# SEQUENCES AND REPERTOIRE OF HUMAN T CELL RECEPTOR $\alpha$ CHAIN VARIABLE REGION GENES IN MATURE T LYMPHOCYTES

# BY YASUNOBU YOSHIKAI, NOBUHIRO KIMURA, BARRY TOYONAGA, AND TAK W. MAK

From The Ontario Cancer Institute; and the Department of Medical Biophysics, University of Toronto, Toronto, Ontario, Canada M4X 1K9

The T cell antigen receptor (TcR),<sup>1</sup> which recognizes antigen and the MHC gene product, seems to be a cell surface protein heterodimer consisting of an acidic ( $\alpha$ ) and a basic ( $\beta$ ) chain (1–3). The molecular cloning of the TcR  $\beta$  chain (4, 5), and subsequently the  $\alpha$  chain (6–8), established that these genes are distinct from Ig genes. Based on sequence analysis of cDNAs and germline sequences, it appears that functional TcR genes are formed by somatic recombinations of variable (V), diversity (D), joining (J), and constant (C) gene segments (4–8, 9). Chromosomal mapping of these genes indicate that they are found at locations different from those of Ig genes, indicating that these genes are different from those used in the rearrangement of Ig genes (10–13). The germline organizations of these TcR and the Ig genes share a basic structure, but definite differences are revealed upon closer examination (14–19). Thus, TcR genes have their own set of germline genes as their basis for functional diversity.

Estimates of the repertoire of TcR  $V_{\alpha}$  gene segments in mouse have been reported (20, 21). The studies suggest that there may be fewer germline  $V_{\alpha}$  gene segments than the number of Ig H and  $\kappa$  chain variable chain segments, but more than the estimated number of TcR  $V_{\beta}$  gene segments in mice (22, 23). Similar sequence analyses to estimate the repertoire of the human TcR  $\alpha$  or  $\beta$ chain V gene segments are not yet available. Since preliminary studies (18) indicate that somatic mutation does not play an important role in the generation of diversity of these genes, the generation of diversity most likely rests on the extent of recombinational joinings, and thus the number of V and J gene segments is of particular significance.

In this study, we have sequenced and analyzed 24 different  $\alpha$  chain cDNA clones derived from human peripheral blood T lymphocytes and T cell lines. The familial organization of the V<sub> $\alpha$ </sub> segments and the variability within the human V<sub> $\alpha$ </sub> genes have been determined.

<sup>&</sup>lt;sup>1</sup> Abbreviation used in this paper: TcR, T cell antigen receptor.

### Materials and Methods

Constructure of cDNA Libraries. Double-stranded (ds) cDNA was synthesized from poly(A)<sup>+</sup> RNA derived from PHA-stimulated peripheral human T cells. After treatment with Eco RI methylase and size selection, the ds cDNA was cloned into the Eco RI site of  $\lambda$ gt10 using Eco RI linkers as described before (13).

Isolation of Human  $\alpha$  Chain cDNA Clones. The peripheral human T cell library was plated on *E. coli* C600/HFL. Screening of duplicate filters was carried out according to the standard procedure (24). Hybridizations were done for 18 h at 65°C in 5 × SSC, 5 × Denhardt's, 100 µg/ml denatured Salmon sperm DNA, and 0.5 µg <sup>32</sup>P-labelled nick-translated PY14  $\alpha$  cDNA probe previously described (13). Filters were washed in 2 × SSC, 0.1% SDS at room temperature several times, followed by washing in 0.2 × SSC at 65°C.

DNA Sequencing. The cDNA inserts were subcloned into M13 mp9 sites of the bacteriophage vector, and the sequences were determined using the specific-primerdirected dideoxynucleotide sequencing technique in conjunction with the dideoxy method (25).

Southern Blot Analysis. DNA was extracted from bone marrow cells and digested with Eco RI and Bam HI. DNA (10  $\mu$ g) was electrophoresed through 0.8% agarose and transferred to nitrocellulose filters as described by Southern (26). Hybridization was for 24 h at 65°C in 5 × SSC, 5 × Denhardt's, 100  $\mu$ g/ml denatured salmon sperm DNA, 10% dextran sulfate, and 0.5  $\mu$ g <sup>32</sup>P-labelled nick-translated cDNA probe. Filters were washed at 65°C with 3 × SSC containing 0.1% SDS.

