p$, as defined in Section 2, In the following, we will always set $\tau=p / 2$ and $\rho=\sigma$. Thus, if $P_{i}$ generates a ciphertext $C=\mathrm{E}_{i}(x, \mathbf{r})$ where $x \in \mathbb{Z}_{p}$ and $\mathbf{r}$ is generated by $\mathcal{D}_{\sigma}^{d}, C$ will be a $(\tau, \rho)$-ciphertext. We will use the zero-knowledge protocols from Section 2.2 They depend on an "information theoretic" security parameter $u$ controlling, e.g., the soundness error. We will say that a semi-homomorphic cryptosystem is admissible if it allows correct decryption of ciphertext produced in those protocols, that is, if $M \geq 2^{5 u+2 \log u} \tau^{2}$ and $R \geq 2^{4 u+\log u} \tau \rho$.

In the following $\left\langle x_{k}\right\rangle$ will stand for the following representation of $x_{k} \in$ $\mathbb{Z}_{p}$ : each $P_{i}$ has published $\mathrm{E}_{i}\left(x_{k, i}\right)$ and holds $x_{k, i}$ privately, such that $x_{k}=$ $\sum_{i} x_{k, i} \bmod p$. For the protocol to be secure, it will be necessary to ensure that the parties encrypt small enough plaintexts. For this purpose we use the $\Pi_{\mathrm{PoPK}}$ described in Section 2.2, and we get the protocol in Figure 8 to establish a set $\left\langle x_{k}\right\rangle, k=1, \ldots, u$ of such random representations.

## $4.2\langle\cdot\rangle$-Multiplication

The final goal of the $\Pi_{\text {TRIP }}$ protocol is to produce triples $\left[a_{k}\right],\left[b_{k}\right],\left[c_{k}\right]$ with $a_{k} b_{k}=c_{k} \bmod p$ in the [•]-representation, but for now we will disregard the MACs and construct a protocol $\Pi_{n \text {-MULT }}$ which produces triples $\left\langle a_{k}\right\rangle,\left\langle b_{k}\right\rangle,\left\langle c_{k}\right\rangle$ in the $\langle\cdot\rangle$-representation $\sqrt[6]{6}$.

We will start by describing a two-party protocol. Assume $P_{i}$ is holding a set of $u(\tau, \rho)$-encryptions $\mathrm{E}_{i}\left(x_{k}\right)$ under his public key and likewise $P_{j}$ is holding $u$

[^3]
## Subprotocol $\Pi_{\text {Share }}$

Share (u):

1. Each $P_{i}$ chooses $x_{k, i} \in \mathbb{Z}_{p}$ at random for $k=1, \ldots, u$ and broadcasts $(\tau, \rho)$-ciphertexts $\left\{\mathrm{E}_{i}\left(x_{k, i}\right)\right\}_{k=1}^{u}$.
2. Each pair $P_{i}, P_{j}, i \neq j$, runs $\Pi_{\mathrm{PoPK}}(u, \tau, \rho)$ with the $\mathrm{E}_{i}\left(x_{k, i}\right)$ 's as input. This proves that the ciphertexts are $\left(2^{2 u+\log u} \tau, 2^{2 u+\log u} \rho\right)$-ciphertexts.
3. All parties output $\left\langle x_{k}\right\rangle=\left(\mathrm{E}_{1}\left(x_{k, 1}\right), \ldots, \mathrm{E}_{n}\left(x_{k, n}\right)\right)$, for $k=1, \ldots, u$, where $x_{k}$ is defined by $x_{k}=\sum_{i} x_{k, i} \bmod p . P_{i}$ keeps the $x_{k, i}$ and the randomness for his encryptions as private output.

Fig. 8. Subprotocol allowing parties to create random additively shared values

## Subprotocol $\Pi_{2 \text {-MULT }}$

$2-\operatorname{Mult}(u, \tau, \rho)$ :

1. Honest $P_{i}$ and $P_{j}$ input $(\tau, \rho)$-ciphertexts $\left\{\mathrm{E}_{i}\left(x_{k}\right)\right\}_{k=1}^{u},\left\{\mathrm{E}_{j}\left(y_{k}\right)\right\}_{k=1}^{u}$. (At this point of the protocol it has already been verified that the ciphertexts are ( $2^{2 u+\log u} \tau, 2^{2 u+\log u} \rho$ )-ciphertexts.)
2. For each $k, P_{i}$ sends $C_{k}=x_{k} \mathrm{E}_{j}\left(y_{k}\right)+\mathrm{E}_{j}\left(r_{k}\right)$ to $P_{j}$. Here $\mathrm{E}_{j}\left(r_{k}\right)$ is a random $\left(2^{3 u+\log u} \tau^{2}, 2^{3 u+\log u} \tau \rho\right)$-encryption under $P_{j}$ 's public key. $P_{i}$ furthermore invokes $\Pi_{\text {Pocm }}(u, \tau, \rho)$ with input $C_{k}, \mathrm{E}_{i}\left(x_{k}\right), \mathrm{E}_{j}\left(y_{k}\right)$, to prove that the $C_{k}$ 's are constructed correctly.
3. For each $k, P_{j}$ decrypts $C_{k}$ to obtain $v_{k}$, and outputs $z_{k, j}=v_{k} \bmod p . P_{i}$ outputs $z_{k, i}=-r_{k} \bmod p$.

