## ABSTRACT

We present simultaneous *Planck*, *Swift*, *Fermi*, and ground-based data for 105 blazars belonging to three samples with flux limits in the soft X-ray, hard X-ray, and  $\gamma$ -ray bands, and we compare our results to those of a companion paper presenting simultaneous *Planck* and multi-frequency observations of 104 radio-loud northern active galactic nuclei selected at radio frequencies. While we confirm several previous results, our unique data set has allowed us to demonstrate that the selection method strongly influences the results, producing biases that cannot be ignored. Almost all the BL Lac objects have been detected by *Fermi* Large Area Telescope (LAT), whereas 30 to 40% of the flat-spectrum radio quasars (FSRQs) in the radio, soft X-ray, and hard X-ray selected samples are still below the  $\gamma$ -ray detection limit even after integrating 27 months of *Fermi*-LAT data. The radio to sub-millimetre spectral slope of blazars is quite flat, with  $\langle \alpha \rangle \sim 0$  up to about 70 GHz, above which it steepens to  $\langle \alpha \rangle \sim -0.65$ . BL Lacs have significantly flatter spectra than FSRQs at higher frequencies. The distribution of the rest-frame synchrotron peak frequency ( $\nu_{\text{peak}}^S$ ) in the spectral energy distribution (SED) of FSRQs is the same in *all* the blazar samples with  $\langle \nu_{\text{peak}}^S \rangle = 10^{13.1 \pm 0.1}$  Hz, while the mean inverse-Compton peak frequency,  $\langle \nu_{\text{peak}}^{\text{IC}} \rangle$ , ranges from  $10^{21}$  to  $10^{22}$  Hz. The distributions of  $\nu_{\text{peak}}^S$  and of  $\nu_{\text{peak}}^{\text{IC}}$  of BL Lacs are much broader and are shifted to higher energies than those of FSRQs; their shapes strongly depend on the selection method. The Compton dominance of blazars ranges from less than 0.2 to nearly 100, with only FSRQs reaching values larger than about 3. Its distribution is broad and depends strongly on the selection method, with  $\gamma$ -ray selected blazars peaking at  $\sim 7$  or more, and radio-selected blazars at values close to 1, thus implying that the common assumption that the blazar power budget is largely dominated by high-energy emission is a selection effect. A comparison of our multi-frequency data with theoretical predictions shows that simple homogeneous SSC models cannot explain the simultaneous SEDs of most of the  $\gamma$ -ray detected blazars in all samples. The SED of the blazars that were not detected by *Fermi*-LAT may instead be consistent with SSC emission. Our data challenge the correlation between bolometric luminosity and  $\nu_{\text{peak}}^S$  predicted by the blazar sequence.

## 1. Introduction

Blazars are jet-dominated extragalactic objects characterized by the emission of strongly variable and polarized non-thermal radiation across the entire electromagnetic spectrum, from radio waves to  $\gamma$ -rays (e.g., Urry & Padovani 1995). As the extreme properties of these sources are due to relativistic amplification of radiation emitted along a jet pointing very close to the line of sight (e.g., Blandford & Rees 1978; Urry & Padovani 1995), they are rare compared to objects pointing their jets at random angles and to radio quiet QSOs where the emitted radiation is due to thermal or reflection mechanisms ultimately powered by accretion onto a supermassive black hole (e.g., Abdo et al. 2010a). Despite that, blazars’ strong emission at all wavelengths makes them the dominant type of extragalactic sources in the radio, microwave,  $\gamma$ -ray, and TeV bands where accretion and other thermal emission processes do not produce significant amounts of radiation (Toffolatti et al. 1998; Giommi & Colafrancesco

2004; Hartman et al. 1999; Abdo et al. 2010a; Costamante & Ghisellini 2002; Colafrancesco & Giommi 2006; Weekes 2008). For these reasons blazars are hard to find at optical and X-ray frequencies, while they dominate the microwave and  $\gamma$ -ray sky at high Galactic latitudes. The advent of the *Fermi* (Atwood et al. 2009) and *Planck*<sup>1</sup> (Tauber et al. 2010; Planck Collaboration 2011a) satellites, that are surveying these two observing windows, combined with the versatility of the *Swift* observatory (Gehrels et al. 2004a), is giving us the unprecedented opportunity to collect multi-frequency data for very large samples of blazars and open the way to a potentially much deeper under-

<sup>1</sup> *Planck* (<http://www.esa.int/Planck>) is a project of the European Space Agency – ESA – with instruments provided by two scientific Consortia funded by ESA member states (in particular the lead countries: France and Italy) with contributions from NASA (USA), and telescope reflectors provided in a collaboration between ESA and a scientific Consortium led and funded by Denmark.

standing of the physics and demographics of these still puzzling objects.

Blazars can be categorized by their optical properties and the shape of their broad-band spectral energy distributions (SEDs). Blazar SEDs always show two broad bumps in the  $\log \nu - \log \nu F_\nu$  space; the lower-energy one is usually attributed to synchrotron radiation while the more energetic one is attributed to inverse-Compton scattering. Blazars showing strong and broad optical emission lines are usually called flat-spectrum radio quasars (FSRQs), while objects with no broad emission lines (i.e., rest frame equivalent width, EW,  $< 5 \text{ \AA}$ ) are called BL Lac objects. Padovani & Giommi (1995) introduced the terms LSP and HSP to distinguish between BL Lacs with low and high values of the peak frequency of the synchrotron bump ( $\nu_{\text{peak}}^S$ ). Abdo et al. (2010a) extended this definition to all types of blazars and defined the terms LSP, ISP, and HSP (corresponding to low, intermediate, and high synchrotron peaked blazars) for the cases where  $\nu_{\text{peak}}^S < 10^{14} \text{ Hz}$ ,  $10^{14} \text{ Hz} < \nu_{\text{peak}}^S < 10^{15} \text{ Hz}$ , and  $\nu_{\text{peak}}^S > 10^{15} \text{ Hz}$ , respectively. In the rest of this paper we will use the LSP/ISP/HSP nomenclature.

It is widely recognized that one of the most effective ways of studying the physics of blazars is through the use of multi-frequency data, ideally simultaneous. There are several examples of studies following this approach (e.g., Giommi et al. 1995; von Montigny et al. 1995; Sambruna et al. 1996; Fossati et al. 1998; Giommi et al. 2002; Nieppola et al. 2006; Padovani et al. 2006), but in most cases the samples are heterogeneous and the data are sparse and non-simultaneous.

Simultaneous and well sampled SEDs require the organization of complex multifrequency observation campaigns, involving the coordination of observations from several observatories. Such large efforts have been carried out only rarely, and almost exclusively on the occasion of large flaring events in a few bright and well known blazars, e.g., 3C 454.3 (Giommi et al. 2006; Abdo et al. 2009a; Vercellone et al. 2009), Mkn 421, (Donnarumma et al. 2009; Abdo et al. 2011), and PKS 2155–304 (Aharonian et al. 2009).

Significant progress has been made recently with the publication of a compilation of quasi-simultaneous SEDs of a large sample of  $\gamma$ -ray bright blazars (Abdo et al. 2010a). This is an important step forward compared to previous compilations, as the sample presented is statistically representative of the population of bright  $\gamma$ -ray selected blazars, and the data were quasi-simultaneous, that is collected within three months of the *Fermi*-LAT observations.

With *Planck*, *Swift*, and *Fermi*-LAT simultaneously in orbit, complemented by other space and ground-based observatories, it is now possible to assemble high-quality multi-frequency datasets that allow us to build simultaneous and well sampled broad-band spectra of large and statistically well-defined samples of AGNs.

In this and a companion paper (Planck Collaboration 2011e) we present the first results of a large cooperative program between the *Planck*, *Fermi*-LAT, and *Swift* satellites and a number of ground-based observatories, carried out to collect multi-frequency data on large samples of blazars selected using different criteria and observed when the sources lie in the field of view of *Planck*.

In this paper we concentrate on blazars selected in the soft X-ray, hard X-ray, and  $\gamma$ -ray bands. We present the simultaneous data, test for flux correlations, and estimate some key parameters characterizing the SEDs. We then compare the results obtained for the different samples. Detailed fits to models, variabil-

ity studies, and more complete theoretical interpretations will be presented elsewhere.

Throughout this paper we define the radio-to-submillimetre spectral index  $\alpha$  by  $S(\nu) \propto \nu^\alpha$ , and we adopt a  $\Lambda$ CDM cosmology with  $H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}$ ,  $\Omega_m = 0.27$ , and  $\Omega_\Lambda = 0.73$  (Komatsu et al. 2011).

