Shore and bar cross-shore migration, rotation, and breathing processes at an embayed beach

Key Points:

- Shoreline and bar migrations, mainly simultaneous, dominate the 2-D variations of morphology
- Shoreline and bar rotations do not respond to the same environmental drivers but often occur simultaneously
- Barline breathing occurs with an overall retreat or progradation of the shoreline and barline

Abstract A principal component analysis (PCA) is used to decompose data on the coupled morphodynamics of the shoreline and nearshore sandbar of a typical single-barred embayed beach (Tairua Beach, New Zealand). Dynamic patterns are classified into simultaneous modes, where the bar and shoreline move at the same time, and nonsimultaneous modes, where the shore moves independently from the bar, and vice versa. Two simultaneous modes accounting for 65% of the variance of the shoreline and barline dominate the system. One mode describes inverse shoreline and sandbar cross-shore migrations (alongshore averaged), occurring with simultaneous rotations in the same direction. The other mode accounts for migration in the same direction accompanied by variations of the barline curvature (similar to “breathing modes” previously described in embayed beach shoreline modeling studies). Two nonsimultaneous modes of lesser importance account separately for independent shoreline and barline rotations (10 to 15% of the variance explained). A PCA applied to the shore and sandbar behaviors modeled by four standard equilibrium models simulating shore and sandbar cross-shore migrations and rotations show that these are interrelated because of a correlation between wave energy and direction. Shore and bar rotations are coupled partially because the shape of the bay induces a correlation of their respective drivers, the wave angle of incidence and the alongshore gradient of wave energy. However, this correlation depends on the wave energy. This, in combination with different shore and sandbar response times (quantified using the models), also explains the independent rotations reflected by the nonsimultaneous modes.

1. Introduction

Embayed beaches are landforms typically found along rugged coastlines exhibiting rocky outcrops. Such headland-bay morphology, accounting for an estimated 50% of the world's coastline [Short, 1999], is also common in urban areas, where groins and breakwaters constitute artificial headlands that embay beach sediments (e.g., in Barcelona, Spain [Ojeda and Guillén, 2008]). Over the past decades, reduced sediment supply often related to river damming [Chaibi and Sedrati, 2009], and the progressive construction of dwellings on coastal dunes [Healy and Soomere, 2008], has increased the risks related to coastal erosion, in particular, in embayed environments [Flor and Flor-Blanco, 2005; Bryan et al., 2013]. Protecting these areas requires an enhanced understanding of their morphodynamics.

Beyond small-scale morphological patterns of sandy coastlines (e.g., beach cusps and rip channels), evolving over daily to weekly timescales [Almar et al., 2008; Gallop et al., 2011; Castelle and Coco, 2012; Stokes et al., 2015], the morphology of embayed beaches also vary at the scale of the embayment (O(1 km)). Related patterns develop over monthly to interannual timescales [Ojeda et al., 2011; Daly et al., 2015] and dominate beach behavior [Clarke and Eliot, 1982; Short and Trembanis, 2004; Ojeda et al., 2011; Loureiro et al., 2012; Turki et al., 2013a]. They typically account for the cross-shore migration and the rotation of the beach shoreline and nearshore sandbars [Ojeda and Guillén, 2008; Ojeda et al., 2011; van de Lageweg et al., 2013], as well as variations of their curvature [Loureiro et al., 2012; Ratliff and Murray, 2014].

Waves and flow circulations are drivers of embayed beach morphodynamics that are strongly controlled by the local geological setting (e.g., the extent and separation of the headlands that enclose the beach) [Short, 1999; Castelle and Coco, 2012; Daly et al., 2014]. This aspect is reflected in the embayed beach classification proposed by Castelle and Coco [2012], based on the ratio of embayment length to time-averaged surfzone width δ . For low values ($\delta < 6$), the geological setting dominates (e.g., high shoreline curvature and one central rip).

On the contrary, high values relate to long embayments where beaches exhibit typical open beach topographies with six or more rip channels. The present paper focuses on such a low-curvature embayed beach that in addition features a single nearshore sandbar.

Cross-shore migrations of the shoreline and nearshore sandbar reflect transitions toward more dissipative or more reflective states depending on the incident wave conditions [van Maanen *et al.*, 2008; Ojeda and Guillén, 2008; van de Lageweg *et al.*, 2013]. Recently, semiempirical models, based on a limited number of key primary processes, have been developed to explain and forecast the migration of the shoreline [Yates *et al.*, 2009; Davidson *et al.*, 2010, 2013; Splinter *et al.*, 2014; Jara *et al.*, 2015] and the nearshore sandbar [Plant *et al.*, 1999, 2006; Splinter *et al.*, 2011; Blossier *et al.*, 2016]. In essence, this type of migration models defines a time-varying equilibrium location of the shoreline (or barline) and a migration intensity that depends on the incoming wave energy.

Rotation results from a contrasting evolution of the beach profile at the extremities of the embayment related to different erosion or accretion rates. Shoreline rotation has been observed in embayments characterized by large δ values (La Barceloneta (Spain), $\delta = 24$ [Ojeda and Guillén, 2008; Turki *et al.*, 2013b]; Collaroy-Narrabeen (Australia), $\delta = 33$ [Harley *et al.*, 2011]; and Tairua [van de Lageweg *et al.*, 2013], which has a $\delta = 31$). A relation between shoreline rotation and alongshore sediment transport was shown by Clarke and Eliot [1982] and Turki *et al.* [2013a], using principal component analyses (PCAs) on upper beach sediment volumes and shoreline planform shapes, respectively. Castelle and Coco [2012] confirmed the role of alongshore transport at embayed beaches of intermediate lengths (1 to 4 km). However, Harley *et al.* [2011, 2015] showed that this concept may not always explain the rotation. Instead, varying cross-shore adaptations of the beach profile along the embayment can be related to alongshore gradients of wave energy, regardless of alongshore transport mechanisms. Blossier *et al.* [2016] showed that such gradient can also induce the rotation of nearshore sandbars at the embayment scale.

Cross-shore migrations and rotations of the shoreline and barline of a beach are processes that are rarely considered together. Research concerning shoreline and barline coupling has focused mainly on medium-sized morphological features such as rip channels (O(100 m)) [Coco *et al.*, 2005; Ruessink *et al.*, 2007; Castelle *et al.*, 2010a, 2010b; van de Lageweg *et al.*, 2013]. On a larger scale, at a double-barred embayed beach, Price and Ruessink [2011] showed that the state of the intertidal bar was influenced by the state of the subtidal bar. However, these studies did not assess if embayment-wide patterns such as cross-shore migrations, rotations, or changes of curvature, which dominate the beach variability at the scale of the embayment, are coupled. Early work has shown that shoreline and sandbars tend to migrate in opposite directions when the beach morphology evolves toward a reflective or dissipative state [e.g., Wright and Short, 1984]. More recently, Ojeda *et al.* [2011] and van de Lageweg *et al.* [2013] reported qualitatively that the shoreline and barline of an embayed beach tend to rotate in the same direction, but they also observed events showing opposite rotations. The connection between sandbar and shoreline has only been quantitatively explored through the study of single profiles [e.g., Roelvink and Brøker, 1993; van Rijn *et al.*, 2003; Grasso *et al.*, 2009; Ludka *et al.*, 2015]. Therefore, the context of the larger-scale embayment-wide coupling remains largely unexplored, even though these spatial scales are critical to understanding beach erosion and recovery.

Therefore, in this paper, we determine the degree to which large-scale shore and bar morphodynamics are coupled and under what forcing conditions such coupling occurs. This is achieved by isolating the dominant morphodynamic patterns of the shoreline and barline considered as one dynamic system using PCA. Our analysis does not presuppose any hypothesis about the shoreline and barline behaviors, but according to the literature, we expect them to account for cross-shore migration, rotation, and change of curvature, and we will assess to which extent this is the case. More fundamentally, the resulting PCA patterns will reveal whether shoreline and barline movements occur at the same time or not. If they do move together, in which case this provides evidence of coupling, we will assess whether this movement is in the same or opposite direction. Otherwise, if the movement does not occur in the shoreline and sandbar together, patterns will describe independent behaviors of the shoreline or barline. We will therefore discriminate between *simultaneous* patterns (coupled behaviors) and *nonsimultaneous* patterns (independent behaviors). After this identification, the potential environmental drivers of these simultaneous and nonsimultaneous patterns will be assessed.

We undertake our analysis at Tairua Beach, a typical example of a single-barred embayed beach located in the north island of New Zealand. Seven years of shoreline and barline positions derived from video imagery data, previously presented in van de Lageweg *et al.* [2013], are studied. To characterize dynamic patterns, this study

introduces a PCA method that has not been used in beach morphology studies, which allows for the combined decomposition of the shoreline and barline dynamics into coupled modes that describe their simultaneous and nonsimultaneous behaviors. To support the interpretation of these modes, standard PCAs are performed separately on the shoreline and barline data sets. Finally, we show that four equilibrium models for shoreline and barline migration and rotation can partially simulate the observed modes, enabling to associate the corresponding beach behaviors with the external wave conditions driving the models.

2. Study Area and External Conditions

2.1. Geological Characteristics

Tairua Beach is located at the east coast of the New Zealand north island, in the Coromandel peninsula (Figure 1). This peninsula is a region of ancient volcanic activity [Booden *et al.*, 2012], accounting for its rugged coastal topography. Along its eastern coastline, rocky shores are intersected by numerous embayed beaches resulting from local sediment supply by rivers or bypassing effects [Hart and Bryan, 2008].

Tairua Beach is 1.2 km long and enclosed between two headlands extending approximately 600 m seaward from the dune foot—Pumpkin Hill at the north and Paku Hill at the south. The beach is partly sheltered from waves by Shoe Island, located 3 km east of Paku Hill and extending over 1 km from south to north.

Tairua Beach is mainly facing easterly and northeasterly long-traveling swell and storm waves. Far offshore, significant wave heights are 1.4 m on average and can reach 6 m during storms [Smith and Bryan, 2007]. The beach, constituted of medium to coarse sand (d_{50} between 300 μm and 600 μm according to Smith and Bryan [2007], van Maanen *et al.* [2008], and our own surveys), is located in a microtidal environment with a tidal range varying between 1.2 and 2 m. Tairua features a single distinct shore-parallel sandbar and shows intermediate beach states mostly ranging from longshore bar and trough to transverse bar and rips [Bogle *et al.*, 2001; van Maanen *et al.*, 2008]. The lower shoreface slope is approximately 0.02 [Blossier *et al.*, 2016], whereas the upper beach slope is rather steep (≈ 0.2 [Smith and Bryan, 2007]). Transient intertidal bars can appear along Tairua Beach shoreline, but they are not taken into account in the present paper.

The beach exhibits regular successive progradation and retreat events as well as shoreline and barline rotations [van Maanen *et al.*, 2008; Bryan *et al.*, 2013; van de Lageweg *et al.*, 2013; Blossier *et al.*, 2016]. Smaller-scale morphological features have also been observed such as beach cusps [Almar *et al.*, 2008] and rip channels [Gallop *et al.*, 2011].

2.2. Wave Data in the Bay of Plenty

There is no permanent wave buoy or other instrument deployed in the vicinity of Tairua Beach, but one buoy has been collecting deep water wave data since 2003, 90 km south of Tairua. It is maintained by the Bay of Plenty Regional Council (BoPRC) and provides continuous bulk wave spectrum parameters every hour since then (B, Figure 1b).

To obtain the wave characteristics at Tairua Beach, a regional wave model was set up in SWAN [Booij *et al.*, 1999] and applied for the Bay of Plenty, nested within the global WaveWatch III hindcast model from the National Oceanic and Atmospheric Administration (NOAA). The main surface driver of the SWAN model is the new Climate Forecast System Reanalysis data set of hourly 0.5° spatial resolution winds from the National Centers for Environmental Prediction. The model was calibrated using the data of the BoPRC buoy (R^2 between 0.7 and 0.9, Relative Mean Absolute Error, RMAE, below 0.1 for the significant wave height H_s and mean wave period T_m , $R^2 = 0.5$ for the wave angle of incidence, increasing to 0.7 for $H_s > 0.7$ m).

To further validate the model in the domain of interest, observations were collected during three 6 week periods in March to April, August to September, and October to November 2011 at three different locations in the vicinity of Tairua Beach, at 8 m depth. S4 instruments (InterOcean) measured pressure and horizontal velocities (PUV) at the extremities of Tairua Beach and immediately south of Paku Hill (S4_N, S4_S, and S4_P, Figure 1d). Comparing the model with observations, R^2 is between 0.5 and 0.8 for H_s , with a root-mean-square error, RMSE, between 0.1 and 0.2. R^2 is below 0.5 for the wave angle of incidence. However, R^2 falls between 0.4 and 0.7 for the wave energy E_y available for alongshore sediment transport ($E_y = E \cos(\theta) \sin(\theta)$, with E the wave energy [Komar and Inman, 1970]). This improvement is potentially due to the fact that E_y minimizes the role of the smallest waves for which the angle of incidence is not simulated as well as for higher waves. H_s and E_y at Tairua Beach are presented in Figure 2.