Fig. 9. Subprotocol allowing two parties to obtain encrypted sharings of the product of their inputs

## Subprotocol $\Pi_{n \text {-MULT }}$

$n$-Mult ( $u$ ):

1. The input is $\left\langle a_{k}\right\rangle,\left\langle b_{k}\right\rangle, k=1, \ldots, u$, created using the $\Pi_{\text {ShARE }}$ protocol. Each $P_{i}$ initializes variables $c_{k, i}=a_{k, i} b_{k, i} \bmod p, k=1, \ldots, u$.
2. Each pair $P_{i}, P_{j}, i \neq j$, runs $\Pi_{2 \text {-MULT }}$ using as input the ciphertexts $\mathrm{E}_{i}\left(a_{k, i}\right), \mathrm{E}_{j}\left(b_{k, j}\right), k=1, \ldots, u$, and adds the outputs to the private variables $c_{k, i}, c_{k, j}$, i.e., for $k=1, \ldots, u, P_{i}$ sets $c_{k, i}=c_{k, i}+z_{k, i} \bmod p$, and $P_{j}$ sets $c_{k, j}=c_{k, j}+z_{k, i} \bmod p$.
3. Each $P_{i}$ invokes $\Pi_{\text {SHARE }}$, where $c_{k, i}, k=1, \ldots, u$ is used as the numbers to broadcast encryptions of. Parties output what $\Pi_{\text {SHARE }}$ outputs, namely $\left\langle c_{k}\right\rangle, k=1, \ldots, u$.

Fig. 10. Protocol allowing the parties to construct $\left\langle c_{k}=a_{k} b_{k} \bmod p\right\rangle$ from $\left\langle a_{k}\right\rangle,\left\langle b_{k}\right\rangle$

## Subprotocol $\Pi_{\text {ADDMACS }}$

Initialize: For each pair $P_{i}, P_{j}, i \neq j, P_{i}$ chooses $\alpha_{j}^{i}$ at random in $\mathbb{Z}_{p}$, sends a $(\tau, \rho)$ ciphertext $\mathrm{E}_{i}\left(\alpha_{j}^{i}\right)$ to $P_{j}$ and then runs $\Pi_{\mathrm{PoPK}}(u, \tau, \rho)$ with $\left(\mathrm{E}_{i}\left(\alpha_{j}^{i}\right), \ldots, \mathrm{E}_{i}\left(\alpha_{j}^{i}\right)\right)$ as input and with $P_{j}$ as verifier.

## AddMacs $(u)$ :

1. The input is a set $\left\langle a_{k}\right\rangle, k=1, \ldots, u$. Each $P_{i}$ already holds shares $a_{k, i}$ of $a_{k}$, and will store these as part of $\left[a_{k}\right]$.
2. Each pair $P_{i}, P_{j} i \neq j$ invokes $\Pi_{2 \text {-MULT }}(u, \tau, \rho)$ with input $\mathrm{E}_{i}\left(\alpha_{j}^{i}\right), \ldots, \mathrm{E}_{i}\left(\alpha_{j}^{i}\right)$ from $P_{i}$ and input $\mathrm{E}_{j}\left(a_{k, j}\right)$ from $P_{j}$. From this, $P_{i}$ obtains output $z_{k, i}$, and $P_{j}$ gets $z_{k, j}$. Recall that $\Pi_{2 \text {-mult }}$ ensures that $\alpha_{j}^{i} a_{k, j}=z_{k, i}+z_{k, j} \bmod p$. This is essentially the equation defining the MACs we need, so therefore, as a part of each $\left[a_{k}\right], P_{i}$ stores $\alpha_{j}^{i}, \beta_{a_{k, j}}^{i}=-z_{k, i} \bmod p$ as the MAC key to use against $P_{j}$ while $P_{j}$ stores $m_{i}\left(a_{k, j}\right)=z_{k, j}$ as the MAC to use to convince $P_{i}$ about $a_{k, j}$.