## 2. Sample selection

In order to explore the blazar parameter space from different viewpoints we have used several different criteria to select the blazars to be observed simultaneously by *Planck*, *Swift*, and *Fermi*. In this paper we consider three samples of blazars that are flux-limited in the high-energy part of the electromagnetic spectrum: soft X-ray (0.1–2.4 keV) from the *ROSAT* All-Sky Survey Bright Source Catalog (1RXS, Voges et al. 1999, hereafter referred to as the RASS sample), hard X-ray (15–150 keV) from the *Swift*-BAT 54 month source catalog (Cusumano et al. 2010, hereafter referred to as the BAT sample), and  $\gamma$ -ray from the *Fermi*-LAT 3-month Bright AGN Source List (Abdo et al. 2009b, hereafter referred to as the *Fermi*-LAT sample).

These high-energy-selected samples are complemented by a radio flux-limited sample of northern sources (hereafter referred to as the radio sample) which is presented in the companion paper (Planck Collaboration 2011e). We use these four samples, defined in widely different parts of the electromagnetic spectrum, to try to disentangle the intrinsic properties of blazars from the heavy selection effects that often afflict blazar samples. Altogether we consider 175 sources.

For the classification as different blazar types we rely on the Roma-BZCAT catalog (Massaro et al. 2010) which is a compilation of known blazars that have been carefully checked in order to determine their blazar type in a uniform and reliable way. Massaro et al. (2010) divide blazars into three categories: BZQ/FSRQ, in which the optical spectrum shows broad emission lines; BZB/BL Lac objects, in which the optical spectrum is featureless or shows only absorption lines from the host galaxy; BZU/Uncertain type, comprising objects for which the authors could not find sufficient data to safely determine the source classification, and objects that show peculiar characteristics (see Massaro et al. 2010, for details). According to this classification 96 of our objects are of the FSRQ type, 40 are BL Lacs, and the rest are of uncertain type. About 160 have been observed by *Swift* simultaneously with *Planck*, mostly through dedicated target of opportunity (ToO) pointings. In the following we describe the selection criteria for each high-energy selected sample. Details for the radio selected sample are given in Planck Collaboration (2011e).

### 2.1. The issue of blazar classification

This classification of blazars into featureless (BL Lacs) and broad-lined objects (FSRQs), although very simple in principle, is not unambiguous, nor it is robust. The borderline between the two blazar subclasses, namely 5  $\text{\AA}$  in the source rest frame for the EW of any emission line, was originally defined as a result of the optical identification campaigns of the sources discovered in the first well defined and complete samples of (bright) radio and X-ray selected objects (Stickel et al. 1991; Stocke et al. 1991). However, we now know that well-known BL Lac objects like OJ 287 – and BL Lac itself – exhibit emission lines with EW well above the 5  $\text{\AA}$  limit on some occasions (Vermeulen et al. 1995; Corbett et al. 1996). Several other BL Lac objects show power-

ful emission lines with EW just below, and sometimes above the 5 Å threshold, depending on the variable continuum level (see e.g. Lawrence et al. 1996; Ghisellini et al. 2011, and references therein). Well-known FSRQs like 3C 279 also appear nearly featureless during bright states (Pian et al. 1999). The recent detection of broad Lyman- $\alpha$  emission in the UV spectrum of classical BL Lacs like Mkn 421 and Mkn 501 (Stocke et al. 2011) further contributes to the blurring of the distinction between the two types of blazars.

The boundary between BL Lac objects and radio galaxies is also fragile as BL Lacs are distinguished from radio galaxies when the 4000 Å Ca H&K break (a stellar absorption feature in the host galaxy) is diluted by non-thermal radiation more than a certain amount first quantified by Stocke et al. (1991) and then revised by Marcha et al. (1996), Landt et al. (2002) and Landt et al. (2004). The level of non-thermal blazar light around 4000 Å reflects the intrinsic radio power of the jet; it can be highly variable and depends strongly on the position of the peak of the synchrotron emission thus making the border between BL Lacs and radio galaxies quite uncertain.

In this work we relied on the blazar classification given in the Roma-BZCAT catalog (Massaro et al. 2010) which re-assessed the blazar subclass of each object after a critical review of the optical data available in the literature and in large public databases like the SDSS (York et al. 2000). Despite that, some uncertainties remain, and our conclusions about the differences between BL Lacs and FSRQs could suffer from that. However, the large size of our samples ensures that a few misclassifications should not significantly affect our results. To assess the impact of blazar misclassification and of transitional objects in a quantitative way it is necessary to perform detailed simulations.

## 2.2. The *Fermi*-LAT ( $\gamma$ -ray flux limited) sample

The  $\gamma$ -ray flux limited sample has been created from the *Fermi* LAT Bright Source List<sup>2</sup> (Abdo et al. 2009b). We have selected all the high Galactic latitude ( $|b| > 10^\circ$ ) blazars detected with high significance ( $TS > 100$ )<sup>3</sup>. To further reduce the size of the sample and to ensure that all the sources are well above the *Planck* sensitivity limit for one survey, we have considered only the sources with radio flux density (taken from BZCAT)  $S_{5\text{ GHz}} > 1 \text{ Jy}$ . We realize that this is a double cut, with a TS limit at  $\gamma$ -ray energies and a flux-density limit in the radio band. Since a TS limit translates into different  $\gamma$ -ray flux limits depending on the  $\gamma$ -ray spectral slope, with higher sensitivity to flat-spectrum sources (see fig. 7 of Abdo et al. 2009b), for our statistical considerations we will also consider the subsample with a flux cut of  $F(E > 100 \text{ MeV}) > 8 \times 10^{-8} \text{ ph cm}^{-2} \text{ s}^{-1}$ , which removes such a dependence. The sample so defined includes 50 sources, 40 of which are brighter than the  $\gamma$ -ray flux limit of  $8 \times 10^{-8} \text{ ph cm}^{-2} \text{ s}^{-1}$ . Relaxing the radio flux density cut would give a purely  $\gamma$ -ray flux limited sample and increase the number of sources to  $\approx 70$ , but with about 40–50% of the objects with  $S_{5\text{ GHz}} < 1 \text{ Jy}$  undetected by *Planck*. We will consider this exclusively  $\gamma$ -ray flux limited sample in the future when more *Swift* simultaneous observations will be available.

Details are presented in Table 1 where column 1 gives the source common name, column 2 gives the *Fermi*-LAT name as it appears in Abdo et al. (2010b), columns 3 and 4 give the

source position in equatorial coordinates, columns 5, 6, and 7 give the redshift,  $V$  magnitude, and X-ray flux (0.1–2.4 keV) from BZCAT (Massaro et al. 2010), column 8 gives the 1.4 GHz or 843 MHz flux density from NVSS (Condon et al. 1998) or from SUMSS (Mauch et al. 2003) with  $\text{Dec} < -40^\circ$ , column 9 gives the  $\gamma$ -ray flux from Abdo et al. (2010b)<sup>4</sup>, and column 10 gives the date of the *Swift* ToO observation made when the source was within the *Planck* field of view.

## 2.3. The *Swift*/BAT (hard X-ray flux limited) sample

We have defined our hard X-ray flux limited sample starting from the *Swift*-BAT 54 month source catalog<sup>5</sup> (Cusumano et al. 2010), and selecting all the sources identified with blazars with X-ray flux  $> 10^{-11} \text{ erg cm}^{-2} \text{ s}^{-1}$  in the 15–150 keV energy band. The BAT catalog includes 70 known blazars that satisfy the X-ray flux condition, but many of them are too faint to be detected at millimetre wavelengths by *Planck*. Therefore, although a pure X-ray selection would be preferable, we have decided to add a mild radio flux-density constraint ( $S_{5\text{ GHz}} > 100 \text{ mJy}$ , with  $S_{5\text{ GHz}}$  taken from BZCAT) to select only sources that can be detected by *Planck* or for which *Planck* will be able to provide meaningful upper limits, leaving enough sources to build a statistically sizable sample. The list of the 34 sources included in this sample is given in Table 2. The column description is the same as for Table 1.

## 2.4. The ROSAT/RASS (soft X-ray flux limited) sample

The soft X-ray flux limited sample was defined starting from the RASS catalog (1RXS) (Voges et al. 1999), and selecting all the sources identified with blazars with count rate larger than 0.3 counts/s in the 0.1–2.4 keV energy band, and radio flux density from BZCAT  $S_{5\text{ GHz}} > 200 \text{ mJy}$ . The reasons to use a mild radio flux constraint are the same as for the hard X-ray flux limited sample; for this case, however, we have chosen 200 mJy to further reduce the size of the sample to be comparable with the  $\gamma$ -ray and hard X-ray samples. The list of the 43 sources included in this sample is given in Table 3. The column description is the same as for Tables 1 and 2.