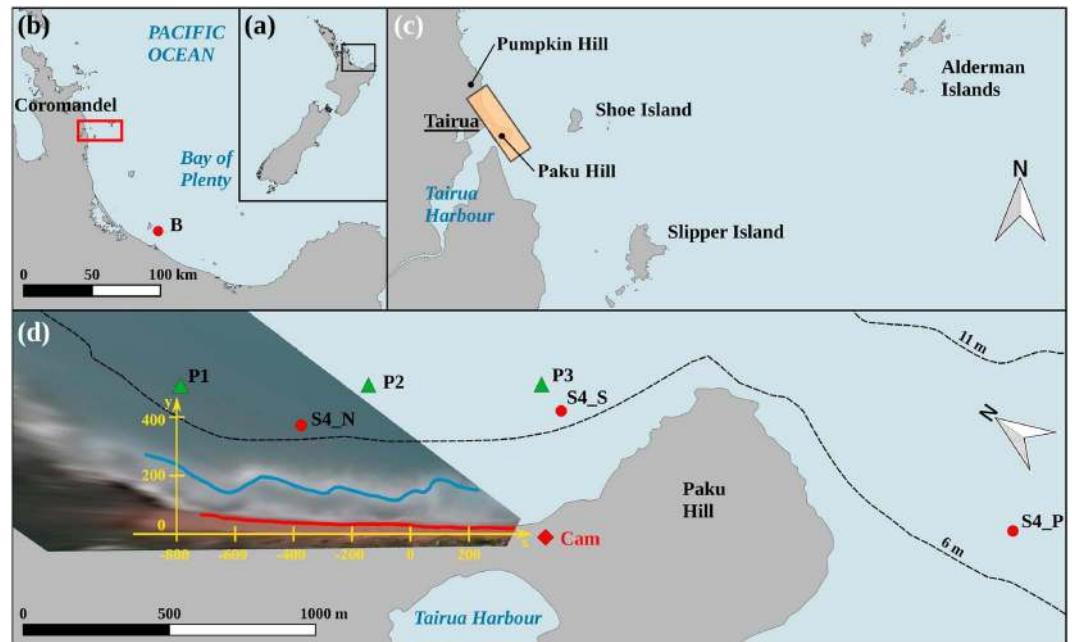

Figure 1. Location of Tairua (c) on the Coromandel peninsula (b) in the north island of (a) New Zealand. The yellow rectangle in Figure 1c shows the area of study which is represented rotated and in detail in Figure 1d. Red dot B in Figure 1b indicates the BoPRC wave buoy location. (d) Red dots S4_N, S4_S, and S4_P show the locations of the S4 used to validate the wave model. Example of extracted barline (27 June 2003, blue) and shoreline (25 June 2003, red) are depicted in Figure 1d over a georectified low tide image taken on 27 June 2003 and the local reference frame (yellow axes). Dashed lines indicate the 6 and 11 m depth contour lines compared to msl.

2.3. Shoreline and Barline Data

A video camera was installed in 1998 at Tairua Beach (Cam-Era network, National Institute for Water and Atmospheric Research, NIWA, Figure 1d), approximately 50 m above mean sea level (msl). Seven years of day-light hourly time exposure (timex) images (600 images averaged over 15 min) are used in the present study, from 1999 to 2005.

Figure 2. Significant (a) wave height H_s , (b) wave energy available for alongshore sediment transport E_y , and (c) alongshore wave energy gradient $\nabla_x(E)$ modeled at Tairua Beach for the study period ($E_y > 0$ relates to southward directed transport). Gray areas represent Events I, II, III, and IV.

Shoreline and barline cross-shore positions have been extracted from the georectified timex images in *van de Lageweg et al.* [2013]. In agreement with *Plant et al.* [2007], shoreline elevations η_s required for the georectification included the tidal level (NIWA numerical model [*Walters et al.*, 2001]), and a wave runup correction [*Bowen et al.*, 1968]. Images corresponding to a runup above 1.5 m were discarded. Below 1.5 m, computed runup values agree with those computed following the more recent work of *Stockdon et al.* [2006] (maximum difference of 20 cm in the vertical, creating a shoreline difference of 1 m in the horizontal which is small compared to the patterns we are studying (see error discussion below)). To limit the influence of the tides on the runup, only high tide images were selected (tidal level between 0.2 and 0.6 m above msl) following *Guedes et al.* [2011]. In the present study, a shoreline is defined as the contour line located 0.9 m above Mean High Water Neap tidal level, i.e., 1.5 m above msl. Using a tolerance of 25 cm ($1.25 \text{ m} < \eta_s < 1.75 \text{ m}$ above msl), 1272 shorelines are selected, resulting in a shoreline reading every 2 days on average. Barlines are extracted at the location of wave breaking, observed as white bands on the timex images. Only low tide images are used when the wave breaking needed to detect barlines was maximized (tidal levels falling between -1 and -0.5 m), resulting in 739 lines, i.e., a barline reading every 3.5 days on average. Shoreline and barline data sets are extracted in the same local reference frame (Figure 1d). A weekly moving average is applied to the data sets to filter out the noise introduced by the digitization and by small potential errors in the water level assessment. To allow for combined analysis, the averaged data sets are linearly interpolated over a 12-hourly time frame, resulting in signals $S(x, t)$ (shorelines) and $B(x, t)$ (barlines) presented in Figures 3a and 3b. In this figure, brown relates to more accreted beach states (accreted shoreline, nearshore barline location) while blue relates to more eroded states (eroded shoreline, offshore barline location).

At intermediate scales, rip channels (which cause undulations in the shoreline and barline) emerge, grow, and disappear along the shoreline (e.g., from December 2001 until July 2002) and the barline (e.g., from September 2000 until July 2002). These shoreline and barline undulations can exhibit a coupling reflected by identical wavelengths (e.g., January 2002), studied in *van de Lageweg et al.* [2013]. At the scale of the embayment, large migration (shoreward and seaward movement) and rotation events occur. To characterize these processes, a linear fit of each extracted shoreline and barline planform shape was performed to compute their alongshore-averaged cross-shore position S_0 and B_0 , and their orientation α_s and α_b (subscripts s and b stand for shoreline and barline, respectively). They are presented in Figures 3c–3f.

The shoreline and barline position and orientation errors were smaller than the patterns on which our study is based. The error for the shoreline position is evaluated by combining the influence of the cross-shore pixel footprint of the georectified images (maximum 0.7 m), the standard deviation of the selected water levels after moving average (± 0.07 m vertically that converts to ± 0.35 m horizontally considering an upper beach slope of 0.2), the uncertainty in wave runup ($+ 0.5$ m and -0.6 m vertically that converts to $+ 2.5$ m and $- 3$ m horizontally [*Bowen et al.*, 1968; *Stockdon et al.*, 2006]), and the possible influence of the tides [*Guedes et al.*, 2011]). All together, the error falls between $+ 3.50$ m and -4 m. The shoreline orientation error was induced by the pixel footprint and the uncertainty in runup (the absolute setup and the tidal level do not cause alongshore variations in error), i.e., 4.4×10^{-3} (all angles given in radians). With a video camera system similar to the system on Tairua Beach, *van Enckevort and Ruessink* [2001] and *Ruessink et al.* [2009] assessed the error in measuring nearshore sandbar locations. Their error was below 10 m, before they would apply corrections for the influence of water level and wave height. This value of 10 m also agrees with the barline observations of *Ribas et al.* [2010]. Therefore, 10 m, already used in *Blossier et al.* [2016], is also used in the present study to assess the influence of error in barline cross-shore position. This results in a barline orientation error of 0.017. For the shoreline and barline orientations, as well as for the barline cross-shore position, the error is less than half the standard deviation of the signal (Table 1). As a result, most of the fluctuations of α_s , B_0 , and α_b are significant compared to the evaluated errors (Figures 3d–3f). For the shoreline cross-shore position S_0 , the error is between a half and one standard deviation, due to the uncertainty related to the runup extent. This does not alter the results of the present study (effect of errors on the results presented here are evaluated in more detail in Appendix A).

Four events have been selected to illustrate the beach behavior (Figure 3). Events I and IV show transitions from more reflective toward more dissipative states with strong erosion of the shoreline (-15 m and -10 m) and large offshore migrations of the barline ($+50$ m and $+60$ m). These migrations are accompanied by strong rotations of the barline in the clockwise direction, mainly due to larger offshore migration of the barline at the north compared to the south (Figure 3b). Shoreline rotation occurs in the same direction but is much smaller. Event II shows part of the transition of the beach toward more reflective states with progradation

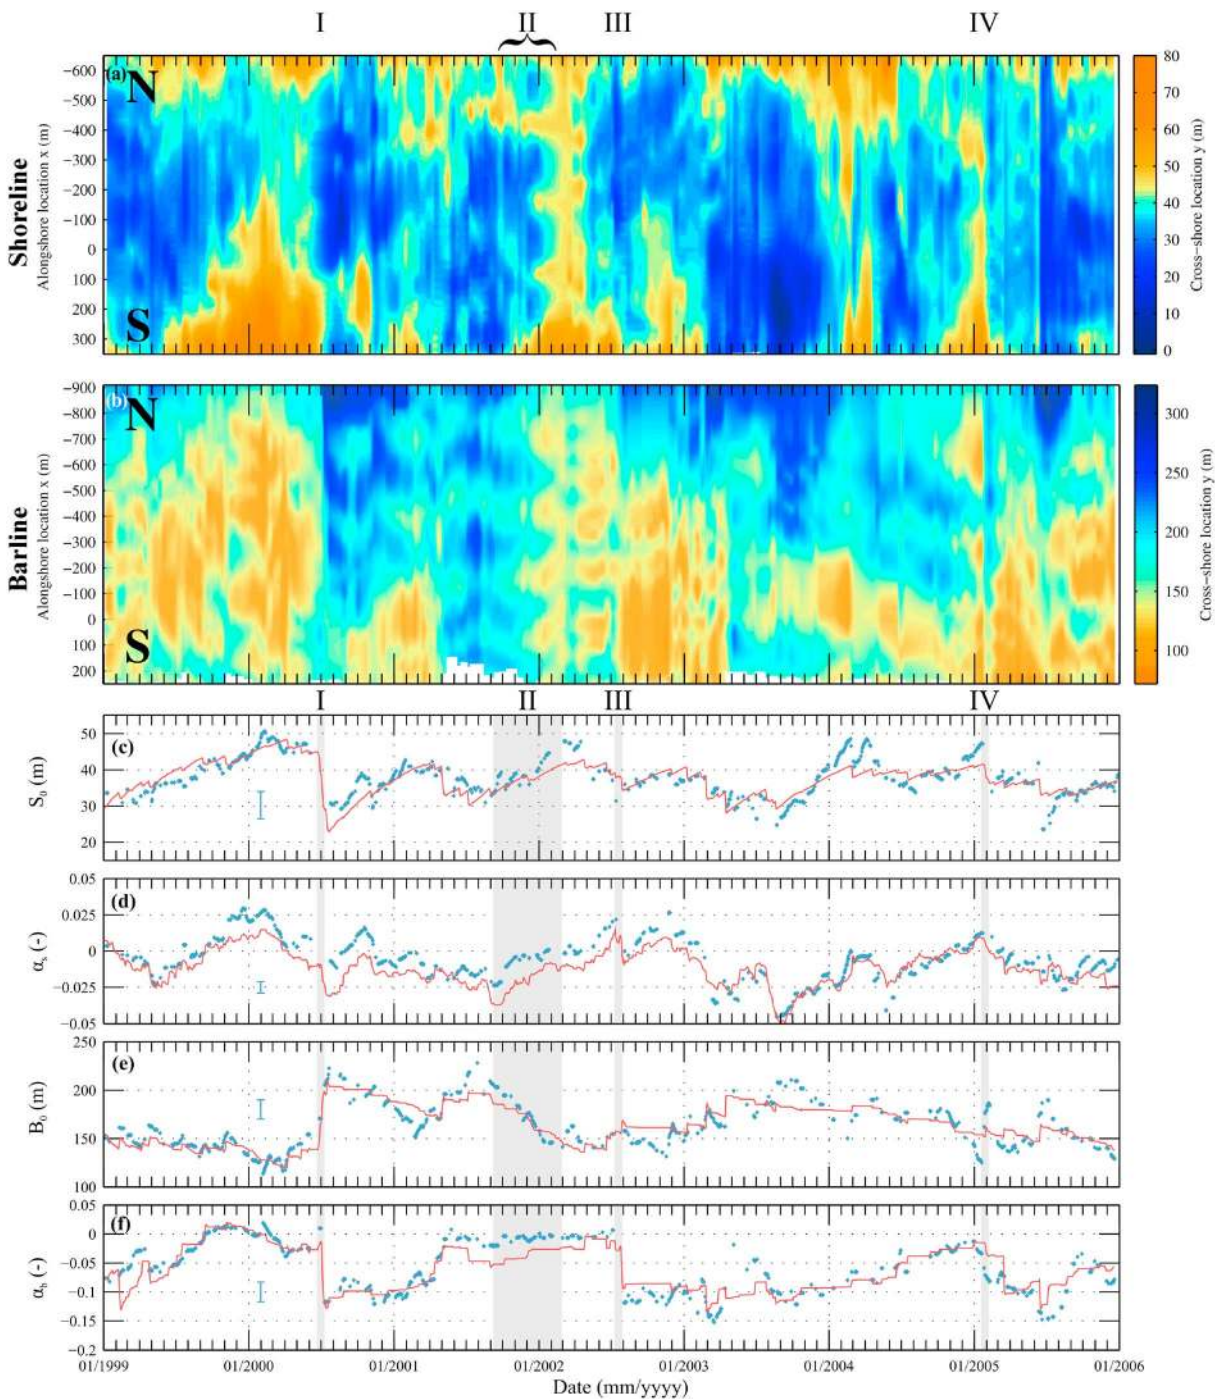

Figure 3. (a) Shoreline $S(x, t)$ (1.5 m above msl) and (b) barline $B(x, t)$ planform shapes derived from 7 years of camera imagery at Tairua Beach [van de Lageweg *et al.*, 2013]. Note that color scales are different for both panels. Observations (blue dots) and semiempirical models results (red lines) for (c) alongshore-averaged shoreline cross-shore position S_0 , (d) shoreline orientation α_s , (e) barline cross-shore position B_0 (e), and (f) barline orientation α_b . Gray areas represent Events I, II, III, and IV. Error bars represent the measurement errors mentioned in the text.