Fig. 11. Subprotocol constructing $\left[a_{k}\right]$ from $\left\langle a_{k}\right\rangle$

## Protocol $\Pi_{\text {TRIP }}$

Initialize: The parties first invoke $\mathcal{F}_{\text {KeyReg }}(p)$ and then Initialize in $\Pi_{\text {AdDMACS }}$. Triples ( $u$ ):

1. To get sets of representations $\left\{\left\langle a_{k}\right\rangle,\left\langle b_{k}\right\rangle,\left\langle f_{k}\right\rangle,\left\langle g_{k}\right\rangle\right\}_{k=1}^{u}$, the parties invoke $\Pi_{\text {share }} 4$ times.
2. The parties invoke $\Pi_{n \text {-MULT }}$ twice, on inputs $\left\{\left\langle a_{k}\right\rangle,\left\langle b_{k}\right\rangle\right\}_{k=1}^{u}$, respectively $\left\{\left\langle f_{k}\right\rangle,\left\langle g_{k}\right\rangle\right\}_{k=1}^{u}$. They obtain as output $\left\{\left\langle c_{k}\right\rangle\right\}_{k=1}^{u}$, respectively $\left\{\left\langle h_{k}\right\rangle\right\}_{k=1}^{u}$.
3. The parties invoke $\Pi_{\text {ADDMACS }}$ on each of the created sets of the representations. That means they now have $\left\{\left[a_{k}\right],\left[b_{k}\right],\left[c_{k}\right],\left[f_{k}\right],\left[g_{k}\right],\left[h_{k}\right]\right\}_{k=1}^{u}$.
4. The parties check that indeed $a_{k} b_{k}=c_{k} \bmod p$ by "sacrificing" the triples $\left(f_{k}, g_{k}, h_{k}\right)$ : First, the parties invoke $\mathcal{F}_{\text {RaNd }}$ to get a random $u$-bit challenge $e$. Then, they open $e\left[a_{k}\right]-\left[f_{k}\right]$ to get $\varepsilon_{k}$, and open $\left[b_{k}\right]-\left[g_{k}\right]$ to get $\delta_{k}$. Next, they open $e\left[c_{k}\right]-\left[h_{k}\right]-\delta_{k}\left[f_{k}\right]-\varepsilon_{k}\left[g_{k}\right]-\varepsilon_{k} \delta_{k}$ and check that the result is 0 . Finally, parties output the set $\left\{\left[a_{k}\right],\left[b_{k}\right],\left[c_{k}\right]\right\}_{k=1}^{u}$.
Singles $(u)$ :
5. To get a set of representations $\{\langle a\rangle\}_{k=1}^{u}, \Pi_{\text {SHARE }}$ is invoked.
6. The parties invoke $\Pi_{\text {ADDMACS }}$ on the created set of representations and obtain $\left\{\left[a_{k}\right]\right\}_{k=1}^{u}$.

Fig. 12. The protocol for the offline phase
$(\tau, \rho)$-encryptions $\mathrm{E}_{j}\left(y_{k}\right)$ under his public key. For each $k$, we want the protocol to output $z_{k, i}, z_{k, j}$ to $P_{i}, P_{j}$, respectively, such that $x_{k} y_{k}=z_{k, i}+z_{k, j} \bmod p$. Such a protocol can be seen in Figure 9. This protocol does not commit parties to their output, so there is no guarantee that corrupt parties will later use their output correctly - however, the protocol ensures that malicious parties know which shares they ought to continue with. To build the protocol $\Pi_{n \text {-MULT }}$, the
first thing to notice is that given $\left\langle a_{k}\right\rangle$ and $\left\langle b_{k}\right\rangle$ we have that $c_{k}=a_{k} b_{k}=$ $\sum_{i} \sum_{j} a_{k, i} b_{k, j}$. Constructing each of the terms in this sum in shared form is exactly what $\Pi_{2 \text {-mult }}$ allows us to do. The $\Pi_{n \text {-Mult }}$ protocol can now be seen in Figure 10. Note that it does not guarantee that the multiplicative relation in the triples holds, we will check for this later.

### 4.3 From $\langle\cdot\rangle$-Triples to [•]-Triples

We first describe a protocol that allows us to add MACs to the $\langle\cdot\rangle$-representation. This consists essentially of invoking the $\Pi_{2 \text {-MULT }}$ a number of times. The protocol is shown in Figure 11. The full protocol $\Pi_{\text {TRIP }}$, which also includes the possibility of creating a set of single values, is now a straightforward application of the subprotocols we have defined now. This is shown in Figure 12. The proof of Theorem 2 can be found in the full paper BDOZ10.

Theorem 2. If the underlying cryptosystem is semi-homomorphic modulo $p$, admissible and IND-CPA secure, then $\Pi_{\text {TRIP }}$ implements $\mathcal{F}_{\text {TRIP }}$ with computational security against any static, active adversary corrupting up to $n-1$ parties, in the $\left(\mathcal{F}_{\text {KeyReg }}, \mathcal{F}_{\text {Rand }}\right)$-hybrid model.