## 2.5. The radio flux-density limited sample

The radio flux-density limited sample is presented in the companion *Planck* paper (Planck Collaboration 2011e) where all the observational details are given. The sample consists of 104 bright northern and equatorial radio-loud AGN characterized by  $S_{37\text{ GHz}} > 1 \text{ Jy}$  as measured with the Metsähovi radio telescope.

Although the samples are defined by different criteria, four sources are common to all samples. These are the well-known objects 3C 273, 3C 279, Mkn 501 and 3C 454.3, which are among the brightest objects across the entire electromagnetic spectrum. A summary of the number of sources common to more than one sample is given in Table 4.

<sup>4</sup> We give average  $\gamma$ -ray fluxes from the 1-year *Fermi* catalog rather than the three-month fluxes that were used to define the sample for consistency with Tables 2 and 3

<sup>5</sup> <http://www.asdc.asi.it/bat54/>

### 3. Data analysis

#### 3.1. Ground-based follow-up data

Following the launch of *Planck*, several follow-up programs with ground-based facilities started collecting simultaneous radio and optical data. In this paper we use data from the observatories listed in Table 5.

##### 3.1.1. APEX

Some sources from our sample were observed in the submillimetre domain with the 12-m Atacama Pathfinder Experiment (APEX) in Chile. The observations were made using the LABOCA bolometer array centered at 345 GHz. Data were taken at two epochs: September 3–4, 2009, and November 12, 2009. The data were reduced using the script package *mini-*

*crush*<sup>6</sup>, version 30-Oct-2009. Uranus was used as a calibrator for the flux densities.

#### 3.1.2. ATCA-PACO

The *Planck*-ATCA Co-eval Observations (PACO) project (Massardi et al. 2011a; Bonavera et al. 2011) observed 480 sources selected from the Australia Telescope 20 GHz catalogue (AT20G, Massardi et al. 2011b), with the Australia Telescope Compact Array (ATCA) in the frequency range 4.5–40 GHz, at several epochs close in time to the *Planck* observations in the period July 2009 to August 2010. The PACO sample is a complete, flux-density limited, and spectrally selected sample of southern sources, with the exception of the region with Galactic latitude

<sup>(d)</sup> *Swift* simultaneous observation not available. <sup>(e)</sup> Optical spectrum completely featureless or not available, redshift unknown

$|b| < 5^\circ$ . A total of 147 PACO point-like sources have at least one observation within 10 days of the *Planck* observations.

### 3.1.3. Effelsberg and IRAM

Quasi-simultaneous cm/mm radio spectra for a larger number of *Planck* blazars have been obtained within the framework of a *Fermi* monitoring program of  $\gamma$ -ray blazars (F-GAMMA; Fuhrmann et al. 2007; Angelakis et al. 2008) on the Effelsberg 100-m and IRAM 30-m telescopes. The frequency range was 2.64–142 GHz.

The Effelsberg measurements were conducted with the secondary focus heterodyne receivers at 2.64, 4.85, 8.35, 10.45, 14.60, 23.05, 32.00, and 43.00 GHz. The observations were performed quasi-simultaneously with cross-scans, that is slew-ing over the source position in azimuth and elevation with the number of sub-scans chosen to reach the desired sensitivity (for details, see Fuhrmann et al. 2008; Angelakis et al. 2008). Pointing offset, gain, atmospheric opacity, and sensitivity corrections have been applied to the data.

The IRAM 30-m observations were carried out with calibrated cross-scans using the EMIR horizontal and vertical polarization receivers operating at 86.2 and 142.3 GHz. The opacity-corrected intensities were converted into the standard temperature scale and finally corrected for small remaining pointing offsets and systematic gain-elevation effects. Conversion to standard flux density scale was based on frequent observations of primary calibrators (Mars, Uranus) and secondary calibrators (W3(OH), K3-50A, NGC 7027).

From this program, radio spectra measured quasi-simultaneously with the *Planck* observations have been collected for a total of 37 *Planck* blazars during the period August 2009 to June 2010.

### 3.1.4. Medicina

The Simultaneous Medicina *Planck* Experiment (SiMPIE, Procopio et al. 2011) is using the 32-m Medicina single dish to make almost simultaneous observations at 5 and 8.3 GHz of the 263 sources of the NEWPS sample (Massardi et al. 2009) with Dec > 0°, and partially overlapping with the PACO observations for –10° < Dec < 0°. The project began in June 2010 and finished in June 2011, observing the sample several times throughout two complete *Planck* surveys. It does not overlap with the *Planck* first survey.

### 3.1.5. Metsähovi

The 37 GHz observations were made with the 13.7-m Metsähovi radio telescope using a 1 GHz bandwidth, dual-beam receiver centered at 36.8 GHz. The observations are ON-ON observations, alternating the source and the sky in each feed horn. A typical integration time to obtain one flux density data point is 1200–1400 s. The telescope detection limit at 37 GHz is ∼0.2 Jy under optimal conditions. Data points with a signal-to-noise ratio below four are handled as non-detections. The flux-density scale is set by observations of DR 21. Sources NGC 7027,

3C 274, and 3C 84 are used as secondary calibrators. A detailed description of the data reduction and analysis is given in (Teräsranta et al. 1998). The error estimate in the flux density includes the contribution from the measurement rms and the uncertainty of the absolute calibration.

### 3.1.6. OVRO

Some of the sources in our samples were monitored at 15 GHz using the 40-metre Telescope of the Owens Valley Radio Observatory as part of a larger monitoring program (Richards et al. 2011). The flux density of each source was measured approximately twice weekly, with occasional gaps due to poor weather or instrumental problems. The telescope is equipped

with a cooled receiver installed at prime focus, with two symmetric off-axis corrugated horn feeds sensitive to left circular polarization. The telescope and receiver combination produces a pair of approximately Gaussian beams (157 arcsec FWHM), separated in azimuth by 12.95 arcmin. The receiver has a center frequency of 15.0 GHz, a 3.0 GHz bandwidth, and a noise-equivalent reception bandwidth of 2.5 GHz. Measurements are made using a Dicke-switched dual-beam system, with a second level of switching in azimuth to alternate source and sky in each of the two horns. Calibration is referred to 3C 286, for which a flux density of 3.44 Jy at 15 GHz is assumed (Baars et al. 1977). Details of the observations, calibration, and analysis are given by (Richards et al. 2011).

### 3.1.7. RATAN

A six-frequency broadband radio spectrum was obtained with the RATAN-600 radio telescope in transit mode by observing simultaneously at 1.1, 2.3, 4.8, 7.7, 11.2, and 21.7 GHz (Parijskij 1993; Berlin & Friedman 1996). Data were reduced using the RATAN standard software FADPS (Flexible Astronomical Data Processing System) reduction package (Verkhodanov 1997). The flux density measurement procedure at RATAN-600 is described by (Aliakberov et al. 1985).

### 3.1.8. UMRAO

Centimetre-band observations were obtained with the University of Michigan 26-m prime focus paraboloid equipped with radiometers operating at central frequencies of 4.8, 8.0, and 14.5 GHz. Observations at all three frequencies utilized rotating polarimeter systems permitting both total flux density and linear polarization to be measured. A typical measurement consisted of 8 to 16 individual measurements over a 20–40 minute time period. Frequent drift scans were made across stronger sources to verify the telescope pointing correction curves; and observations of program sources were intermixed with observations of a grid of calibrator sources to correct for temporal changes in the antenna aperture efficiency. The flux scale was based on observations of Cassiopeia A (Baars et al. 1977). Details of the calibration and analysis techniques are described by Aller et al. (1985).

### 3.1.9. VLA

The Very Large Array (VLA) and, since Spring 2010, the Expanded VLA (EVLA), observed a subset of the sources as simultaneously as possible. Most of the VLA and EVLA runs were 1–2 hour chunks of time. In a one-hour chunk of time, in addition to flux calibrators and phase calibrators, typically 5–8 *Planck* sources were observed. In many cases, VLA flux-density and phase calibrators were themselves of interest, since they were bright enough to be detected by *Planck*. For these bright sources, the integration times could be extremely short.