Table 1. Minimum, Maximum, and Standard Deviation of S_0 , α_s , B_0 , and α_b (Figures 3c–3f) and Model Skills for 7 Year Calibrated Shoreline and Barline Parameters

Parameter	Min	Max	σ	RMSE	R^2	Bss
S_0	24.7	50.5	5.3	3.2	0.67	0.64
α_s	−0.05	0.03	0.02	0.010	0.79	0.62
B_0	113.5	228.2	23.7	11.8	0.75	0.75
α_b	−0.15	0.02	0.05	0.022	0.77	0.77

of the shoreline (+15 m) and shoreward migration of the barline (−50 m). During this accretionary sequence, the shoreline rotates in the counterclockwise direction (+0.025) and the barline orientation is nearly stable (note also the development of rip channels). In contrast with Events I, II, and IV, Event III exhibits very little migration of the shoreline and barline; however, large clockwise rotations are observed for the shoreline (−0.025) and the barline (−0.125).

Other large-scale morphodynamic processes can be observed such as the variability of the curvature of the shoreline and barline. In Figures 3a and 3b, a large curvature can be characterized by a central area of the shoreline (or barline) that is located more seaward, or more shoreward, than its two extremities (e.g., June 1999 until June 2000 and February to April 2004 for the shoreline; e.g., June 1999 until June 2000 and May 2003 until January 2004 for the barline). Low curvature can be characterized by similar cross-shore positions of the extremities and central areas (e.g., February 1999, January 2002, and June 2005 for the shoreline; e.g., March 1999, February to June 2002, and January 2005 for the barline). These patterns can sometimes be hidden by medium-scale patterns such as undulations or superimposed large-scale patterns such as shoreline or barline obliquity observed after rotation events, which can make them difficult to identify.

3. Analysis Methodology

3.1. Principal Component Analyses

PCA has been widely used to characterize dominant modes of dynamic systems where multiple patterns occur together such as Tairua Beach. Examples of use include beach profiles [Winant *et al.*, 1975; Wijnberg and Terwindt, 1995; Karunathna *et al.*, 2012; Ludka *et al.*, 2015; Kuriyama and Yanagishima, 2016], shoreline planforms [Miller and Dean, 2007a; Hansen and Barnard, 2010; Harley *et al.*, 2011; Turki *et al.*, 2013b], and alongshore bar patterns [Lippmann and Holman, 1990; Dai *et al.*, 2008]. In this paper, PCA is used to reveal the simultaneity of the shoreline and barline dynamics at Tairua Beach by identifying coupled shoreline and barline patterns. PCA is well-suited for this purpose since it can extract such patterns without assuming anything about their nature a priori.

A PCA decomposes a two-dimensional signal into two separate sets of orthogonal vectors. A pair of equally ranked vectors in each set constitute a *mode* (i.e., a dynamic pattern). In the usual PCA approach in climate and morphodynamics studies, one signal dimension is often temporal, while the other is usually physical (e.g., the alongshore position). Short and Trebanis [2004], Alvarez-Ellacuria *et al.* [2011], Turki *et al.* [2013a], and Harley *et al.* [2011] focused on such 2-D signals (shoreline cross position defined as a function of time and alongshore position). They extracted a small number of modes (usually 2), which together often explained more than 80% of the shoreline variability. In this paper, this approach (hereafter referred to as Method 1, Figure 4) leads to two independent decompositions for the demeaned and normalized shoreline and barline signals, $\hat{S}(x_s, t)$ and $\hat{B}(x_b, t)$, respectively:

$$\hat{S}(x_s, t) = \sum_i \lambda_{s,i} c_{s,i}(t) e_{s,i}(x_s), \quad (1)$$

$$\hat{B}(x_b, t) = \sum_i \lambda_{b,i} c_{b,i}(t) e_{b,i}(x_b) \quad (2)$$

with λ scalars with no unit (\hat{S} and \hat{B} are normalized), c temporal vectors, and e spatial vectors. Subscript i refers to the mode rank, and subscript s (b) refers to shoreline (barline). For instance, the pair of equally ranked vectors $c_{s,i}$ and $e_{s,i}$ constitutes mode $M_{s,i}$ and describes a dynamic pattern. The contribution of mode $M_{s,i}$ and its associated pattern to the variance of $\hat{S}(x_s, t)$ is expressed by $\lambda_{s,i}^2$, since modes are orthogonal and the sum of $\lambda_{s,i}^2$ is 1 (due to the normalization). This method extracts the dominant patterns of the shoreline and barline

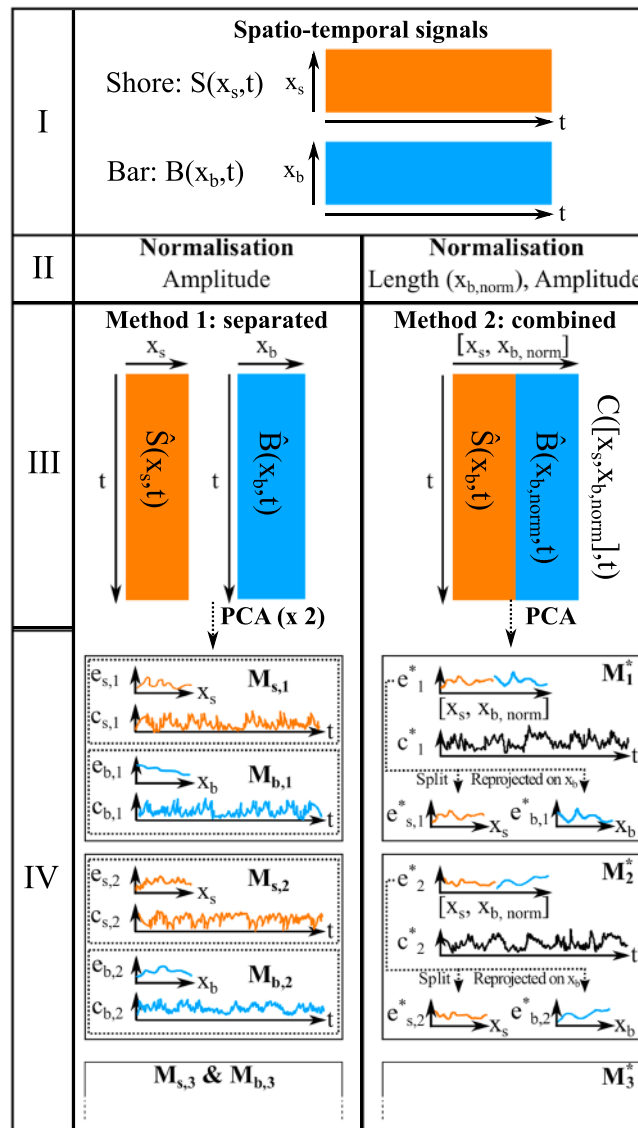

Figure 4. Description of the two methods used in the present paper to perform PCA on the shoreline and barline signals. I: shoreline and barline signals as depicted in Figures 3a and 3b. II: normalization of the signals. III: stacking of the shoreline and barline arrays for Method 2. IV: Extraction of the modes with their spatial vectors and associated time functions. Method 1: the shoreline and barline are decomposed into separated modes $M_{s,i}$ and $M_{b,i}$, each with their spatial vector ($e_{s,i}$ and $e_{b,i}$) and time function ($c_{s,i}$ and $c_{b,i}$). Method 2: modes are extracted for the stacked {shoreline-barline} signal. For each mode M_i^* , the spatial vector e_i^* and time function c_i^* account for both the shoreline and barline. Vector e_i^* is split into two parts related to the shoreline ($e_{s,i}^*$) and to the barline ($e_{b,i}^*$) for readability.

behaviors separately without considering their interrelation. In this study, the significance (95%) level of each PCA mode is established using the rule of thumb of North *et al.* [1982], and a Monte Carlo approach using surrogate red noise spectra. Autocorrelation in signals is taken into account following Zwiers and von Storch [1995]. More details can be found in Appendix B.

However, Method 1 does not allow for the PCA to identify simultaneous and nonsimultaneous shoreline and barline behaviors. Therefore, a second approach (hereafter referred to as Method 2, Figure 4) is proposed, in which the PCA is applied to a 2-D signal that accounts for the variability of both the shoreline and barline. For this, $\hat{B}(x_b, t)$ is further normalized so that it can be expressed in the same scale of variation as $\hat{S}(x_s, t)$, giving $\hat{B}(x_{b, norm}, t)$, where $x_{b, norm}$ is a spatial vector of the same size as x_s (Figure 4, II). This ensures that $\hat{S}(x_s, t)$ and $\hat{B}(x_{b, norm}, t)$ contain identical amounts of variability. This is critical since without complete normalization, the PCA decomposition would be controlled by the variance of the barline, which is an order of magnitude above

the variance of the shoreline. Then, $\hat{S}(x_s, t)$ and $\hat{B}(x_{b,\text{norm}}, t)$ are stacked along the spatial dimension, resulting in one signal $C([x_s, x_{b,\text{norm}}], t)$ (Figure 4, III). This method of stacking is commonly used in applying PCA to 3-D (two spatial, one time) measurements such as atmospheric pressure [Hannachi et al., 2007]. Finally, a standard PCA is applied on C :

$$C([x_s, x_{b,\text{norm}}], t) = \sum_i \lambda_i^* c_i^*(t) e_i^*([x_s, x_{b,\text{norm}}]), \quad (3)$$

$$e_i^*([x_s, x_{b,\text{norm}}]) = \begin{bmatrix} e_{s,i}^*(x_s) \\ e_{b,i}^*(x_{b,\text{norm}}) \end{bmatrix} \quad (4)$$

with superscript $*$ standing for this second method and $[,]$ indicating stacked vectors or signals. The PCA outcome is therefore a set of stacked shoreline and barline vectors e_i^* and a set of corresponding temporal vectors c_i^* that constitute modes M_i^* (Figure 4, IV). The stacked vectors e_i^* are split into shoreline and barline shapes ($e_{s,i}^*$ and $e_{b,i}^*$, respectively) to assist in interpretation and to allow comparison with the first method. In the following, $e_{b,i}^*(x_{b,\text{norm}})$ is expressed on x_b for easier comparison with $e_{b,i}$, with the same notation $e_{b,i}^*$. With this method, shoreline and barline vectors of same rank i , $e_{s,i}^*$ and $e_{b,i}^*$ correspond to the same mode M_i^* and single temporal vector c_i^* (Figure 4, IV). A key implication is that the temporal variations of the shoreline and barline shapes occur simultaneously.

This is not sufficient to conclude that the shoreline and barline behavior described by mode M_i^* is simultaneous. For instance, an independent behavior of the shoreline could be captured by a mode M_i^* in which the part describing the barline behavior is true but trivial. In other words, the shoreline part of the mode, $e_{s,i}^*$ and c_i^* , would explain a significant amount of the variability of the shoreline (above 5%) while the barline part of the mode, $e_{b,i}^*$ and c_i^* , would be nonsignificant (below 5%).

In the following, M_i^* is defined as a *simultaneous mode* and therefore describes a simultaneous dynamic pattern of the shore and bar, if it explains more than 5% for both the shoreline and the barline variability. On the contrary, if the amount of variability explained by M_i^* is above 5% for the shoreline only (or for the barline only), then M_i^* describes a dynamic pattern of the shoreline only (or barline only) and is therefore named a *nonsimultaneous mode*.

3.2. Identification of Drivers

Different methods were used in the literature to relate dynamic patterns to external forcing conditions. For instance, Miller and Dean [2007b] and Harley et al. [2011] studied the correlations between PCA temporal vectors and external forcing conditions, while Larson et al. [2000] and Ruiz de Alegria-Arzaburu et al. [2010] used a linear statistical procedure, the Canonical Correlation Analysis. These methods assume that the temporal behavior of the extracted modes depends linearly on forcing conditions. However, it has been shown that the response of a beach to varying external conditions can be influenced by its present state [Miller and Dean, 2004; Yates et al., 2009; Sénéchal et al., 2015] and can be strongly nonlinear [Splinter et al., 2011; Blossier et al., 2016].

Therefore, in this paper, we use another approach. The two PCA methods applied to the data are also applied to the alongshore-averaged cross-shore position and orientation of Tairua Beach shoreline and barline, when simulated by four equilibrium models. Resulting *model-based* modes and vectors are marked with a tilde (e.g., \tilde{M}_i^* , $\tilde{e}_{s,i}^*$). If *data-based* modes (e.g., M_i^*) and *model-based* modes (e.g., \tilde{M}_i^*) are similar, then not only the models will explain some of the variance of the data-based modes induced by migration and rotation but these two processes will be found to be sufficient to explain the dominant behavior of Tairua Beach. In addition, the simple formulation of the equilibrium models will allow for a limited number of wave forcing parameters (e.g., wave height, period, and angle of incidence) to be associated with a large-scale dynamic pattern of the beach (potentially composed of mixed migration, rotation, and change of curvature of the shoreline and/or barline).

Short descriptions of the four semiempirical models used to simulate the alongshore-averaged cross-shore position and orientation of the shoreline and barline at Tairua Beach are given here, while details can be found in Appendix C.