# Results

Sequence of Human  $\alpha$  Chain cDNA Clones. To examine the repertoire of the human TcR  $\alpha$  chain genes, we have cloned  $\alpha$  chain-homologous cDNAs from a library of human PHA-stimulated peripheral blood T lymphocytes. The library was screened using a constant region probe from the human TcR  $\alpha$  chain, PY14 (9), and 24 cDNAs clones were randomly chosen. The inserts were subcloned into M13 mp9, and the nucleotide sequences of the cDNAs were determined (Fig. 1). The deduced protein sequence of these clones is presented in Fig. 2. The nucleotide sequence of cDNA PY14 (9) has been included for comparison. Examination of this cDNA sequences showed great variation in the N-terminal half, which correspond to the variable region of the TcR  $\alpha$  chain gene. These variable genes can be divided into at least two gene segments corresponding to the V and I gene segments. The exact junctions between these sequences were determined by comparison of the cDNA sequences to those previously reported for human germline  $V_{\alpha}$  and  $J_{\alpha}$  genes (16). As can be seen in Fig. 1, some of the sequences of the V gene segments are identical to other V gene segments. For example,  $V_{\alpha}$  gene segments of clone HAP10 and clone HAP60 contain identical V gene segments. Similarly, identical V sequences can be found between clones HAP26 and HAP71; HAP05 and HAP44; HAP41, HAP17, and HAP49; and HAP02, HAP28, HAP29, and HAP32. A high degree of sequence homology can also be found between some cDNA clones, suggesting that they belong to the same V gene family. For example, clones HAP(10,60) and PY14; HAP21 and HAP12, HAP(41,17,49,50) and HAP50 are related to each other at above 75% homology at the nucleotide level. Lower degrees of homology exist between members of the different families, with regions of conserved sequences that code for structurally important amino acids. These conserved nucleotides and deduced amino acids for which they code are also indicated in Fig. 1. On the basis of

these sequence analysis, 14 of the 22  $V_{\alpha}$  gene segments isolated are unique. Thus 14 is the lower limit for the number of different  $V_{\alpha}$  segments used in mature T cells.

The deduced protein sequences of the  $V_{\alpha}$  gene segments have been aligned for maximum homology to each other. The deduced sequence from the cDNA clone PGA is included for comparison (8). Both inter- and intrafamilial similarities between  $V_{\alpha}$  genes are even more pronounced at the protein level. Two examples of this are indicated (+) in Fig. 2.

Examination of the I gene segment sequences indicated that, although there are some segments with similar or identical sequences, a large number of distinct sequences can be found. The deduced amino acid sequences of these V and [ segments is summarized in Figs. 2 and 3. These consensus sequences illustrate roughly the hypervariable and framework regions of V and I segments. Comparison of the  $J_{\alpha}$  nucleotide sequences determined in this study (Fig. 1) and elsewhere (16, 28) are illustrated in Fig. 3a, while protein sequence comparison can be seen in Fig. 3 c. Germline  $J_{\alpha}$  gene segments from Yoshikai et al. (16) are included in Fig. 3b for comparison. An examination of  $V_{\alpha}$  and  $I_{\alpha}$  used in different clones (Fig. 1), and their respective familial origins (Fig. 3) suggest that there are no constraints on the association between  $V_{\alpha}$  and  $J_{\alpha}$  segments. An interesting observation is that the  $I_{\alpha}$  gene segment located closest to the  $C_{\alpha}$  in the germline appears to be used four times. The assignment of  $J_{\alpha}$  families is arbitrary and extends the collection sequenced from genomic germline DNA by Yoshikai et al. (16). The combined number of different cDNAs and germline  $J_{\alpha}$  sequences indicated that there are more than 21 independent  $I_{\alpha}$  segments that can be used in the human T cell receptor.

At this time the exact source of sequence diversity at the  $V_{\alpha}$ -J<sub> $\alpha$ </sub> boundary is not known. The 3-20 nucleotide junctional sequences may have arisen from insertion of nucleotides, or merely by the use of as yet unknown germline  $V_{\alpha}$ ,  $D_{\alpha}$ , or J<sub> $\alpha$ </sub> sequences. The 3' variability of the germline J<sub> $\alpha$ </sub> sequences introduces further variability at the J<sub> $\alpha$ </sub>C<sub> $\alpha$ </sub> junction, presumably by splicing of the germline J<sub> $\alpha$ </sub> sequence into the C<sub> $\alpha$ </sub> gene.