Integration times were about 30 s at 4.86 GHz and 8.46 GHz, 100 s at 22.46 GHz, and 120 s at 43.34 GHz. All VLA/EVLA flux density measurements were calibrated using standard values for one or both of the primary calibrator sources used by NRAO, 3C 48 or 3C 286, and the *u-v* data were flagged, calibrated, and imaged using standard NRAO software (AIPS or CASA). It is important to bear in mind that the VLA and EVLA were in different configurations at different times in the several months duration of the observations. As a consequence, the angular resolution changed. In addition, for a given configuration, the resolution was much finer at higher frequencies. For that reason, sources that showed signs of resolution in any VLA configuration or at any VLA frequency have been carefully flagged.

### 3.1.10. KVA

Optical observations were made with the 35 cm KVA (Kunliga Vetenskapsakademiet) telescope at La Palma, Canary islands. All observations were made through the *R*-band filter ( $\lambda_{\text{eff}} = 640 \text{ nm}$ ) using a Santa Barbara ST-8 CCD camera with a gain factor of  $2.3 e^-/\text{ADU}$  and readout noise of 14 electrons. Pixels were binned  $2 \times 2$  pixels giving a plate scale of 0.98 arcsec/pixel. We obtained 3–6 exposures of 180 s per target. The images were reduced in the standard way of subtracting the bias and dark frames and dividing by twilight flat-fields. The fluxes of the target and 3–5 stars in the target field were measured with aperture photometry and the magnitude difference between the target and a primary reference star in the same field was determined. Using differential mode makes the observations insensitive to variations in atmospheric transparency and accurate measurements can be obtained even in partially cloudy conditions. The *R*-band magnitude of the primary reference star was determined from observations made on photometric nights, using compari-

son stars in known blazar fields as calibrators (Fiorucci & Tosti 1996; Fiorucci et al. 1998; Raiteri et al. 1998; Villata et al. 1998; Nilsson et al. 2007) and taking into account the color term of the *R*-band filter employed. After the *R*-band magnitude of the primary reference star was determined, the object magnitudes were computed from the magnitude differences. At this phase we assumed  $V - R = 0.5$  for the targets. Several stars in the field were used to check the quality of the photometry and stability of the primary reference. The error bars of the magnitudes include the contribution from both measurement and calibration errors.

### 3.1.11. Xinglong

The monitoring at Xinglong Station, National Astronomical Observatories of China, was performed with a 60/90 cm f/3 Schmidt telescope. The telescope is equipped with a 4096×4096 E2V CCD, which has a pixel size of  $12\text{ }\mu\text{m}$  and a spatial resolution of  $1''.3\text{ pixel}^{-1}$ . The observations were made with an intermediate-band filter, the *I* filter. Its central wavelength and passband width are 6685 Å and 514 Å, respectively. The exposure times were mostly 120 s but ranged from 60 to 180 s, depending on weather and lunar phase.

## 3.2. *Planck* microwave data

*Planck* (Tauber et al. 2010; Planck Collaboration 2011a) is the third generation space mission to measure the anisotropy of the cosmic microwave background (CMB). It observes the sky in nine frequency bands covering 30–857 GHz with high sensitivity and angular resolution from  $31'$  to  $5'$ . Full sky coverage is attained in  $\sim 7$  months. The Low Frequency Instrument (LFI; Mandolesi et al. 2010; Bersanelli et al. 2010; Mennella et al. 2011) covers the 30, 44, and 70 GHz bands with amplifiers cooled to 20 K. The High Frequency Instrument (HFI; Lamarre et al. 2010; Planck HFI Core Team 2011a) covers the 100, 143, 217, 353, 545, and 857 GHz bands with bolometers cooled to 0.1 K. Polarization is measured in all but the highest two bands (Leahy et al. 2010; Rosset et al. 2010). A combination of radiative cooling and three mechanical coolers produces the temperatures needed for the detectors and optics (Planck Collaboration 2011b). Two Data Processing Centers (DPCs) check and calibrate the data and make maps of the sky (Planck HFI Core Team 2011b; Zaccari et al. 2011). *Planck*'s sensitivity, angular resolution, and frequency coverage make it a powerful instrument for Galactic and extragalactic astrophysics as well as cosmology. Early astrophysics results are given in Planck Collaboration, 2011h–z.

The Early Release Compact Source Catalog (ERCSC, Planck Collaboration 2011c) contains all sources, both Galactic and extragalactic, detected with high confidence over the full sky during the period between August 12, 2009 and June 6, 2010 (corresponding to *Planck* operational days 91 to 389). The ERCSC only contains average intensity information for the sources. However, many of the sources were observed more than once during the time period spanned by the ERCSC, and some of the *Swift* observations used for this paper have been carried between June and October 2010. Therefore, in order to have simultaneous data, we have produced separated maps for the first (OD 91–274), the second (OD 275–456), and the beginning of the third *Planck* survey (OD 457–550) through the LFI and HFI pipelines described in Zaccari et al. (2011) and Planck HFI Core Team (2011b), and we have extracted the flux densities from each map using IFACMEX, an implementation of

the Mexican Hat Wavelet 2 (MHW2) algorithm available at the LFI DPC. The MHW2 tool has been extensively used to detect point-like objects in astronomical images, both with simulations from various experiments and data from the *WMAP*, *Planck*, and Herschel satellites (González-Nuevo et al. 2006; López-Caniego et al. 2006, 2007; Massardi et al. 2009). This wavelet is defined as the fourth derivative of the two-dimensional Gaussian function, where the scale of the filter *R* is optimized to look for the maximum in the signal-to-noise ratio of the sources in the filtered map. In practice, the IFACMEX code, our implementation of the MHW algorithm, deals with FITS maps in Healpix format (Górski et al. 2005) and can be used to detect sources in the whole sky or at the position of known objects. For this analysis we have looked for objects above the  $4\sigma$  level at the positions corresponding to the 105 sources of our sample. The results of the analysis of *Planck* simultaneous data are reported in Table 6 where columns 1 and 2 give the source name, columns 3 and 4 give the observation start and end times, and columns 5–13 give the flux densities in units of Jy at 30, 44, 70, 100, 143, 217, 353, 545, and 857 GHz.

Owing to source variability, we do not expect these simultaneous flux densities to be the same as the time-averaged ERCSC measurements, except in the case of the sources that have been observed only once during the ERCSC time range and for which we have estimated the *Planck* flux densities, simultaneous with the *Swift* observation, in the same period. We have verified that, for the sources fulfilling these requirements, the flux densities extracted for this paper are in good agreement with those of the ERCSC.

## 3.3. *Swift* optical, UV and X-ray data

The *Swift* Gamma-Ray-Burst (GRB) Explorer (Gehrels et al. 2004b) is a multi-frequency space observatory devoted to the discovery and rapid follow up of GRBs. There are three instruments on board the spacecraft: the UV and Optical Telescope (UVOT, Roming et al. 2005), the X-Ray Telescope (XRT, Burrows et al. 2005) sensitive in the 0.3–10.0 keV band, and the Burst Alert Telescope (BAT, Barthelmy et al. 2005) sensitive in the 15–150 keV band. Although the primary scientific goal of the satellite is the observation of GRBs, the wide frequency coverage is suitable for blazar studies, because it covers the region where the transition between synchrotron and inverse-Compton emission usually occurs.

When not engaged in GRB observations, *Swift* is available for Target of Opportunity (ToO) requests, and the *Swift* team decided to devote an average of three ToO observations per week to this project for simultaneous observation of blazars.

### 3.3.1. UVOT

The *Swift* UVOT telescope can produce images in each of its six lenticular filters (V, B, U, UVW1, UVM2, and UVW2). However, in an effort to reduce the use of mechanical parts after several years of orbital operations, observations are carried out using only one filter, unless specifically requested by the user. Thus images are not always available for all filters.

The photometry analysis of all our sources was performed using the standard UVOT software distributed within the HEAsoft 6.8.0 package and the calibration included in the latest release of the “Calibration Database”. A specific procedure has been developed at the ASI Science Data Center (ASDC) to process all ToO observations requested for the blazar sam-

ple. Counts were extracted from aperture of 5'' radius for all filters and converted to fluxes using the standard zero points (Poole et al. 2008). The fluxes were then de-reddened using the appropriate values of  $E(B - V)$  for each source taken from (Schlegel et al. 1998) with  $A_\lambda/E(B - V)$  ratios calculated for UVOT filters using the mean Galactic interstellar extinction curve from (Fitzpatrick 1999). No variability was detected within single exposures in any filter. The processing results were carefully validated including checks for possible contamination from nearby objects within the source and background apertures. Some sources, such as 3C 273 and NGC 1275, needed special analysis, and results for some other sources had to be discarded.