The model of Yates et al. [2009], describing the *shoreline alongshore-averaged cross-shore position* S_0 , is adapted by using only one free coefficient instead of different ones for shoreline accretion and erosion, and by allowing

for a linear trend of S_0 . This trend accounts for accretion or erosion processes that are not related to wave-induced cross-shore transport, similar to Davidson *et al.* [2013]. The model is

$$\frac{d\tilde{S}_0}{dt} = C_s \sqrt{E} (E - p_s \tilde{S}_0 - p_s q_s t - r_s) + q_s \quad (5)$$

where C_s ($m^2 s^{-1}$), p_s (m), q_s (ms^{-1}), and r_s (m^2) are free constant coefficients of the model, E (m^2) is the alongshore-averaged incident wave energy at time t , and \tilde{S}_0 (m) is the modeled S_0 .

The second model relates the shoreline rotation rate to the amount of wave energy available for alongshore sediment transport [Komar and Inman, 1970], defining the equilibrium orientation of the shoreline as the normal to the wave angle of incidence θ [Turki *et al.*, 2013b]. For small values of the shoreline orientation α_s , the model formulation becomes:

$$\frac{d\tilde{\alpha}_s}{dt} = C_{\alpha_s} E [\sin(\theta) \cos(\theta) - \tilde{\alpha}_s \cos(2\theta)], \quad (6)$$

where C_{α_s} ($m^2 s^{-1}$) is a free coefficient of the model and $\tilde{\alpha}_s$ (–) the modeled α_s .

The barline parameters are modeled by semiempirical models developed and validated in Blossier *et al.* [2016]. The barline alongshore-averaged cross-shore position B_0 is described by

$$\frac{d\tilde{B}_0}{dt} = C_b \sqrt{E} (E - (a_b \tilde{B}_0 + b_b)) f_b(H_s, H_b), \quad (7)$$

$$f_b(H_s, H_b) = \min \left(\left[\frac{H_s}{H_b} \right]^p, 1 \right) \quad (8)$$

with f_b (–) is a morphodynamic damping factor related to the morphodynamic activation of the bar and depending on the ratio of offshore significant wave height at 8 m depth (H_s (m)) over the breaking wave height at the bar crest (H_b (m)). Coefficient p is equal to 8, and C_b ($m^2 s^{-1}$), a_b (m), and b_b (m^2) are free coefficients of the model. \tilde{B}_0 (m) is the modeled B_0 .

The model of Blossier *et al.* [2016] suggests that the barline orientation α_b is controlled by the alongshore gradient of wave energy along the embayment $\nabla_x(E)$ (i.e., lower wave energy relates to the bar being closer to the shore and vice versa):

$$\frac{\partial \tilde{\alpha}_b}{\partial t} = C_{\alpha_b} \left[\sqrt{E} (\nabla_x(E) - \delta_b a_b (\tilde{\alpha}_b - \alpha_{eq})) + \frac{1}{2\sqrt{E}} \nabla_x(E) (E - (a_b \tilde{B}_0 + b_b)) \right] f_b(H_s, H_b) \quad (9)$$

where C_{α_b} ($m^2 s^{-1}$), δ_b (–), and α_{eq} (–) are free parameters of the model and the values of a_b and b_b are determined during the calibration of the migration model (equation (7)). $\tilde{\alpha}_b$ (–) is the modeled α_b .

The significant wave height and the incident wave angle required to run the models are extracted from the wave model output at point P2 (Figure 1d). To run the barline rotation model driven by the alongshore gradient of wave energy along the embayment (Figure 2c), significant wave heights are extracted at points P1 and P3 (Figure 1d).

The hindcasts of the four semiempirical models calibrated over the 7 year data set are presented in Figures 3c–3f. The four semiempirical models simulate alongshore-averaged cross-shore positions and orientations of the shoreline and barline with fair to good skills. In each case, about 70% of the variance is explained (Table 1), and Brier skill scores fall between 0.6 and 0.8 (a fair to good fit, according to van Rijn *et al.* [2003]). The performance of the models is similar to the studies of Yates *et al.* [2009], Davidson *et al.* [2013] and Splinter *et al.* [2014] (shoreline migration), Plant *et al.* [1999] and Splinter *et al.* [2011] (barline migration), and Turki *et al.* [2013b] (shoreline rotation). Details on the calibration, validation, and performance are provided in Appendix C (shoreline) and Blossier *et al.* [2016] (barline).

Although a correlation study would be sufficient to evaluate the amount of variability of modes $M_{s,j}$, $M_{b,j}$, and M_j^* that can be explained by the equilibrium models, applying the PCA to the models' outcomes will allow us to assess if the models are able to simulate the dynamic patterns described by $M_{s,j}$, $M_{b,j}$, and M_j^* , i.e., if they capture and describe the dominant scales of motion of the beach. To perform these PCAs, the modeled

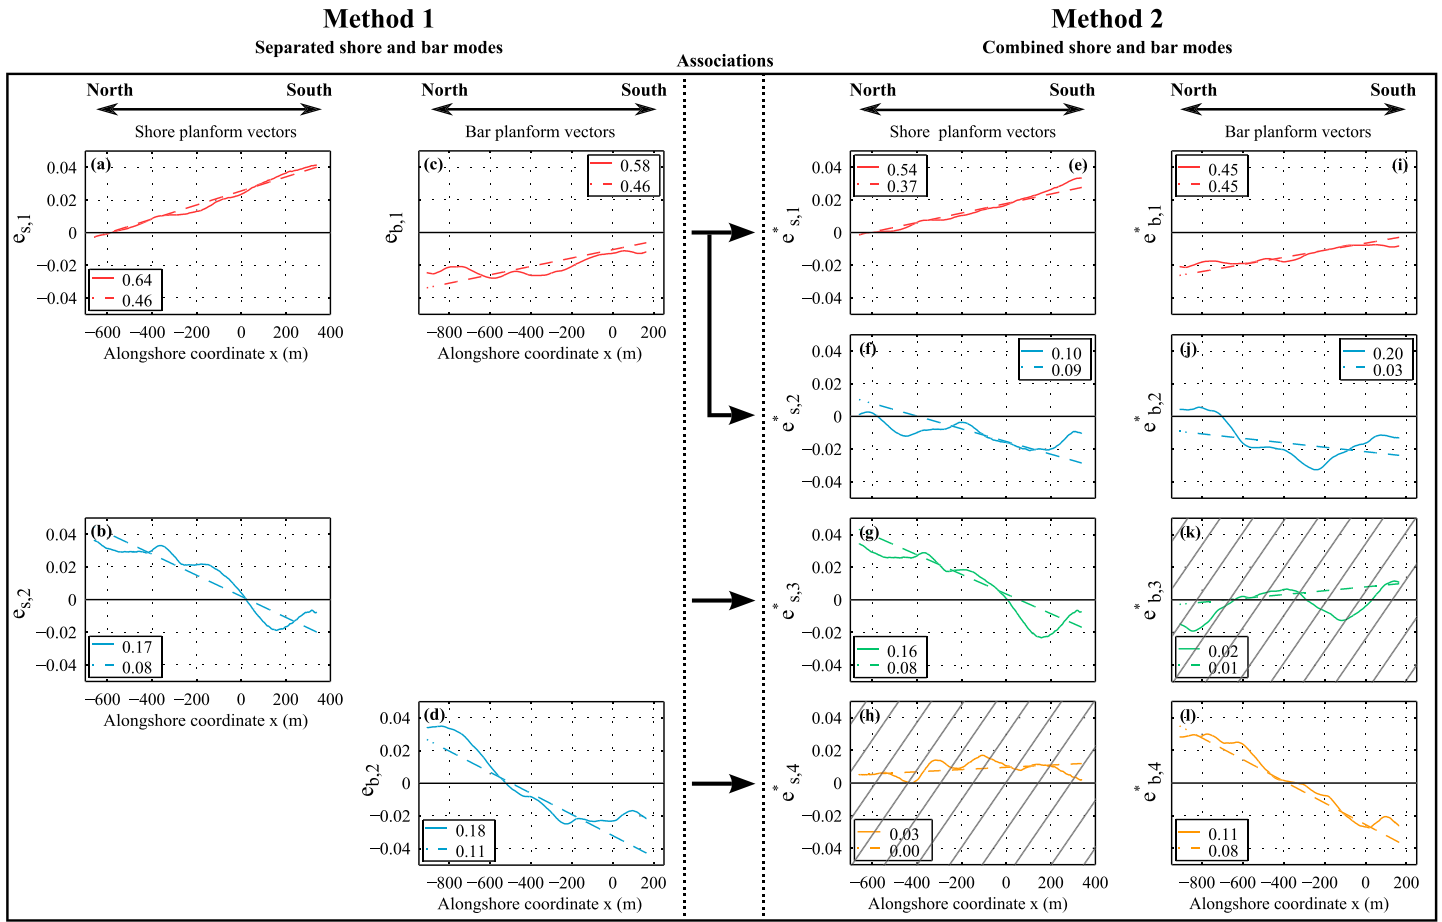

Figure 5. First and second spatial vectors computed for the shoreline ((a) $e_{s,1}$; (b) $e_{s,2}$) and the barline ((c) $e_{b,1}$; (d) $e_{b,2}$) using Method 1. Four first spatial vectors computed for the shoreline ((e–h) $e_{s,j=1-4}^*$) and the barline ((i–l) $e_{b,j=1-4}^*$) using Method 2. Solid lines are related to observed data. Dashed lines are related to modeled data. The amount of shoreline and barline variability explained by the modes is given in the legends (R^2). Spatial vectors associated with data-based modes explaining less than 5% of variability are hatched. Black arrows in the center indicate the associations of modes issued from Method 1 and Method 2 as described in the text.

shoreline and barline two-dimensional signals, $\tilde{S}(x, t)$ and $\tilde{B}(x, t)$, respectively, are reconstructed based on \tilde{S}_0 and $\tilde{\alpha}_s$ (shoreline), and \tilde{B}_0 and $\tilde{\alpha}_b$ (barline):

$$\tilde{S}(x, t) = \tilde{S}_0(t) + (x - L_s/2)\tilde{\alpha}_s(t), \tag{10}$$

$$\tilde{B}(x, t) = \tilde{B}_0(t) + (x - L_b/2)\tilde{\alpha}_b(t), \tag{11}$$

with L_s and L_b the alongshore positions of the centers of the shoreline and barline observation areas, respectively.

4	4	-	-	-	5	-	-	-	3	2	-	-	11	-	10	-

^aFor each mode, a cell contains successively R^2 values for the overall signal (R^2), its migration (R_M^2), its rotation (R_R^2), and its change of curvature (R_U^2) (with $R^2 \geq R_M^2 + R_R^2 + R_U^2$). Values corresponding to modes presented in Figure 5 are shown in bold.

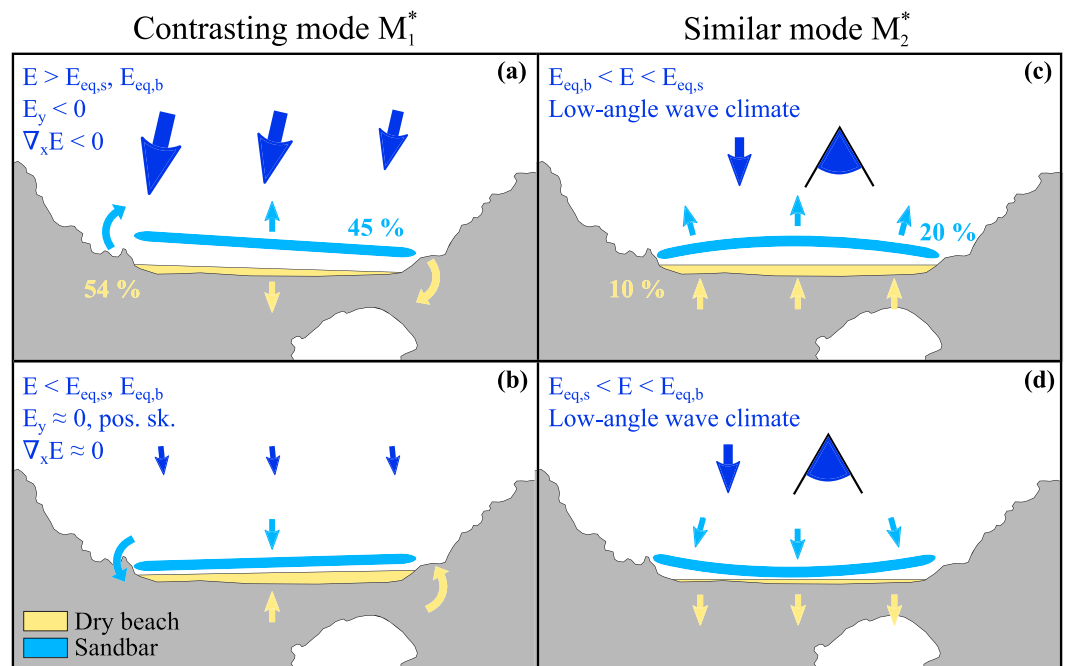

Figure 6. Schematic representations of dominant shore and bar behaviors observed at Tairua (simultaneous modes M_1^* ((a) $c_1^* < 0$; (b) $c_1^* > 0$) and M_2^* ((c) $c_2^* < 0$; (d) $c_2^* > 0$)). Percentages indicate the amount of variability explained by each mode for the shoreline (yellow) and barline (light blue). Arrows of the same colors indicate migration, rotation, and breathing patterns. Dark blue arrows and angular sectors relate to relevant wave climate properties described in each top left corner (pos. sk. = positive skewness).