Southern Analysis of V Gene Segments in Human Germline DNA. To determine the extent of variability of  $V_{\alpha}$  gene segments within germline DNA, Southern blot analyses of Bam HI- or Eco RI-digested human germline DNA was performed using the cDNAs from Fig. 1 as probes. Representative results are presented in Fig. 4. In most cases, multiple bands hybridizing to the cDNAs probes can be observed at reasonably high stringency. The fragments corresponding to the constant region are denoted. The number of V gene segments appear to range from one to seven. These results support the hypothesis that the  $V_{\alpha}$  gene families have more  $V_{\alpha}$  gene members than  $V_{\beta}$  gene families in mouse (22, 23). On the basis of the Southern gel results, the number and size of  $V_{\alpha}$ gene families can be estimated (Table I) to contain ~40 members (12 families).

Homologies Within the Variable Regions of the Human TcR  $\alpha$  Chain Genes. Alignment of DNA and protein sequences of the 22 cDNA  $V_{\alpha}$  regions reveals regions of high and low homology reminiscent of the Ig hypervariable regions proposed by Wu and Kabat (29). A variability plot of the protein sequences in their optimized alignments (from Fig. 2) is given in Fig. 5. In this

FIGURE 3. Nucleotide and deduced protein sequences from  $J_{\alpha}$  gene segments of the human T cell receptor (a) nucleotide sequences of cDNAs, (b) germline J segment protein sequences, (c) deduced protein sequences of messages 'Yoshikai et al. (16); <sup>3</sup>C. T. Denny et al. (28) SUPT1B V segment sequences are from an IgH V family; <sup>3</sup>Yanagi et al. (9); <sup>4</sup>Sim et al. (8); <sup>5</sup>deduced amino acid from all but one sequence, HAP10.

plot, three regions of high variability can be seen which correspond to amino acid positions 20-35, 55-75, and the region of V-D-J joining, amino acid 100-110. This pattern of variability is similar to that found upon analysis of 12 Nterminally blocked human Ig  $V_H$  sequences (30), with the notable exception of the additional variability at the  $J_{\alpha}C_{\alpha}$  junction, which is not found in Ig V<sub>H</sub> sequences.

# Discussion

In this paper, we have presented the sequences and analyses of the variable regions of 24 different human  $\alpha$  chain TcR cDNAs. All 18 of the 24 cDNAs that contain V segment sequences seem to be messages resulting from productive

TABLE I	
Human T Cell Receptor $\alpha$ Chain Variable Segment Gene Fam	ilies

Human T cell receptor  $\alpha$  chain variable segments (Figs. 1 and 2); PY14.1 (ref. 9), PY14.2 (ref. 16), and PGA (ref. 8) were grouped on the basis of crosshybridization (Fig. 4).

FIGURE 5. Kabat-Wu variability plot based on data presented in Fig. 2. Position: amino acid residues starting from the N terminus.

 $\alpha$  chain TcR gene rearrangements, which are capable of encoding functional proteins since they show continuous open reading frames through variable, joining, and constant regions.

Examination of the  $V_{\alpha}$  gene segments by DNA sequencing and Southern blot analysis of germline genomic DNA shows that there are at least 12 V<sub> $\alpha$ </sub> families comprised of 40 or more  $V_{\alpha}$  gene segments. It is unlikely that there are many more families used than the 12 described here, as data from our laboratory indicates that, of 10 additional  $\alpha$  chain messages from another individual belong to these same 12 V<sub> $\alpha$ </sub> families described here (Kimura, N., unpublished data). Furthermore, the number of fragments detected is similar in DNA from different individuals. Thus, although it is possible that this report may not describe all the human  $\alpha$  chain V gene segments, it is fairly representative of the several individuals we have surveyed. The number of V regions of the human TcR  $\alpha$ chain is considerably higher than those of the  $\lambda$  light chain Ig genes and the TcR  $\beta$  chain genes in the mouse (22, 23). However, it may be lower than that predicted by the number of heavy (31) and  $\kappa$  light (32) Ig V gene segments. The number of members in each family varies considerably among the Ig and TcR genes. For example, while there are 10-50 members in each V gene family of the heavy and  $\kappa$  light Ig chain genes (31, 32), there are very few V<sub> $\beta$ </sub> gene segments, often one per family in the mouse (22, 23). The human  $V_{\beta}$  gene families, however, are larger.<sup>2</sup> The murine  $V_{\alpha}$  gene families are composed of one to eight members (20, 21), and our results indicate similar sizes for the human  $V_{\alpha}$  families.