The results of UVOT data analysis are summarized in Table 7 where columns 1 and 2 give the source name, columns 3 and 4 give the observation date and the *Swift* observation ID, and the remaining columns give the magnitudes in the six UVOT filters with errors.

### 3.3.2. XRT

The *Swift* XRT is usually operated in “auto-state” mode which automatically adjusts the CCD read-out mode to the source brightness, in an attempt to avoid pile-up (Burrows et al. 2005; Hill et al. 2004). As a consequence, some of the data were collected using the most sensitive Photon Counting (PC) mode while Windowed Timing (WT) mode was used for bright sources.

The XRT data were processed with the XRTDAS software package (v. 2.5.1, Capalbi et al. (2005)) developed at the ASI Science Data Center (ASDC) and distributed by the NASA High Energy Astrophysics Archive Research Center (HEASARC) within the HEASoft package (v. 6.9). Event files were calibrated and cleaned with standard filtering criteria using the *xrtpipeline* task and the latest calibration files available in the *Swift* CALDB. Events in the energy range 0.3–10 keV with grades 0–12 (PC mode) and 0–2 (WT mode) were used for the analysis.

Events for the spectral analysis were selected within a circle of 20 pixel ( $\sim 47''$ ) radius, which encloses about 90% of the PSF at 1.5 keV (Moretti et al. 2005), centered on the source position. For PC mode data, when the source count rate is above  $\sim 0.5$  counts/s data are significantly affected by pile-up in the inner part of the Point Spread Function (PSF). For such cases, after comparing the observed PSF profile with the analytical model derived by (Moretti et al. 2005), we removed pile-up effects by excluding events detected within up to 6 pixels from the source position, and used an outer radius of 30 pixels. The value of the inner radius was evaluated individually for each observation affected by pile-up, depending on the observed source count rate.

Ancillary response files were generated with the *xrtmkarf* task applying corrections for the PSF losses and CCD defects. Source spectra were binned to ensure a minimum of 20 counts per bin to utilize the  $\chi^2$  minimization fitting technique. We fitted the spectra adopting an absorbed power-law model with photon index  $\Gamma_x$ . When deviations from a single power law model were found, we adopted a log-parabolic law of the form  $F(E) = KE^{(a+b\log E)}$  (Massaro et al. 2004) which has been shown to fit the X-ray spectrum of blazars of the HSP type well (e.g. Giommi et al. 2005; Tramacere et al. 2009). This spectral model is described by only two parameters:  $a$ , the photon index at 1 keV, and  $b$ , the curvature of the parabola. For both models the amount of hydrogen-equivalent column density ( $N_H$ ) was fixed to the Galactic value along the line of sight (Kalberla et al. 2005). For a fraction of the sources fitted with a power-law model ( $\sim 15\%$ )

we found evidence of an absorption excess at low energies and the hydrogen column density  $N_H$  parameter was left free.

The results of the spectral fits with a power-law model and Galactic  $N_H$  are shown in Table 8 where columns 1 and 2 give the source name, column 3 gives the *Swift* observation date, column 4 gives the best fit photon index  $\Gamma_x$ , column 5 gives the Galactic  $N_H$ , columns 6 and 7 give the 0.1–2.4 and 2–10 keV X-ray fluxes, column 8 gives the value of the reduced  $\chi^2$ , and column 9 gives the number of degrees of freedom.

In Table 9 we report data obtained using a log-parabola to describe the spectrum model. Column 1 and 2 give the source name, column 3 gives the *Swift* observation date, column 4 and 5 give the log parabola parameters  $a$  and  $b$ , column 6 gives the Galactic  $N_H$ , columns 7 and 8 give the 0.1–2.4 and 2–10 keV X-ray fluxes, column 9 gives the value of the reduced  $\chi^2$ , and column 10 gives the number of degrees of freedom.

Finally, in Table 10 we report the results of the spectral fits that have been performed leaving the hydrogen column density  $N_H$  as a free parameter. Columns 1 and 2 give the source name, column 3 gives the *Swift* observation date, column 4 gives the best fit photon index  $\Gamma_x$ , column 5 gives the estimated  $N_H$ , columns 6 and 7 give the 0.1–2.4 and 2–10 keV X-ray fluxes, column 8 gives the value of the reduced  $\chi^2$ , and column 9 gives the number of degrees of freedom.

### 3.4. Fermi-LAT $\gamma$ -ray data

The Large Area Telescope (LAT) on-board *Fermi* is an electron-positron pair conversion telescope sensitive to  $\gamma$ -rays of energies from 20 MeV to  $> 300$  GeV. The Fermi-LAT consists of a high-resolution silicon microstrip tracker, a CsI hodoscopic electromagnetic calorimeter and an anticoincidence detector for charged particle background identification. A full description of the instrument and its performance can be found in Atwood et al. (2009). The large field of view ( $\sim 2.4$  sr) allows the LAT to observe the full sky in survey mode every 3 hr. The LAT point spread function (PSF) depends strongly on both the energy and the conversion point in the tracker, but less on the incidence angle.

The LAT  $\gamma$ -ray spectra of all AGN sources are studied in Abdo et al. (2010b) based on 11 months of Fermi-LAT data. Here we derive the  $\gamma$ -ray spectra of the blazars for which we build the simultaneous SEDs, integrating for two weeks encompassing the whole duration of the *Planck* observations.

The *Fermi*-LAT data considered for this analysis cover the period from August 4, 2008 to November 4, 2010 and have been analyzed using the standard *Fermi*-LAT ScienceTools software package<sup>7</sup> (version v9r16 and selecting for each source only photons above 100 MeV, belonging to the diffuse class (Pass6 V3 IRF; Atwood et al. 2009) which have the lowest background contamination. For each source, we selected only photons within a 15° region of interest (RoI) centered around the source itself. In order to avoid background contamination from the bright Earth limb, time intervals where the Earth entered the LAT Field of View (FoV) were excluded from the data sample. In addition, we have excluded observations in which the source under study was viewed at zenith angles larger than 105° where Earth’s atmospheric  $\gamma$ -rays increase the background contamination. The data were analyzed with a binned maximum likelihood technique (Mattox et al. 1996) using the analysis software *gtlike* de-

<sup>7</sup> <http://fermi.gsfc.nasa.gov/ssc/data/analysis/documentation/Cicerone>

veloped by the LAT team<sup>8</sup>. A model accounting for the diffuse emission and nearby  $\gamma$ -ray sources is included in the fit.

The diffuse foreground, including Galactic interstellar emission, extragalactic  $\gamma$ -ray emission, and residual CR background, has been modelled with *gll\_iem\_v02*<sup>9</sup> for the Galactic diffuse emission and *isotropic\_iem\_v02* for the extragalactic isotropic emission. Each source under study has been modelled with a power law function

$$\frac{dN}{dE} = \frac{N(\Gamma + 1)E^\Gamma}{E_{\max}^{\Gamma+1} - E_{\min}^{\Gamma+1}} \quad (1)$$

where both the normalization factor  $N$  and the spectral index  $\Gamma$  are left free in the model fit. The model also includes all the sources within a  $20^\circ$  RoI included in Fermi-LAT one year catalog Abdo et al. (2010c) and modelled using power law functions. If a source included in the model is a pulsar belonging to the *Fermi*-LAT pulsar catalog Abdo et al. (2010d), we have modelled the spectrum with a power law with exponential cutoff using the spectral parameters in the pulsar catalog.

For the evaluation of the  $\gamma$ -ray SEDs, the whole energy range from 100 MeV to 300 GeV is divided into two equal logarithmically spaced bins per decade. In each energy bin the standard *gt-like* binned analysis has been applied assuming power-law spectra with photon index = -2.0 for all the point sources in the model. Assuming that in each energy bin the spectral shape can be approximated by a power law, the flux of the source in all selected energy bins is evaluated, requiring in each energy bin a TS greater than 10. If the TS is lower than 10, an upper limit (UL) is evaluated in that energy bin. Only statistical errors for the fit parameters are shown in the plots. Systematic errors, due mainly to uncertainties in the LAT effective area derived from the on-orbit estimations, are < 5% near 1 GeV, 10% below 0.1 GeV, and 20% above 10 GeV.