4. Results

4.1. Method 1: Separated Modes

PCA was first applied independently to the 7 year shoreline and barline data sets following Method 1. Spatial vectors $e_{s,i}$ and $e_{b,i}$ of the first two modes $M_{s,i}$ and $M_{b,i}$ are presented in Figures 5a–5d. In addition, a decomposition of the amount of variability explained by each PCA mode (R^2) in terms of migration (R_M^2), rotation (R_R^2), and change of curvature (R_U^2) is given in Table 2 (details on the computation method are provided in Appendix D).

Modes $M_{s,1}$ and $M_{s,2}$ account for 64 and 17% of the shoreline variability, respectively (Figures 5a and 5b). They both account for shoreline movement that is a combination of migration and rotation (see R_M^2 and R_R^2 in Table 2). According to the dominant mode $M_{s,1}$, the shoreline tends to rotate counterclockwise when it accretes (positive slope and positive alongshore-averaged value of $e_{s,1}$), and vice versa (when the corresponding temporal vector, $c_{s,1}$, becomes negative).

Modes $M_{b,1}$ and $M_{b,2}$ account for 58 and 18% of the barline variability, respectively (Figures 5c and 5d). According to Table 2, $M_{b,1}$ describes barline movement that is dominated by migration and account for little rotation and change of curvature (the barline tends to rotate clockwise when it migrates seaward, with its center migrating further offshore, and vice versa). $M_{b,2}$ describes a rotation which is well separated from barline migration (explained by $M_{b,1}$) and accounts for curvature variations.

The results of the PCAs applied to $\tilde{S}(x, t)$ and $\tilde{B}(x, t)$ (shoreline and barline signals simulated by the equilibrium models) are also presented in Figure 5 (dashed lines). There is a general good agreement between the model- and data-based spatial vectors $\tilde{e}_{s,i}$, $e_{s,i}$ and $\tilde{e}_{b,i}$, $e_{b,i}$. Model-based modes necessarily describe less shoreline or barline variability (about 20 to 30% less) as they do not account for spatial alongshore variability other than the overall shoreline or barline oblique orientation.

4.2. Method 2: Combined Modes

PCA is then performed on the stacked shoreline and barline signal (Method 2). In this case, spatial vectors $e_{s,i}^*$ and $e_{b,i}^*$ share the same temporal vectors c_i^* , so that modes M_i^* characterize dynamic shoreline and barline patterns. The four first modes $M_{i=1-4}^*$ of the combined PCA analysis (Method 2) are presented in Figure 5.

Table 3. Correlations (r) Between Model- and Data-Based Temporal Vectors ($c_{s,i}$ and $\tilde{c}_{s,i}$, $c_{b,i}$ and $\tilde{c}_{b,i}$, and c_i^* and \tilde{c}_i^*)^a

Mode nb.	Shore	Bar	Shore & Bar
1	0.85	0.89	0.90
2	0.70	0.84	0.70
3	−0.02	−0.09	0.70
4	−0.11	0.03	0.75

^aCorrelations above 0.70 are indicated in bold.

Subsequent modes explain little variability and are therefore ignored in the present study. Note that R^2 values in Figure 5, Method 2, do not refer to the variability of the stacked shore and bar signal but were recomputed separately for the shoreline and for the barline, after the PCA. They can therefore be directly compared to the values obtained for modes $M_{i=1-2}$ (Method 1).

M_1^* and M_2^* are simultaneous modes since they describe dynamic patterns that account for more than 10% of both the shoreline and barline variability. Vectors $e_{s,1}^*$ and $e_{b,1}^*$ show that M_1^* describes the simultaneous progradation of the shoreline and shoreward migration of the barline both accompanied by counterclockwise rotation, and vice versa (Figures 5e and 5i). In contrast to M_1^* , $e_{s,2}^*$ and $e_{b,2}^*$ show that M_2^* describes the simultaneous retreat (or progradation) of both the shoreline and barline, accompanied by changes of barline curvature and minor rotations (slight clockwise rotation of shoreline and barline with beach retreat, and vice versa, Figures 5f and 5j). A schematic representation of the beach behaviors described by M_1^* and M_2^* is proposed in Figure 6.

M_3^* and M_4^* are characterized by a nonnegligible contribution to the shoreline and the barline (more than 10%), respectively, and a trivial contribution vice versa. For example, M_3^* describes a dynamic pattern that is relevant for the shoreline (it explains 16% of its variability, Figure 5g). On the contrary, it describes a dynamic pattern for the barline that does not explain any of its variability (2% is below significant level, Figure 5k). Therefore, M_3^* and M_4^* are nonsimultaneous modes. They account for independent shoreline and barline behaviors, essentially rotations (Table 2).

Model-based modes \tilde{M}_1^* , \tilde{M}_3^* , and \tilde{M}_4^* show good agreement with data-based modes M_1^* , M_3^* , and M_4^* . In the two latter cases, good agreement is only relevant for the shoreline (M_3^*) or the barline (M_4^*). M_2^* is only partially simulated by the models (poor fit between $e_{s,2}^*$ and $\tilde{e}_{s,2}^*$, and curved shapes of $e_{s,2}^*$ and $e_{b,2}^*$ that cannot be simulated by the models). However, the alongshore-averaged values of $e_{s,2}^*$ and $\tilde{e}_{s,2}^*$, and of $e_{b,2}^*$ and $\tilde{e}_{b,2}^*$ agree well, showing that the equilibrium models simulate part of the cross-shore migration described by M_2^* . Correlations above 0.7 reflect a fair correspondence between model- and data-based temporal vectors $c_{i=1-4}^*$ and $\tilde{c}_{i=1-4}^*$ (Table 3).

5. Discussion

5.1. Simultaneity of Shore and Bar Behaviors

5.1.1. Simultaneity

PCA using Method 1 showed that more than 60% of the variability of Tairua Beach is dominated by the shoreline and barline moving through combinations of migration and rotation ($M_{s,1}$ and $M_{b,1}$, Table 2). In addition, $M_{s,1}$ and $M_{b,1}$ can immediately be compared with M_1^* ($e_{s,1}^*$ and $e_{b,1}^*$ are similar to $e_{s,1}$ and $e_{b,1}$ (Figures 5a, 5c, 5e, and 5i), and the temporal vectors c_1^* , $c_{s,1}$, and $c_{b,1}$ agree well ($R^2 > 0.7$, Figure 7a)). A decrease of approximately 10% of the variability explained by M_1^* compared to $M_{s,1}$ and $M_{b,1}$ suggests that the missing amount could be explained by M_2^* (shoreline: 10%; barline: 20%). The combinations of migration and rotation described by dominant modes $M_{s,1}$ and $M_{b,1}$ seem therefore to be described by two simultaneous modes M_1^* and M_2^* , suggesting that the migration and rotation captured by these modes are coupled (Figures 5a, 5c, 5e, 5f, 5i, and 5j).

Secondary behaviors are represented by modes $M_{s,2}$ and $M_{b,2}$ (Method 1, Figures 5b and 5d). These modes account mainly for rotation ($R_R^2 > 10\%$, Table 2), with $M_{s,2}$ accounting also for minor migration and $M_{b,2}$ for minor changes in curvature. The simultaneity or nonsimultaneity of these behaviors is revealed by Method 2. Indeed, $M_{s,2}$ can be compared with M_3^* and $M_{b,2}$ can be compared with M_4^* (spatial vector $e_{s,2}$ compares well

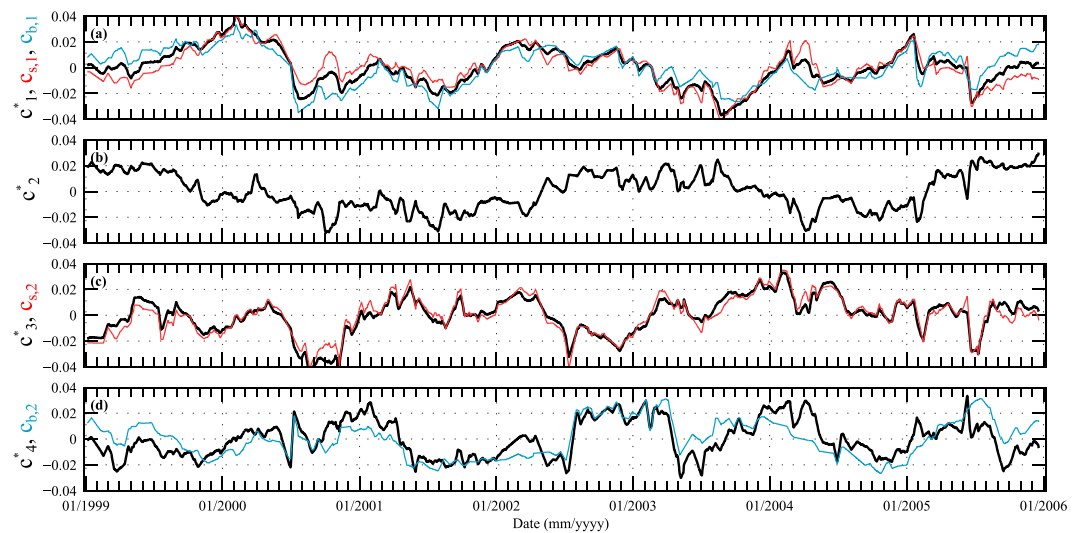

Figure 7. Main PCA modes temporal vectors. Black lines: temporal vectors corresponding to modes $M_{i=1-4}^*$ extracted with Method 2 ((a) $c_{1,1}^*$, (b) $c_{2,2}^*$, (c) $c_{3,3}^*$, and (d) $c_{4,4}^*$). Red lines: Shoreline temporal vectors extracted with Method 1 ((a) $c_{s,1}$ and (c) $c_{s,2}$). Blue line: Barline temporal vectors extracted with Method 1 ((a) $c_{b,1}$ and (d) $c_{b,2}$).

with $e_{s,3}^*$, while temporal vectors $c_{s,2}$ and $c_{s,3}^*$ correlate with $R^2 = 0.9$; $e_{b,2}$ compares well with $e_{b,4}^*$, while $c_{b,2}$ and $c_{b,4}^*$ correlate with $R^2 = 0.5$). Therefore, we can conclude that secondary modes are nonsimultaneous and that the rotations of the shoreline and barline that they essentially capture are independent behaviors.

5.1.2. Dominant Simultaneous Behaviors

Unlike other beaches, the dominant behavior of Tairua beach includes migration and rotation of the shoreline and barline that do not occur independently. Indeed, the PCA analyses did not separate them either in the case of the shoreline ($M_{s,1}$), the barline ($M_{b,1}$) analyzed separately, or for both of them considered together (M_1^*). M_1^* , that describes opposed migration directions of the shoreline and barline (e.g., the shoreline erodes while the bar moves seaward), accompanied by rotations in identical sense, is named *contrasting mode* hereafter. This mode can be associated with the transition of the beach toward more reflective or dissipative states and reflects the beach behaviors identified during Events I, II, and IV. The second simultaneous mode, M_2^* , mainly accounts for simultaneous cross-shore migrations, in identical direction, of the shoreline and barline. Therefore, M_2^* is referred to as the *similar mode* hereafter.

M_2^* also includes curvature variation of the barline (R_{ij}^2 , Table 2). *Ratliff and Murray* [2014] studied the long-term behavior of embayed beach shorelines by modeling longshore sediment transport between headlands using the model of *Ashton et al.* [2001] and *Ashton and Murray* [2006]. They named a new dynamic mode *breathing* that relates to fluctuations in the curvature of the *shoreline*, which is not observed here. However, spatial vector $e_{b,2}^*$ (Figure 5j) of the similar mode (M_2^*) shows a curved planform shape that could relate to such a breathing process of the barline. In addition, M_2^* accounts for an overall retreat or progradation of the shoreline and barline system. Moreover, temporal vector $c_{s,2}^*$ exhibits interannual fluctuations with time periods of 3 to 4 years, which would agree with the characteristic time scales found by *Ratliff and Murray* [2014] for low-angle wave climate (Figure 7b). Such climate is found at Tairua, where only 8% of the 7 year simulated waves exceed an angle of incidence of 45° , which could explain the emergence of the similar mode (Figures 6c and 6d).

The contrasting and similar modes, M_1^* and M_2^* , suggest that the dominant behavior of the beach could be associated with a strong coupling between the shoreline and barline, influencing each other at the scale of the embayment, as suggested in *Harley et al.* [2015]. By focusing on the simultaneous dynamic patterns of Tairua Beach, Method 2 was also able to extract a process that has similarities with the breathing of embayed beaches described by *Ratliff and Murray* [2014]. In Tairua, this process concerns the entire shore and bar system, exhibiting simultaneous, potentially coupled, shoreline and barline cross-shore migrations, and barline curvature variations.

5.2. Environmental Drivers

It is not clear whether the coupling between the bar and shoreline (as evidenced by the simultaneous behavior) is caused by a direct effect of one on the other, or by them both responding independently (but simultaneously) to changes in wave forcing. In this section, the dependence on wave forcing is explored with simple equilibrium models and associated model-based PCA modes, as described in the methods.

5.2.1. Model-Based Modes

All aforementioned results and observations depend on the quality of the data set and the reliability of the PCA methods. In the following, the association of PCA modes with external forcing conditions rely on the reliability of the equilibrium models. Therefore, it is important to discuss the performance of these models in simulating the data-based modes $M_{s,i}$, $M_{b,i}$, and M_i^* . Apart from $\tilde{e}_{s,2}^*$, $e_{s,2}^*$ and $\tilde{e}_{b,2}^*$, $e_{b,2}^*$, a good agreement was already found between the model- and data-based spatial vectors shapes. Apparent poor agreement between $\tilde{e}_{s,2}^*$, $e_{s,2}^*$ and $\tilde{e}_{b,2}^*$, $e_{b,2}^*$ should be interpreted in the context that their alongshore-averaged values agree well, showing that the equilibrium models simulate part of the cross-shore migration described by M_2^* . Good agreement between data- and model-based modes is confirmed by R^2 values above 0.7 found between their corresponding temporal vectors ($\tilde{c}_{s,i}$, $c_{s,i}$; $\tilde{c}_{b,i}$, $c_{b,i}$; \tilde{c}_i^* , c_i^* , Table 3).