The human  $I_{\alpha}$  gene segments differ from the other immunorecognition genes in number, lack of clustering, and in length. Our previous analysis of the germline genomic  $I_{\alpha}$  organization suggested that there may be numerous  $J_{\alpha}$  segments present spread over a very large distance (16). The data from the present study is consistent with this observation. In fact, the number of the  $J_{\alpha}$  gene segments presented here are unique. Although the exact number of  $I_{\alpha}$  in the human TcR  $\alpha$  chain locus cannot be determined at this time, it must be considerably more than the 21 unique sequences isolated to date. A statistical estimation assuming a random assortment predicted ~55 J<sub> $\alpha$ </sub> gene segments (D. Tritchler, personal communication). The  $J_{\alpha}$  segments are several codons longer than those of the TcR  $\beta$  chain or the Ig chains. These extra codons may be accounted for by either N-terminal sequence diversity upon  $V_{\alpha}$ - $J_{\alpha}$  joining, the incorporation of putative  $D_{\alpha}$  segments, or by longer germline  $V_{\alpha}$  gene segments. It is not known whether the extra codons could affect the three-dimensional structure and folding of the  $\alpha$  and  $\beta$  T cell receptor heterodimer. Nonetheless, the large number and extra length of the  $J_{\alpha}$  gene segments are consistent with a high level of diversity within this region of the human T cell receptor  $\alpha$  chain gene, and may be responsible for the high levels of boundary diversity in the TcR  $\alpha$  chain.

There are many fine differences in both function and structure between Ig and T cell receptor molecules. The former are expressed exclusively on the surface of B cells and serves as a receptor that can recognize free antigen while

#### YOSHIKAI ET AL.

the latter are found solely on T cell surfaces and can recognize antigen only in the context of major histocompatibility products (30). Subtle differences, such as in the lengths of the V regions among the Ig, TcR  $\alpha$  and  $\beta$  genes also exist.

In spite of these distinctions, the gross overall structures of these genes are probably quite similar, based on previous DNA and deduced protein sequence analysis. From the results reported here, this prediction can be extended, since the variable region TcR  $\alpha$  chain gene was found to consist of three hypervariable regions, which correspond roughly to the CDR1, CDR2, and CDR3 hypervariable regions of the Ig (H or L) gene. A similar parallel between hypervariable regions is found in the murine system (20, 21). Should the T cell receptor  $\alpha$  and  $\beta$  heterodimer possess no more than the same three hypervariable regions as Ig, and should the basic three-dimensional structures of these T and B cell recognition proteins be similar, then the mechanism for T cell receptor recognition of antigen only in the context of the MHC products (33) becomes even more mysterious.

### Summary

24 human T cell receptor  $\alpha$  chain messages have been examined by cDNA sequence analysis and Southern blot. The data indicate that there are ~40  $\alpha$ chain T cell receptor variable gene segments, which can be divided into 12 families. Comparison of the J gene segments from the cDNAs to previously determined germline  $J_{\alpha}$  sequences places the number of  $J_{\alpha}$  gene segments over 21, and indicates their number to be ~55. Identical nucleotide sequences in independent isolates of  $V_{\alpha}$  and  $J_{\alpha}$  gene segments indicate that hypermutation may not be a common mechanism for the expansion of diversity in these genes, and suggest that the major source of diversity within the  $\alpha$  chain repertoire is a result of recombinational joinings between germline  $V_{\alpha}$  and  $J_{\alpha}$  sequences, combined with imprecise junctional joining. Analysis of the V regions of these  $\alpha$ chain messages reveals the presence of three domains of hypervariability roughly analogous to the CDR1, CDR2, and CDR3 regions of immunoglobulin.

We thank Beth Chin and Maurizio Laudisa for technical assistance, and Nicolette Caccia for comments on the manuscript.