For each source, we have considered the three different integration periods for the  $\gamma$ -ray data:

- *Simultaneous observations*: data accumulated during the period of *Planck* observation of the source. As the *Planck* instruments point in slightly different directions and the field of view depends on the frequency of observation, a typical observation covering all *Planck* channels takes about one week, the exact integration time depending on the position of the source.
- *Quasi-simultaneous observations*: data integrated over a period of two months centered on the *Planck* observing period of the source.
- *27 month Fermi-LAT integration*: data integrated over a period of 27 months from August 4, 2008 to November 4, 2010, i.e., the entire *Fermi*-LAT data set available for this paper.

Tables 11 and 12 give a summary of the  $\gamma$ -ray detections (TS > 25) in all our samples. The fraction of sources detected by *Fermi*-LAT during the simultaneous integrations is not very large and varies from  $\sim 40\%$  in the *Fermi*-LAT sample to just  $\sim 20\%$  in the soft X-ray selected sample. We note that even considering all the *Fermi*-LAT data available at the time of writing (27 month integration), a sizable fraction of the blazars in the radio, soft and hard X-ray selected samples have not been detected.

<sup>8</sup> [http://fermi.gsfc.nasa.gov/ssc/data/analysis/documentation/Cicerone/Cicerone\\_Likelihood](http://fermi.gsfc.nasa.gov/ssc/data/analysis/documentation/Cicerone/Cicerone_Likelihood)

<sup>9</sup> <http://fermi.gsfc.nasa.gov/ssc/data/access/lat/BackgroundModels.html>

**Table 11.** Summary of  $\gamma$ -ray detections with significance TS > 25.

Sample	No. of detected sources			Sources in sample
	simult.	2 months	27 months	
<i>Fermi</i> -LAT	18 (36%)	40 (80%)	50 (100%)	50
<i>Swift</i> -BAT	9 (26%)	12 (35%)	27 (79%)	34
<i>ROSAT/RASS</i>	10 (23%)	15 (35%)	24 (56%)	43
Radio	22 (21%)	38 (37%)	78 (75%)	104

**Table 12.** Statistics of  $\gamma$ -ray detections (TS > 25) in the 27 month *Fermi*-LAT data set.

Sample	No. of detected sources		
	FSRQs	BL Lacs	Uncertain
<i>Fermi</i> -LAT	28 (100%)	14 (100%)	8 (100%)
<i>Swift</i> -BAT	17 (63%)	7 (100%)	3 (50%)
<i>ROSAT/RASS</i>	8 (53%)	14 (88%)	2 (17%)
Radio	48 (72%)	16 (100%)	9 (64%)

Detailed results of the *Fermi*-LAT analysis are given in Tables 13–18 where the observed fluxes or upper limits are given in six or three energy bands depending on the source brightness.

Two sources (PKS 0548–322 and NGC 7213) appear as significant  $\gamma$ -ray detections in our 27 month data set although they have not been included in any of the *Fermi*-LAT catalogues published so far (Abdo et al. 2009b, 2010c, and <sup>10</sup>). These should therefore be considered as new  $\gamma$ -ray detections.

#### 4. The importance of simultaneity

Blazars are, by definition, highly variable sources. It is therefore important to use simultaneous multi-frequency data to build SEDs for comparison with theoretical models. In this section we compare our measurements with data taken from the literature in order to derive an estimate of the uncertainties introduced by the use of non-simultaneous data in different parts of the spectrum.

Figure 1 plots the *Planck* flux density at 44 GHz presented in this paper versus the *WMAP* flux density at 41 GHz from the *WMAP* point source catalogs (Bennett et al. 2003; Wright et al. 2009a). Some scatter is present, but most of the points lie between the two solid lines indicating a factor of two variability.

Figure 2 plots the X-ray fluxes of the sources observed by *Swift* simultaneously with *Planck* (see Table 8) against the X-ray fluxes of the same sources from the BZCAT catalog (Massaro et al. 2009, 2010). In this case a large scatter is present, with variations of over a factor of ten.

Figure 3 shows the *Fermi*-LAT  $\gamma$ -ray fluxes of our sources measured simultaneously with *Planck* plotted against their  $\gamma$ -ray fluxes in the *Fermi*-LAT 1FGL catalog (Abdo et al. 2010c). As in the X-ray sample, a scatter with variations larger than a factor of ten is observed.

We conclude that SEDs built with non-simultaneous data suffer from uncertainties in the microwave region that are relatively modest and generally limited to about a factor of two, while the high energy part of the spectrum (X-ray and  $\gamma$ -ray) is much more affected, with uncertainties due to flux variations

<sup>10</sup> <http://heasarc.gsfc.nasa.gov/W3Browse/all/fermilpsc.html>

**Fig. 1.** The *Planck* 44 GHz flux density of the sources in our sample is plotted against the 41 GHz flux density from the *WMAP* 5-year catalog (81 sources). The three solid lines represent equal flux densities (i.e., no variation) and a factor of two variability above or below the equal flux level. Almost all the points lie between the factor of two variability lines.

**Fig. 3.** The *Fermi*-LAT  $\gamma$ -ray flux of the sources in our samples detected during the simultaneous integration with *Planck* is plotted against the flux reported in the *Fermi*-LAT 1-year catalog. The three solid lines represent equal fluxes (i.e., no variation) and a factor of two variability above or below the equal flux level. Note that several points are outside the factor of two variability lines, revealing variability of up to about a factor ten.

**Fig. 2.** The *Swift* X-ray (0.1–2.4 keV) flux of the sources in our sample measured simultaneously with *Planck* is plotted against the 0.1–2.4 keV flux reported in the BZCAT catalog (83 sources). The three solid lines represent equal fluxes (i.e., no variation) and a factor of two variability above or below the equal flux level. Note that several points are outside the factor of two variability lines, revealing variability of up to about a factor ten.

of up to a factor of ten or more. Of course the same uncertainties apply when searching for correlations in non-simultaneous multi-frequency data.

## 5. Spectral Energy Distributions

We have constructed the SEDs of all the blazars in our samples from the simultaneous multi-frequency data described above us-

ing the ASDC SED Builder, an on-line service developed at the ASI Science Data Center (ASDC)<sup>11</sup> (Stratta et al. 2011). This is a WEB-based tool that allows users to build multi-frequency SEDs combining data from local catalogs and external services (e.g., NED, SDSS, USNO) with the user’s own data. The tool converts observed fluxes or magnitudes into de-reddened fluxes at a given frequency using standard recipes that take into account the instrument response and assumed average spectral slopes. The SED builder can display SEDs both in flux and in luminosity (if redshift information is given); it also provides useful tasks such as the overlay of templates for blazar host galaxies and nuclear optical emission (blue-bump), and allows users to compare the SED with models including one or more SSC components.

The SEDs of all the sources in our samples are shown in Figs. 25–42. Red points represent strictly simultaneous multi-frequency data; green points represent  $\gamma$ -ray data integrated over a period of two months centered on the *Swift/Planck* observations, or ground-based data taken quasi-simultaneously; blue points represent  $\gamma$ -ray data integrated over the full period of 27 months. In the few cases where no *Swift* simultaneous observations could be obtained we plot only *Planck*, *Fermi*-LAT, and ground-based data. Two-sigma upper limits are indicated by arrows.

### 5.1. Separating the non-thermal/jet-related radiation from QSO accretion and host galaxy emission

In the following we use the simultaneous SEDs of Figs. 25–42 to determine some parameters that can constrain the physical mechanisms powering blazars. However, before doing so we must identify and separate radiation that is unrelated to the non-thermal, relativistically amplified emission from the jet of the blazars; that is, radiation from accretion onto the central black

<sup>11</sup> <http://tools.asdc.asi.it/SED/>

**Fig. 4.** Top panel: The SDSS template of Vanden Berk et al. 2001 for the broad-line and thermal emission from a QSO. Bottom panel : The giant elliptical galaxy template of Mannucci et al. 2001. See text for details.

hole and from the host galaxy (see, e.g., Perlman et al. 2008). To do so we estimated the contamination from the host galaxy assuming that all blazars are hosted by giant elliptical galaxies (e.g., Kotilainen et al. 1998; Nilsson et al. 2003; León-Tavares et al. 2011) with absolute magnitude of  $M_R = -23.7$ . As Scarpa et al. (2000) and Urry et al. (2000) have demonstrated, this value is within 1 magnitude of the observed values in a sample of over 100 BL Lacs observed with the *Hubble* Space Telescope. For the spectral shape we used the elliptical galaxy template of Mannucci et al. 2001 (bottom panel of Fig. 4), which is based on low resolution observations of a number of nearby galaxies in the wavelength range  $0.12 - 2.4 \mu\text{m}$  and is a good match to the predictions of spectrophotometric models for giant ellipticals Mannucci et al. 2001.