Such agreement shows explicitly that the equilibrium models are able to simulate the dynamic shoreline and barline patterns that dominate the beach behavior (as identified by the PCA). It also shows that the models simulate a ratio of migration and rotation of the shoreline and barline at the embayment-wide scale, which is similar to the observations (otherwise the model-based modes would be reshaped by, for instance, migration dominating over rotation, or shoreline dynamics dominating over barline dynamics). Therefore, we can proceed to use these models to explore the relationship of patterns to forcing condition.

5.2.2. Migration

Under adequate wave conditions, equilibrium models simulate the similar and contrasting modes. According to the migration models' formulations (equations (5) and (7)), the contrasting mode M_1^* should be activated when the incident wave energy is higher than the shoreline and barline equilibrium energies ($E > E_{eq,s}$ and $E > E_{eq,b}$), inducing barline seaward migration and shoreline erosion. An incident energy lower than the equilibrium energies ($E < E_{eq,s}$ and $E < E_{eq,b}$) also drives the contrasting mode (landward barline migration associated with shoreline progradation). In the same manner, the similar mode M_2^* describes an overall landward or seaward migration of both the shoreline and barline. This could occur not only due to a breathing process but also when the incident wave energy falls between the shore and bar equilibrium energies ($E_{eq,s} < E < E_{eq,b}$).

These relations between modes and equilibrium wave energies are reflected by the 7 year distribution of incident wave energy above, below, or in between $E_{eq,s}$ and $E_{eq,b}$. Time series of equilibrium and incident wave energy are presented in Figure 8. In total, 80% of the overall incident wave energy at Tairua Beach is likely to drive the contrasting mode 90% of the time ($E > E_{eq,s}$ and $E > E_{eq,b}$ occur 7% of the time, accounting for 35% of the overall wave energy; $E < E_{eq,s}$ and $E < E_{eq,b}$ occur 83% of the time, accounting for 45% of the overall wave energy). Regarding the similar mode, the remaining incident wave energy corresponding to $E_{eq,s} < E < E_{eq,b}$ occurs only 10% of the time and accounts for 20% of the overall wave energy. The ratio of wave energy likely to drive the contrasting mode (80%) over the wave energy likely to drive the similar mode (20%) reflects the dominance of the contrasting mode (shoreline: 54%; barline: 45%) over the similar mode (shoreline: 10%; barline: 20%). This supports the association of the migration described by the contrasting and similar modes with the models' equilibrium theories.

Since *Wright and Short* [1984], it is not surprising that shoreline and barline cross-shore migrations occur simultaneously during beach state transitions. However, such simultaneity should only be partial since shoreline and barline are expected to adapt with different response time to changes in incident wave conditions. This is illustrated by recent attempts to model cross-shore sandbar migration, which showed that wave breaking over the bar crest was the main driver [*Plant et al.*, 1999; *Splinter et al.*, 2011; *Blossier et al.*, 2016], which does not appear in shoreline models [*Yates et al.*, 2009; *Splinter et al.*, 2014]. For instance, in this paper, equations (5) and (7) lead, for steady conditions of wave energy E_0 , to the following response times τ_{s_0} (shore) and τ_{b_0} (bar):

$$\tau_{s_0} = \frac{1}{C_s \sqrt{E_0} p_s}, \quad (12)$$

$$\tau_{b_0} = \frac{1}{C_b \sqrt{E_0} a_b f_b}, \quad (13)$$

Figure 8. Orange line: Barline equilibrium energy $E_{eq,b}$. Green line: Shoreline equilibrium energy $E_{eq,s}$. Dots: Incident wave energy at 8 m depth (P2, Figure 1d). Colors indicate the corresponding amount of energy available for alongshore sediment transport E_y .

$$\frac{\tau_{B_0}}{\tau_{S_0}} = \frac{C_s p_s}{C_b a_b f_b} \approx 0.2, \text{ for } f_b = 1. \tag{14}$$

τ_{S_0} ranges from above 80 days ($H_s < 1$ m) to below 20 days ($H_s > 4$ m). When waves break over the bar crest ($H_s > H_b$ and $f_b = 1$, i.e., barline seaward migration), the bar migrates at the maximal migration rate (about 5 times more quickly than the shoreline) toward its equilibrium position equation (14). During intermediate conditions ($E_{eq,s} < E < E_{eq,b}$), τ_{B_0} and τ_{S_0} get closer (average ratio of 0.8), so that the barline and shoreline still migrate together. However, during calm conditions, the barline model states that the barline should be nearly inactive (the term accounting for wave breaking, f_b equation (8), leads to much slower response during calm conditions, with a ratio τ_{B_0} over τ_{S_0} above 10 for 70% of these conditions).

This does not fully agree with the PCA analyses that show that nearly all cross-shore migration is explained by simultaneous modes (M_1^* and M_2^*). However, the models do not perfectly simulate M_1^* and M_2^* (20% of the variance is unexplained for the shoreline (M_1^*) and for the barline (M_2^*)). This suggests the existence of processes that are not taken into account in the equilibrium theories; processes that may potentially couple the shoreline and the barline migrations, as suggested by *Splinter et al.* [2017]. Such processes would likely involve an influence of the bar on the hydrodynamics in the vicinity of the shoreline, especially on the wave field. For instance, the emergence of rip channels along the sandbar affects barline migration [*Splinter et al.*, 2011] and can induce wave refraction, shoaling, and breaking patterns that can influence shoreline morphodynamics [*Coco et al.*, 2005; *Ruessink et al.*, 2007; *Castelle et al.*, 2010a, 2010b; *van de Lageweg et al.*, 2013]. On a larger scale, the overall barline state could play a role in the erosion (or accretion) at the shoreline [*Price and Ruessink*, 2011; *Harley et al.*, 2015; *Splinter et al.*, 2017]. Other processes such as the (unmodeled) breathing process mentioned earlier could also be involved.

5.2.3. Rotation

The PCA outcomes showed that the shoreline and the barline partly rotate simultaneously, in the same sense (M_1^*). Such behavior can be explored using the equilibrium theories for rotation. Equation (6) associates shoreline rotation with the amount of wave energy contributing to alongshore transport ($E_y = E \cos(\theta) \sin(\theta)$) while equation (9) relates barline rotation to alongshore wave energy gradients ($\nabla_x(E)$). Therefore, the distributions of E_y and $\nabla_x(E)$ corresponding to the wave energy conditions triggering the contrasting mode should relate to the associated directions of rotation.

When the contrasting mode M_1^* is active, barline seaward migration and shoreline erosion are likely to occur with clockwise rotations (such as during Event I). This case is driven by storm conditions, $E > E_{eq,s}$ and $E > E_{eq,b}$ (see previous section), for which the distributions of E_y and $\nabla_x(E)$ are shifted within a quarter standard deviation toward negative values (for E_y , see the dominance of blue dots above $E_{eq,b}$, Figure 8). This favors simultaneous clockwise rotations of the shoreline and barline (Figure 6a).

The contrasting mode M_1^* also describes beach recovery (barline shoreward migration, shoreline accretion), which it associates with counterclockwise rotations (such as during Event II). This case occurs when $E < E_{eq,s}$ and $E < E_{eq,b}$ (see previous section). Under these conditions, the distributions of E_y and $\nabla_x(E)$ have averaged values close to zero and standard deviations about 5 times smaller than during energetic conditions.

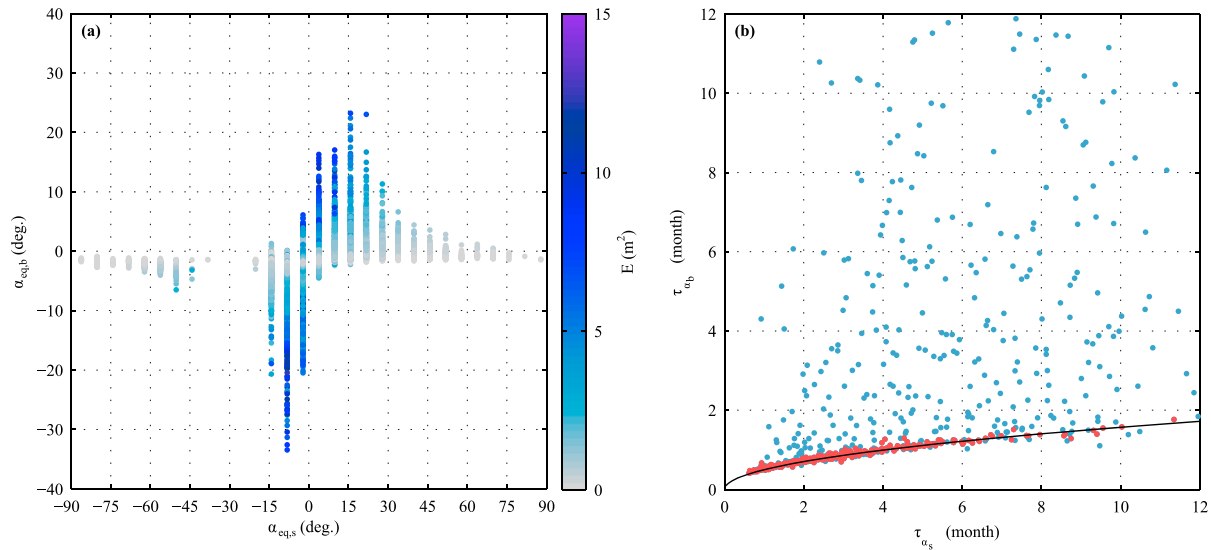

Figure 9. (a) Equilibrium orientation of the barline $\alpha_{eq,b}$ (equation (16)) on the vertical axis as a function of the equilibrium orientation of the shoreline (equation (15)). Values are given in degrees. The color scale indicates the intensity of the incident wave energy. (b) Red and blue dots represent the response time of the barline orientation τ_{α_b} as a function of the shoreline orientation τ_{α_s} (only values shorter than 12 months are shown). Red dots correspond to a damping factor $f_b = 1$ and a limited wave incidence $|\theta| < 10^\circ$. The black line represents the relation between τ_{α_b} and τ_{α_s} for $f_b = 1$ and $\theta = 0$ (equation (19)).

Therefore, after a storm event during which the shoreline and barline rotated clockwise, these tend to rotate back toward a near-zero orientation during recovery; i.e., they rotate counterclockwise. In addition, the distribution of E_y shows a significant positive skewness (see the large number of red dots below $E_{eq,s}$, Figure 8) that can enhance counterclockwise rotation during shoreline accretion (Figure 6b).

Little rotation is explained by the similar mode M_2^* (Figures 5f, and 5j, and R_R^2 in Table 2). This mode is active when $E_{eq,s} < E < E_{eq,b}$ (see previous section). In agreement with the PCA, these conditions correspond to slightly negative averaged values of E_y and $\nabla_x(E)$ that are negligible compared to standard deviations (1 order of magnitude). The relations between wave climate properties and the activation of modes M_1^* and M_2^* are summarized in Figure 6.

Despite the simultaneous rotation patterns discussed above, the PCA outcomes showed that shoreline and barline rotations are strongly nonsimultaneous (R_R^2 about 10% for M_3^* and M_4^* , i.e., 30 and 60% of the shoreline and barline rotation, respectively), and so we should expect them to behave independently. In addition, M_3^* and M_4^* show that rotation can occur without substantial migration, such as during Event III. The rotation models' formulations support these observations by involving different physical processes, which do not relate to the shoreline or barline migration. The shoreline rotation is driven by E_y , representing alongshore sediment transport induced by longshore currents, while barline rotation is driven by $\nabla_x(E)$, which relates to a differential adaptation of the cross-shore position of the barline along the beach via cross-shore processes. Consequently, shoreline and barline rotations should respond toward different equilibrium orientations with different response times, explaining the emergence of nonsimultaneous modes.

Under steady wave conditions (incident wave energy E_0 and wave angle θ_0), equilibrium orientations $\alpha_{eq,s}$ and $\alpha_{eq,b}$ can be inferred from equations (6) and (9) for the shoreline and barline, respectively:

$$\alpha_{eq,s} = \theta_0, \tag{15}$$

$$\alpha_{eq,b} = \alpha_{eq} + \frac{1}{\delta_b a_b} \frac{\partial E_0}{\partial x}, \tag{16}$$

These two quantities are represented in Figure 9a with their corresponding incident wave energy. While $\alpha_{eq,s}$ relates directly to the wave angle of incidence, in agreement with Turki et al. [2013a, 2013b] and Blossier et al. [2015], $\alpha_{eq,b}$ relates to the alongshore wave energy gradient, in agreement with Bryan et al. [2013] and Blossier et al. [2016].

Simultaneous shoreline and barline rotation patterns would suppose a nearly constant ratio between shoreline and barline rotation rates. This is more likely to be the case if $\alpha_{eq,s}$ and $\alpha_{eq,b}$ are correlated. However, Figure 9a shows that wave energy strongly influences the relationship between $\alpha_{eq,s}$ and $\alpha_{eq,b}$. The average ratio $\alpha_{eq,b}$ over $\alpha_{eq,s}$ decreases with decreasing wave energy (2 for $E \geq 10 \text{ m}^2$, 1.5 for $5 \leq E < 10 \text{ m}^2$; 0.7 for $2.5 \leq E < 5 \text{ m}^2$; 0.23 for $1 \leq E < 2.5 \text{ m}^2$, ($R^2 \geq 0.6$)). For incident wave energy below 1 m^2 , there is no significant correlation and $\alpha_{eq,b}$ falls between -9° and 5° for any value of $\alpha_{eq,s}$.

This explains why strong rotations of the bar are observed during storms even at low angles of incidence, such as Events I and IV (Figure 3). During these events, high waves ($H_s = 3.8$ and 3 m , respectively, Figure 2a) and low angle of incidence ($\theta \sim -5^\circ$ and -2° , respectively, not shown) induce large alongshore negative gradients of wave energy (-2.5 and $-1 \text{ m}^2/\text{m}$, Figure 2c) driving large clockwise barline rotation, while clockwise shoreline rotation is limited for Event I and does not occur for Event IV (E_y close to 0, Figure 2b). Conversely, under low wave conditions, regardless of the wave angle, low alongshore wave energy gradients lead to a rotation of the bar toward $\alpha_{eq,b} \sim \alpha_{eq} = -0.028$ (equation (16), see Figure 3, year 1999, August 2000 to February 2001, and year 2004).

Not only can the shoreline and barline equilibrium angles induce nonsimultaneity of the shoreline and barline rotations but also their characteristic response times toward equilibria, τ_{α_s} and τ_{α_b} , respectively:

$$\tau_{\alpha_s} = \frac{1}{C_{\alpha_s} E_0 \cos(2\theta_0)}, \quad (17)$$

$$\tau_{\alpha_b} = \frac{1}{C_{\alpha_b} \sqrt{E_0} f_b \delta_b a_b}, \quad (18)$$

$$\tau_{\alpha_b} = \frac{\sqrt{C_{\alpha_s}}}{C_{\alpha_b} \delta_b a_b} \sqrt{\tau_{\alpha_s}} \approx 2.7 \sqrt{\tau_{\alpha_s}}, \text{ for } f_b = 1 \text{ and } \theta_0 = 0. \quad (19)$$

Values of τ_{α_s} and τ_{α_b} are represented in Figure 9b. Equation (19) provides the relation between τ_{α_s} and τ_{α_b} for energetic conditions (waves break offshore of the bar crest, i.e., $f_b = 1$), and near-normal wave incidence. Under these conditions, mode M_1^* is active. The barline orientation responds much more quickly than the shoreline orientation and oblique wave angles can even increase this difference (dots below the black line, Figure 9b). However, the beach experiences more often calm conditions ($f_b < 1$). As a result, in the models, $\tau_{\alpha_b} > \tau_{\alpha_s}$ for 75% of the evaluated time steps, showing that the barline is less active than the shoreline in general, inducing nonsimultaneous rotations.

To summarize, shoreline and barline rotations are partly simultaneous, as shown by M_1^* , partly nonsimultaneous, as shown by M_3^* and M_4^* . Simultaneity can be associated with the partial correlation of E_y and $\nabla_x(E)$, driving the shoreline and barline rotation, respectively. However, this correlation depends on the wave energy, resulting in wave energy-dependent relationships between equilibrium angles $\alpha_{eq,s}$ and $\alpha_{eq,b}$ and response times τ_{α_s} and τ_{α_b} . This contributes to the nonsimultaneity of the shoreline and barline rotations.

Drivers behind beach rotation are regularly questioned in the literature [Harley *et al.*, 2011; Bryan *et al.*, 2013; Turki *et al.*, 2013b; Harley *et al.*, 2015; Blossier *et al.*, 2016]. Here at Tairua Beach, the good agreement between the PCAs and equilibrium models' outcomes argues in favor of the wave oblique incidence and consequent longshore transport to be the main driver of shoreline rotation. It also confirms that barline rotation is likely to be driven by the cross-shore adaptation of the barline position to alongshore wave energy gradients. Shoreline rotation due to upper beach steepening or flattening induced by wave energy gradients is ignored in the present shoreline rotation model. It would induce rotations in opposite sense compared to observations (i.e., opposed to sandbar sense of rotation), and so may only occur in a very limited manner (among 21% of shoreline rotation unexplained by the model, Table 1). Shoreline and barline rotations seem to be coupled mainly via the coupling of the wave field parameters E_y and $\nabla_x(E)$. This strongly infers the importance of the local geological setting in the observed embayment-wide rotation patterns.

6. Conclusion

This study explored the potential coupling of the shoreline and sandbar of a single-barred embayed beach. A combined approach based on the outcomes of two different PCA methods and four equilibrium models has been used to characterize the dominant coupled patterns of the shoreline and barline. Classical PCAs showed

that dominant patterns occur at the scale of the embayment and are combinations of cross-shore migrations and rotations of the beach shoreline and sandbar.

A new application of PCA leads to a quantification of how much of these patterns were induced simultaneously by the shore and bar dynamics. The two major coupled dynamical patterns that were isolated were beach transitions toward more reflective or more dissipative states (contrasting mode) and shoreline and barline cross-shore migrations in identical directions (similar mode). This similar mode also involved a breathing of the barline, showing that breathing modes are not limited to shoreline morphodynamics.

A general good agreement between data- and model-based PCA modes indicates that equilibrium models can capture and describe the dominant scales of motion, i.e., the dynamic patterns at the embayment scale that involve simultaneous or nonsimultaneous shore and bar behaviors. According to the theories underlying the models, cross-shore migrations of the shoreline and barline are mainly controlled by the incident wave energy intensity while shoreline rotation is driven by the wave angle of incidence and consequent longshore sediment transport. Barline rotation is driven by alongshore wave energy gradients and cross-shore sediment transport.

The contrasting mode reveals the nature of the simultaneous shore and barline behavior. The simultaneity in shore and bar cross-shore migration can be either explained by the fact that they obey the same driver, i.e., the wave energy intensity, or because these features can be physically coupled by, for instance, the influence of the sandbar on the shoreline hydrodynamics or cross-shore transfers of sediment. During higher wave energy conditions, the alongshore gradient in wave height (which drives barline rotation) and the alongshore wave energy flux (which drives shoreline rotation) are activated together, which results in rotations in identical sense that depends on the local wave climate properties. Wave angles and alongshore gradients in wave height can be related because of the geological setting (for example, when changes in the wave angles also cause one end of the beach to get shadowed by a headland or island).

Drivers identified in this study are likely to occur at any intermediate single-barred embayed beach, suggesting that coupled, embayment-wide shoreline and sandbar patterns can probably be observed in such environments. However, the occurrence of similar patterns at multiple-barred beaches, involving the shoreline and multiple sandbars, remains largely unexplored. The PCA method used in the present study could be an efficient approach to assess if such patterns occur, and to evaluate the role of intermediate sandbars, located between the shoreline and the outermost sandbar.

Appendix A: Influence of Errors on the Results

The influence of measurement errors on the PCAs of this study was assessed. One hundred surrogate shoreline and barline signals were generated by superimposing noise signals to the original signals. For the shoreline, a nearly Gaussian noise in time and space, $\mathcal{N}_{s,\text{pixel}}(x_s, t)$ was generated with a standard deviation of 0.4 m and a maximum amplitude of 0.7 m to simulate the pixel footprint accuracy. This was added to an alongshore-uniform Gaussian noise in time, $\mathcal{N}_{s,\text{runup}}(t)$ with a standard deviation of 3.5 m to simulate the uncertainty in water level (including tidal level, wave setup and runup). For the barline, an alongshore-uniform Gaussian noise in time, $\mathcal{N}_{b,\text{error}}(t)$ with a standard deviation of 10 m, was used to account for the overall error in bar digitization.

Overall, the spatial vectors $e_{s,i}$, $e_{b,i}$, $e_{s,i}^*$ and $e_{b,i}^*$ are nearly unchanged (not shown). Largest (but still very small) changes are observed for $e_{b,3}^*$ and $e_{s,4}^*$, which were found to be the trivial part of nonsimultaneous modes M_3^* and M_4^* in the main text. Changes in R^2 values are usually $\pm 1-2\%$, always below 5% except for M_2^* (up to +8% for the shoreline). Larger differences are found within the temporal vectors $c_{s,i}$, $c_{b,i}$, $c_{s,i}^*$ and $c_{b,i}^*$. Indeed, with unchanged spatial vectors and R^2 values, they reflect directly the synthetic noise in the signals.

Appendix B: Significance of PCA Modes

The rule of thumb of *North et al.* [1982] is commonly applied to identify sets of degenerated modes within a PCA analysis. In such a set, any linear combination of modes is as significant as one of them, yielding to difficult interpretations [*Hannachi et al.*, 2007; *Reeve et al.*, 2008; *Wilks*, 2011; *Karunaratna et al.*, 2012]. In theory these degenerated modes should have the same eigenvalue ($\lambda_{s,i}$, $\lambda_{b,i}$ in equations (1) and (2)). The rule of thumb

proposes a formulation of the error in the computation of eigenvalues and states that modes are degenerated if the spacing between successive eigenvalues falls within this error. The error δ_{λ_i} for eigenvalue λ_i is given by

$$\delta_{\lambda_i} = \sqrt{\frac{2}{N^*}} \lambda_i \quad (B1)$$

where N^* is the number of independent samples of the data set, related to the total number of samples N by the autocorrelation coefficient of the time series [Zwiers and von Storch, 1995]. A mode is significant if

$$\lambda_i - \lambda_{i+1} < \delta_{\lambda_i} \quad (B2)$$

In addition to the rule of thumb, a Monte Carlo approach based on surrogate data is used here to assess the significance of the modes at the 95% level. It is assumed that the beach morphodynamics behave as a red noise in time, which is confirmed by comparing the spectra of beach characteristics (not shown for the shoreline; see Blossier *et al.* [2016] for the barline) to a red noise spectrum. Then for each time step, the spectral decomposition of the beach shoreline (or barline) is computed. Phases are randomly shifted and a new profile is generated by performing an inverse Fourier transform resulting in a full set of profiles $S'(x_s, t)$ ($B'(x_b, t)$) spectrally equivalent to the observed profiles $S(x_s, t)$ ($B(x_b, t)$), for the shoreline (barline), respectively. For instance, for the shoreline, the red noise-based surrogate signal S_n is then generated by

$$S_n(x_s, t + \Delta t) = r_1(x_s)S(x_s, t) + S'(x_s, t + \Delta t) \quad (B3)$$

where Δt is the data set sampling time and $r_1(x_s)$ is a vector of the first autocorrelation coefficient (in time) at each alongshore position. A thousand surrogate signals S_n are generated. The 95 % level of significance is determined at alongshore position x_s by computing the 95% percentile of the $R^2(x_s)$ coefficients computed between measured ($S(x_s, t)$) and generated ($S_n(x_s, t)$) signals. For both the shoreline and barline, R^2 values fall below 5%, showing that any mode explaining more than 5% of variability is significant.

Appendix C: Semiempirical Models

C1. Formulations

Four semiempirical models based on existing literature are used in the present study to simulate the morphodynamics of Tairua Beach in terms of alongshore-averaged cross-shore position and orientation of both the beach shoreline and barline. This appendix focuses on shoreline models. Concerning the barline cross-shore and rotation models, we refer the reader to the work of Blossier *et al.* [2016] that provides extensive details about their formulation, calibration, and validation. The same parameters are used in the present work.

The shoreline model that describes the cross-shore position of the beach shoreline is based on the formulation of Yates *et al.* [2009]. Here using different coefficients quantifying accretion and erosion rates of the shoreline did not improve the performance of the model and therefore, only one is used. However the model was found not to be able to describe long-term trends. As such, the shoreline position S_0 is decomposed as a part described by the model S'_0 and a linear trend, similar to Davidson *et al.* [2013]:

$$S_0 = q_s t + m_s + S'_0, \quad (C1)$$

$$E_{eq,s} = p_s S'_0 + n_s, \quad (C2)$$

$$\frac{\partial S'_0}{\partial t} = C_s \sqrt{E}(E - E_{eq}) = C_s \sqrt{E}(E - p_s S'_0 - n_s) \quad (C3)$$

where q_s ($m s^{-1}$) is the linear trend coefficient, m_s (m) is an offset, E_{eq} is the equilibrium energy linearly depending on the current position of the shoreline S'_0 with coefficients p_s (m) and n_s (m^2). E is the incident wave energy at time t and C_s ($m^{-2} s^{-1}$) is a calibration coefficient. In this appendix, unlike in the main text, notation $\tilde{\sim}$ is not used to mark modeled values such as S_0 .