The radiation due to accretion was estimated from the composite optical spectrum built by Vanden Berk et al. (2001) using over 2200 optical spectra of radio-quiet QSOs taken from the SDSS database (York et al. 2000) (top panel of Fig. 4), and the expected soft X-ray emission of radio quiet AGN from Grupe et al. 2010.

The ratio of optical to soft X-ray light has been known to be a function of optical luminosity since the time of the *Einstein* observatory (Avni & Tananbaum 1986). Recently this dependence has been confirmed using simultaneous optical and soft X-ray data from *Swift* (Grupe et al. 2010) and *XMM-Newton* (Vagnetti et al. 2010). In this paper we use the relationship given by Grupe et al. (2010):

$$\alpha_{\text{UV-X(Radio-quietQSO)}} = 0.114 \log(L_{2500 \text{ \AA}}) - 1.177 \quad (2)$$

where  $L_{2500 \text{ \AA}}$  is the rest-frame luminosity of the thermal emission at  $2500 \text{ \AA}$  in units of  $\text{W Hz}^{-1}$  and  $\alpha_{\text{UV-X(radio-quietQSO)}}$  is the usual slope between the UV ( $2500 \text{ \AA}$ ) and the soft X-ray (2 keV) flux in radio quiet QSOs (e.g., Vagnetti et al. 2010).

Examples of the emission from these components unrelated to the jet are shown in Fig. 5, which shows the SEDs of Mkn 501 and of Mkn 421, where the optical light is dominated by the host galaxy.

Figs. 6 and 7 show the SEDs of BL Lacertae, where part of the UV light is thought to be due to disk emission (Raiteri et al. 2009), the nearby FSRQ 3C 273 ( $z = 0.158$ ), and the high-redshift FSRQs 4C 38.41 ( $z = 1.814$ ) and 1Jy 0537–286 ( $z = 3.104$ ) where the optical/UV light is heavily, or completely, contaminated by radiation coming from the accretion onto the central black hole.

We assess the amplitude of the optical thermal emission compared to non-thermal radiation using the parameter  $\alpha_{\text{R-O(Thermal)}}$ , defined as the spectral slope between the 5 GHz radio flux density and the  $5000 \text{ \AA}$  optical flux density that can be attributed to the blue-bump/disk/thermal emission. This quantity depends both on the relativistic amplification factor and the intrinsic ratio between non-thermal/jet radiation and disk emission. In the case of FSRQs the optical spectrum shows emission lines by definition, therefore we can constrain  $\alpha_{\text{R-O(Thermal)}}$  by adjusting the optical thermal emission at the same level as the data. When the thermal blue bump is seen directly in the optical/UV part of the SED (e.g., Figs. 6 and 7) we fit the template of Vanden Berk et al. (2001) to the observed data; when the disk emission is not obviously visible we set the intensity of the blue-bump template just below the observed optical/UV emission where the broad emission lines have been detected.

BL Lacs do not show emission lines in their optical spectrum, so for this class of objects we can only set upper limits on  $\alpha_{\text{R-O(Thermal)}}$ . We do that by assuming that the template for the optical thermal emission is at least one order of magnitude below the observed data, that is sufficiently low to hamper any broad line detection. The estimation of  $\alpha_{\text{R-O(Thermal)}}$  relies strongly on the quality of the optical data available, in particular on the simultaneous UVOT data. Therefore we define an “optical data quality” flag as follows:

- 0: no simultaneous data available;
- 1: poor quality (e.g., only one UVOT filter available);
- 2: good quality (e.g., two or three UVOT filters available);
- 3: excellent quality (all UVOT filters available).

In Figure 8 (upper panel) we show the distribution of  $\alpha_{\text{R-O(Thermal)}}$  for all the FSRQs with excellent optical data for the whole sample and for each of our samples independently. The distribution of the  $\alpha_{\text{R-O(Thermal)}}$  upper limits for BL Lac objects is shown in the bottom panel. The results suggest a possible difference in the  $\alpha_{\text{R-O(Thermal)}}$  distribution in different samples. In fact, as reported in Table 19, when only sources with excellent optical data are considered we obtain  $\langle \alpha_{\text{R-O(Thermal)}} \rangle = -0.64 \pm 0.05$  for the *ROSAT/RASS* sample, to be compared with  $\langle \alpha_{\text{R-O(Thermal)}} \rangle = -0.73 \pm 0.02$  for the *Fermi*-LAT sample.

In order to assess the possible presence of a thermal component in the X-ray emission, for each source we compare the predicted thermal emission from accretion with the actual X-ray spectrum, and we also include the uncertainties in the parameters of Eq. 2 in order to build 1, 2, and  $3\sigma$  bands. We therefore define the following X-ray thermal contamination flag:

- 0: no X-ray data available;
- 1: X-ray emission mostly or entirely due to accretion/reflection (data agree with the expectations for accretion emission within  $1\sigma$ );
- 2: X-ray emission probably contaminated by the accretion component (data agree with the expectations for accretion emission within  $2\sigma$ );
- 3: X-ray emission mostly of non-thermal origin (data are at  $2-3\sigma$  from the expectations for radio quiet QSOs);

**Fig. 5.** The SEDs of Mkn 501 (*left*) and Mkn 421 (*right*) showing the expected emission from the host galaxy (giant elliptical) as an orange line. The green lines are the best fit to the simultaneous non-thermal data using a third degree polynomial function. See text for details.

**Fig. 6.** *Left:* the SED of BL Lacertae showing the expected emission from the host galaxy (just below the observed non-thermal radiation, giant elliptical, orange line) and of the blue bump emission (blue line, see also Raiteri et al. 2009). *Right:* the SED of 3C 273 showing the thermal emission from the blue bump and the expected X-ray emission from accretion (purple and blue lines, see text for details). The vertical parallel lines represent the optical window (4 000–10 000 Å). The green lines are the best fit to the simultaneous non-thermal data using a third degree polynomial function.

**Table 19.** Contamination of the X-ray emission from a thermal component and  $\langle \alpha_{R-O(Thermal)} \rangle$  estimated for FSRQs in the whole sample and for each sample independently, for various thresholds on the quality of the optical data (see the text for a description of the flag).

Opt Data quality	ALL			<i>Fermi</i> -LAT			<i>Swift</i> -BAT			ROSAT/RASS		
	cont/total	%	$\langle \alpha_{R-O(Thermal)} \rangle$	cont/total	%	$\langle \alpha_{R-O(Thermal)} \rangle$	cont/total	%	$\langle \alpha_{R-O(Thermal)} \rangle$	cont/total	%	$\langle \alpha_{R-O(Thermal)} \rangle$

- 4: X-ray emission certainly of non-thermal origin (data are more than  $3\sigma$  away from the expectations for radio quiet QSOs).

Results for all the FSRQs with good or excellent optical data are shown in Figure 9, and summarized in Table 19 for the whole

sample and for each sample independently. There is a large difference between the *Fermi*-LAT and *Swift*-BAT samples, where  $\lesssim 15\%$  of the sources show a thermal component in the X-ray emission, and the ROSAT/RASS sample, where  $\sim 50\%$  of the sources are contaminated. This demonstrates that the thermal

**Fig. 7.** The SEDs of 4C 38.41 ( $z = 1.814$ ; *left*) and of 1Jy 0537–286 ( $z = 3.104$ ; *right*). Simultaneous data are shown in red; non simultaneous literature or archival data are shown in light gray. Note that the UVOT data of these medium and high redshift objects matches quite well the QSO template of Vanden Berk et al. (2001) that we use to estimate the thermal emission from the blue bump (*blue line*). The emission from the host galaxy (*orange line*) is very low compared to other components. The observed X-ray emission from these sources is more than  $3\sigma$  above the expected emission from accretion. In both cases the optical light is dominated by accretion while the X-rays are from the non-thermal component.

**Fig. 8.** Distribution of  $\alpha_{R-O(\text{Thermal})}$  for all the sources and for each blazar sample. Only SEDs with good or excellent optical data (flag = 2 or 3, see text) were used. Black solid histograms: radio sample; red dashed histograms: *Fermi* sample; green dot-dashed histograms: *Swift* BAT sample; blue dotted histograms: RASS sample. Distributions for BL Lac objects refer to upper limits only.

component in the X-ray emission of blazars cannot be neglected, even in bright sources.