Equations (C1) and (C3) can be alongshore-averaged using the following hypotheses:

1. The shoreline linear trend is uniform in the embayment (q_s and m_s are constant).
2. p_s and n_s are symmetric in the embayment.
3. C_s , controlling the accretion and erosion rates, is constant in the embayment.
4. E and S'_0 can be linearized with an alongshore-averaged value (\bar{E} , \bar{S}'_0), and an alongshore-varying value (\check{E} , \check{S}'_0)
5. $\check{E} \ll \bar{E}$

Table C1. Shoreline Migration and Rotation Models Coefficients and Skill for the 7 Year and Five 3 Year Long Time Periods

Time	Migration					Rotation			
	C_s ($m^{-2} s^{-1}$)	p_s (m)	q_s (m/yr)	r_s (m^2)	R^2 -	Bss -	C_{α_s} ($m^{-2} s^{-1}$)	R^2 -	Bss -
1999–2006	−0.079	−0.084	−1.81	5.73	0.67	0.64	0.004	0.79	0.62
1999–2002	−0.061	−0.026	−0.51	3.31	0.84	0.84	0.006	0.89	0.30
2000–2003	−0.064	−0.107	−2.37	7.02	0.79	0.78	0.006	0.88	0.32
2001–2004	−0.086	−0.119	−3.03	7.79	0.72	0.71	0.006	0.86	0.64
2002–2005	−0.127	−0.088	−1.05	5.54	0.74	0.73	0.004	0.81	0.62
2003–2006	−0.118	−0.067	−3.40	5.61	0.75	0.74	0.004	0.80	0.61
Average	−0.091	−0.082	−2.07	5.85	0.77	0.76	0.005	0.85	0.50
Standard deviation	±0.030	±0.037	±1.25	±1.71	±0.05	±0.05	±0.001	±0.04	±0.17

Using a Taylor expansion of $\sqrt{\bar{E} + \bar{\xi}}$, equations (C1) and (C3) become

$$\bar{S}_0 = q_s t + m_s + \bar{S}'_0, \quad (C4)$$

$$\frac{d\bar{S}'_0}{dt} = C_s \sqrt{\bar{E}} \left(\bar{E} - \bar{p}_s \bar{S}'_0 - \bar{n}_s \right) + O\left(\frac{\bar{\xi}^2}{\sqrt{\bar{E}}}\right) \quad (C5)$$

The last term is indeed negligible for more than 94% of the modeled wave conditions.

Combining equations (C4) and (C5) leads to the following model for \bar{S}_0 :

$$\frac{d\bar{S}_0}{dt} = C_s \sqrt{\bar{E}} \left(\bar{E} - \bar{p}_s \bar{S}_0 - \bar{n}_s + \bar{p}_s q_s t + \bar{p}_s m_s \right) + q_s, \quad (C6)$$

$$= C_s \sqrt{\bar{E}} \left(\bar{E} - \bar{p}_s \bar{S}_0 + \bar{p}_s q_s t - r_s \right) + q_s, \quad (C7)$$

$$r_s = \bar{n}_s - \bar{p}_s m_s \quad (C8)$$

where the migration rate depends now on four free coefficients C_s , \bar{p}_s , q_s , and r_s . Symbol $\bar{\quad}$ for alongshore averaging is ignored in the main text and in the following.

The second model describes the rotation of the shoreline, and its formulation is based on the results of a statistical linear analysis [Blossier et al., 2015] showing a clear relationship between the shoreline rotation rate and the amount of wave energy available for alongshore sediment transport [Komar and Inman, 1970]. These observations are in agreement with the model of Turki et al. [2013b], and therefore, the present shoreline rotation model is a simplified formulation of their model assuming an equilibrium orientation of the beach shoreline perpendicular to the incoming wave direction θ . The formulation of Turki et al. [2013b] is

$$\frac{d\alpha_s}{dt} = 2 \frac{K}{L^2 h^*} \rho_w g H_b^2 c_{g,b} \sin(\theta - \alpha_s) \cos(\theta - \alpha_s), \quad (C9)$$

with α_s the shoreline orientation, K ($m^2 s^2 kg^{-1}$) a coefficient accounting for the sediment properties, L (m) the length of the shoreline, h^* (m) the closure depth, ρ_w ($kg m^{-3}$) the water density, g ($m s^{-2}$) the gravity acceleration, H_b (m) the breaking wave height, and $c_{g,b}$ ($m s^{-1}$) the wave group celerity at breaking. Linearly expanded to the first order for small values of α_s , using wave height values at 8 m depth and neglecting the variations of the wave group celerity, the formulation is simplified to

$$\frac{d\alpha_s}{dt} = C_{\alpha_s} E [\sin(\theta) \cos(\theta) - \alpha_s \cos(2\theta)], \quad (C10)$$

with C_{α_s} ($m^{-2} s^{-1}$) a free parameter of the model.

Table C2. Models Skills for 2 Year Forecasts With Increasing Training Periods

Training	S_0		α_s		B_0		α_b	
	RMSE	R^2	RMSE	R^2	RMSE	R^2	RMSE	R^2
1999–2000	9.7	0.11	0.013	0.83	18.4	0.66	0.049	0.62
1999–2001	4.8	0.34	0.010	0.91	21.6	0.40	0.029	0.78
1999–2002	4.0	0.70	0.009	0.90	19.6	0.45	0.038	0.70
1999–2003	4.4	0.59	0.007	0.78	16.6	0.35	0.036	0.62
1999–2004	3.9	0.57	0.008	0.56	13.9	0.44	0.034	0.70

C2. Performance

Performance was evaluated using two different approaches. First the models were calibrated using the entire 7 year shoreline data set and five 3 year data sets. The resulting hindcasts were compared to the observations (Table C1). Then they were trained over 1 to 5 years of data, and the skill of the forecasts was evaluated on the two successive years (Table C2).

The semiempirical models (shoreline migration and rotation) hindcast the 7 year beach behavior with fair to good skill (about 70% of variance explained (Table C1), Brier skill scores about 0.6, i.e., a fair to good fit, according to *van Rijn et al.* [2003]). These results are confirmed by the runs on 3 year data sets (Table C1). The coefficients of the models presented in Table C1 are quite stable over the different calibration period. In particular, average values of the coefficients over the five 3 year calibration periods are similar to the coefficients obtained for the 7 year calibration.

Then, models were validated using 2 year simulations after a 1 to 5 year calibration period. RMSE values and R^2 coefficients are provided in Table C2. The four models perform reasonably for 3 years of training or more. In this case, root-mean-square errors are systematically below the standard deviations of the observed parameters and R^2 coefficients range from 0.35 to 0.90.

Appendix D: Contribution of PCA Modes to Migration, Rotation, and Change of Curvature

Table 2 presents the contributions of the different PCA modes computed in this study to the shoreline and barline signals, in terms of migration, rotation, and change of curvature. This is achieved by first evaluating the R^2 coefficients between the spatial vectors computed in sections 4.1 and 4.2 ($e_{s,i}$, $e_{b,i}$, $e_{s,i}^*$, and $e_{b,i}^*$) and three normalized “idealized” orthogonal vectors (ideal shoreline/barline shapes).

These three idealized vectors represent an alongshore-uniform shape, an oblique shape with zero mean, and a hyperbolic cosine-shaped shape with zero mean. Therefore, their time variation would represent a migration, a rotation, and a breathing [Ratliff and Murray, 2014]. These profiles have been selected as they represent the most common behavior of embayed beach shoreline and barline found in the literature; they correspond to the model abilities (migration and rotation simulation) and to the preliminary observations (see section 2.3).

At this point, R^2 values only reflect how the mode variability is spread over migration, rotation, and change of curvature (for instance, 80% describes migration, 10% describes rotation, 5% describes curvature variations, and 5% describes other patterns). To relate this to the shoreline or barline variability, these R^2 values are scaled by the variability explained by each mode (columns R^2 in Table 2, also found in Figure 5). Resulting coefficients $R_{M'}^2$, $R_{R'}^2$, and R_U^2 quantify the contributions of each mode to the shoreline or barline variability, in terms of migration, rotation, and curvature variations. For instance, $M_{s,1}$ explains 64% of the shoreline variability, which can be decomposed into 41% in terms of migration and 23% in terms of rotation.

Notation

- a_b free parameter, m.
- α_b barline orientation (slope of the linear fit to each barline profile).
- α_{eq} free parameter,
- $\alpha_{eq,s}$, $\alpha_{eq,b}$ equilibrium shoreline and barline orientations,
- α_s shoreline orientation (slope of the linear fit to each shoreline profile),

- B_0 barline alongshore-averaged cross-shore position, m.
 $B(x_b, t)$ barline cross-shore position, described over alongshore dimension and time, m.
 b_b free parameter, m^2 .
 B_{SS} Brier Skill Score.
 C stacked shoreline and barline signal for PCA using Method 2,
 c_i^* temporal vectors of PCA mode i , Method 2,
 $c_{b,i}, c_{s,i}$ temporal vectors of barline and shoreline, respectively (modes i , Method 1),
 $c_{g,b}$ wave group celerity at breaking, $m\ s^{-1}$.
 C_{ab} free parameter, $m^{-2}\ s^{-1}$.
 C_{a_s} free parameter, $m^{-2}\ s^{-1}$.
 C_b free parameter, $m^{-2}\ s^{-1}$.
 C_s free parameter, $m^{-2}\ s^{-1}$.
 d_{50} median grain size, μm .
 δ embayed beaches classification parameter,
 δ_b free parameter,
 δ_{λ_i} uncertainty of PCA eigenvalue λ_i ,
 E incident wave energy defined as the square of the significant wave height H_s , m^2 .
 E_0 steady wave energy condition, m^2 .
 $e_{b,i}^*, e_{s,i}^*$ splitted spatial vectors from e_i^* (mode i , Method 2), for barline and shoreline,
 e_i^* spatial vectors of stacked shoreline and barline (mode i , Method 2),
 $e_{b,i}, e_{s,i}$ spatial vectors of barline and shoreline, respectively (modes i , Method 1),
 $E_{eq,b}$ equilibrium wave energy corresponding to the instantaneous barline position, m^2 .
 $E_{eq,s}$ equilibrium wave energy corresponding to the instantaneous shoreline position, m^2 .
 E_y wave energy available for alongshore sediment transport, m^2 .
 f_b damping factor.
 g gravity acceleration, $m\ s^{-2}$.
 H_b breaking wave height over the bar crest, m.
 $H_{b,0}$ breaking wave height, m.
 h^* closure depth, m.
 H_s significant wave height, m.
 K coefficient accounting for sediment properties,
 $\lambda_{b,i}, \lambda_{s,i}$ PCA eigenvalues for the barline and shoreline, Method 1,
 λ_i PCA eigenvalue,
 λ_i^* PCA eigenvalue, Method 2,
 L beach length, m.
 L_b, L_s alongshore positions of the center of the barline and shoreline, m.
 M_i^* PCA modes i of stacked shore- and barline, Method 2,
 $M_{b,i}, M_{s,i}$ PCA modes i of barline and shoreline, Method 1,
 m_s offset, m.
 $\nabla_x(E)$ alongshore gradient of wave energy, m.
 $\mathcal{N}_{b,error}$ Gaussian noise simulating barline position measurement error, m.
 $\mathcal{N}_{s,pixel}$ Gaussian noise simulating pixel footprint error, m.
 $\mathcal{N}_{s,runup}$ Gaussian noise simulating runup evaluation error, m.
 N^* number of independent samples of a data set,
 n_s free parameter, m^2 .
 p parameter used in the formulation of the damping factor, 8.
 p_s free parameter, m.
 q_s linear trend coefficient, $m\ s^{-1}$ (given in $m\ yr^{-1}$ in Table C1).
 r_1 first autocorrelation coefficient,
 r_s free parameter, m^2 .
 R^2 squared correlation coefficient.
 $R_{M'}^2, R_R^2, R_U^2$ variance explained by PCA modes in terms of migration, rotation, and breathing,
 ρ_w water density, $kg\ m^{-3}$.
 RMAE relative mean average error.
 RMSE root-mean-square error.

- σ standard deviation, m.
 S_0 shoreline alongshore-averaged cross-shore position, m.
 S'_0 detrended shoreline alongshore-averaged cross-shore position, m.
 $S_n(x_s, t)$ surrogate shoreline cross-shore position signal n , described over alongshore dimension and time, m.
 $S(x, t)$ shoreline cross-shore position, described over alongshore dimension and time, m.
 $S'(x_s, t)$ synthetic shoreline cross-shore position, described over alongshore dimension and time, m.
 t time, s.
 τ_{ab} instantaneous characteristic response time of the barline rotation, day.
 τ_{as} instantaneous characteristic response time of the shoreline rotation, day.
 τ_{B_0} instantaneous characteristic response time of the barline cross-shore migration, day.
 τ_{S_0} instantaneous characteristic response time of the shoreline cross-shore migration, day.
 θ peak incident wave angle,
 θ_0 steady peak incident wave angle condition,
 T_m mean wave period,
 x alongshore dimension in the local reference frame, increasing southward, m.
 x_b, x_s alongshore vectors on which the barline and shoreline are defined, m.
 $x_{b, \text{norm}}$ x_b normalized to the size of x_s , m.
 y cross-shore dimension in the local reference frame, increasing seaward, m.
 $\hat{}$ demeaned, normalized signal.
 \sim indication of a variable modeled by an equilibrium model.
 $\bar{}$ alongshore averaging (appendix).
 $\check{}$ alongshore asymmetric part of a signal in an embayment (appendix).

Acknowledgments

The present research was funded through the DFG (Deutsche Forschungsgemeinschaft) International Research Training Group INTERCOAST (Integrated Coastal Zone and Shelf-Sea Research) and MARUM (Center for Marine Environmental Sciences). Wave buoy data were kindly provided by the Bay of Plenty Regional Council (NZ). The Land Information New Zealand (LINZ) government department provided the bathymetric data used in the wave model, and the National Oceanic and Atmospheric Administration (NOAA, USA) provided the wave hindcast data. The CamEra system was installed by the Waikato Regional Council. The authors would like to thank George Payne (NIWA) for providing the images and maintaining the CamEra system and Wietse van de Lageweg for digitizing the shoreline and barline data used in the present paper. As well, the authors want to acknowledge Dirk Immenga for his precious assistance in collecting local wave data and beach profiles at Tairua Beach in 2011. The data used in this study are available on PANGAEA (<http://www.pangaea.de>) using the doi of the present publication. We deeply acknowledge four anonymous reviewers for their helpful comments on an early version of the manuscript.