## 5.2. SED parameter estimation

We have used the SEDs of all the objects in our samples to estimate the values of important physical parameters such as  $v_{\text{peak}}^S$ ,  $v_{\text{peak}}^S F(v_{\text{peak}}^S)$ ,  $v_{\text{peak}}^{\text{IC}}$  and  $v_{\text{peak}}^{\text{IC}} F(v_{\text{peak}}^{\text{IC}})$  (see Table 20) taking into account only the non-thermal radiation and fitting third-degree

**Fig. 9.** Distribution of the thermal emission flag for all the FSRQs with good or excellent optical data flag (see text for details). Black solid histograms: radio sample; red dashed histograms: *Fermi*-LAT sample; green dot-dashed histograms: *Swift* BAT sample, blue dotted histograms: RASS sample. As all BL Lacs showed no contamination of their X-ray emission, they are not plotted here.

polynomials as described in Abdo et al. (2010a) (see Figs. 5, 6, and 7 for examples).

For the sources that were not detected by *Fermi*-LAT even in the 27 month integration we estimated limits to  $v_{\text{peak}}^{\text{IC}}$  and  $v_{\text{peak}}^{\text{IC}} F(v_{\text{peak}}^{\text{IC}})$  by constraining the polynomial in the high-energy part of the SED with the 27 month *Fermi*-LAT upper limits as shown in Fig. 10.

In some HSP BL Lacs with particularly high  $v_{\text{peak}}^S$  values (see, e.g., Figs. 31, 32, 37, and 39) the *Fermi*-LAT data alone are not sufficient to ensure a good measure of  $v_{\text{peak}}^{\text{IC}}$ , as the spectra are still rising at the highest *Fermi*-LAT energies and no simulta-

**Table 20.** Rest-frame  $\langle v_{\text{peak}}^{\text{S}} \rangle$  and  $\langle v_{\text{peak}}^{\text{IC}} \rangle$  values for different samples and classes.

neous TeV data are available. The  $v_{\text{peak}}^{\text{IC}}$  values for these sources should therefore be considered as lower limits.

**Fig. 10.** The SED of the blazar PKS 0003–066, illustrating the estimation of the upper limits on  $v_{\text{peak}}^{\text{IC}}$  and on  $v_{\text{peak}}^{\text{IC}} F(v_{\text{peak}}^{\text{IC}})$  by combining the X-ray data with the 27 month *Fermi*-LAT upper limits.

## 6. The spectral slope of blazars in the radio–microwave region

While *WMAP* results are consistent with a single flat spectral index in the relatively narrow frequency range 23–94 GHz (Wright et al. 2009b; Gold et al. 2011), the blazar spectrum must steepen at frequencies closer to the synchrotron peak. Adding *Planck* data and simultaneous ground-based observations at centimetre wavelengths to the *WMAP* data improves the spectral coverage, and allows us to probe the spectral shape of blazars over the much wider frequency range  $\sim 1$  GHz to  $\sim 1$  THz.

We have studied the low frequency (LF) and the high frequency (HF) regions of the centimetre to sub-millimetre blazar spectra separately in order to search for differences in the spectral index  $\alpha$  and to determine the frequency at which the spectral index changes. We have fitted the two frequency regions independently with power laws to estimate the spectral indices at low frequencies ( $\alpha_{\text{LF}}$ , for  $\nu \leq \nu_{\text{Break}}$ ) and at high frequencies ( $\alpha_{\text{HF}}$ ,

for  $\nu > \nu_{\text{Break}}$ ), assuming a range of values of the break frequency,  $\nu_{\text{Break}}$ , from 30 to 100 GHz. In Fig. 11 we show the distributions of  $\alpha_{\text{LF}}$  and  $\alpha_{\text{HF}}$  for  $\nu_{\text{Break}} = 70$  GHz and 100 GHz; the blazar spectra steepen from  $\alpha_{\text{LF}} \sim 0$  to  $\alpha_{\text{HF}} \sim -0.65$ .

In order to verify the robustness of the results we have repeated the analysis imposing two minimum numbers of independent frequencies needed to perform the fit, namely 3 and 5, and the results are consistent (Table 21).

We have also analysed the different classes of blazars – Flat Spectrum Radio Quasars (FSRQ), BL Lac objects (BL Lac), and AGN of unknown classification (AGN) – separately, and we have found a difference at a level of about  $3\sigma$  in  $\alpha_{\text{HF}}$ , which is  $\sim -0.7$  for FSRQ but  $\sim -0.5$  for BL Lacs.

The spectral steepening and the difference in  $\alpha_{\text{HF}}$  are visible in Figure 12, where we show  $\alpha_{\text{LF}}$  vs.  $\alpha_{\text{HF}}$  for the sources that meet the requirements on the minimum number of independent data at both low and high frequency.

Our results are in complete agreement with the findings of Planck Collaboration 2011e for the radio selected sample, i.e., flat spectral index at low frequency and  $\alpha_{\text{HF}} \sim -0.6$  at high frequency with a break frequency  $\sim 70$  GHz, suggesting that this is a general feature of all blazars regardless of the selection criteria. There is also general agreement with the results presented in Planck Collaboration 2011d for all the sources in the *Planck* ERCSC catalogs, and the slight discrepancy in the spectral index estimated at low frequency can be explained by the fact that, unlike Planck Collaboration 2011d, we have included the ground-based observations at 5–30 GHz.

## 7. Searching for correlations between fluxes in different energy bands

In this section we use our simultaneous and average multi-frequency data to test for the presence of correlations between fluxes measured in different energy bands. As some of the blazars in our samples have not been detected by *Fermi*-LAT or by *Planck*, we estimate the significance of the correlations using the ASURV code Rev1.2 (Lavalley et al. 1992), which takes account of flux limits as described in Isobe et al. (1986).

### 7.1. Microwave vs. X-ray

Figure 13 shows the *Planck* 143 GHz flux density versus the simultaneous *Swift*-XRT X-ray flux for all the sources where the

**Fig. 11.** Radio/microwave low frequency ( $\nu < 70$  GHz, LF; left side) and high frequency ( $\nu > 70$  GHz, HF; right side) spectral index distributions of FSRQs and BL Lacs in our samples for the case  $\nu_{Break} = 70$  GHz. While the distributions of low frequency spectral indices are very similar in both types of blazars with  $\langle \alpha_{LF} \rangle \sim -0.1$ , the distributions of the high frequency slopes indicate that FSRQs ( $\langle \alpha_{HF} \rangle = -0.73 \pm 0.04$ ) might be somewhat steeper than BL Lacs ( $\langle \alpha_{HF} \rangle = -0.51 \pm 0.07$ ). A KS test gives a probability of less than 3% that the HF distributions for FSRQs and BL Lacs come from the same parent distribution.

**Table 21.** Radio LF and HF spectral index distributions for different values of the break frequency  $\nu_{Break}$  and of the minimum number of frequency bands considered for the fit.

$\nu_{Break}$	n. of frequencies	Class	n. of sources	Low Frequency		n. of sources	High Frequency

X-rays are expected to be due to the inverse-Compton component (that is all LSP blazars) and not significantly contaminated by X-ray emission that is unrelated to the jet such as that due to the accretion process (see Sect. 5.1 for details). Sources that were not detected by *Planck* are plotted as upper limits; all the sources were detected in the X-ray band.

A correlation, although with some scatter, is clearly present. The Spearman rank coefficients ( $\rho$ ) and the corresponding probabilities that the observed correlation is the result of chance are given in Table 22. Results obtained using *Planck* flux densities at other frequencies from 30 to 217 GHz are similar and are not shown here.

## 7.2. Microwave vs. $\gamma$ -ray

The relationship between radio/microwave and  $\gamma$ -ray fluxes is a topic that has been addressed several times in the literature; generally a positive correlation between the radio and  $\gamma$ -ray fluxes is found, though with a large scatter (e.g., Kovalev et al. 2009; León-Tavares et al. 2010; Giroletti et al. 2010; Ghirlanda et al.

2010; Mahony et al. 2010; Peel et al. 2010; Linford et al. 2011; Ackermann et al. 2011; Leon-Tavares et al. 2011). However, in most cases radio and *non-simultaneous*  $\gamma$ -ray data for sources *detected in both energy bands* are compared; here for the first time we present simultaneous microwave and  $\gamma$ -ray data and we take into account upper limits.

The top panel of Figure 14 shows the simultaneous *Fermi*-LAT  $\gamma$ -ray flux plotted versus the *Planck* flux density at 143 GHz. Sources with  $TS < 25$  in the *Fermi*-LAT data and below  $4\sigma$  in *Planck* maps are shown as upper limits. The plot shows a clear trend; but from Table 23, which gives the Spearman's  $\rho$  correlation parameter and the probability  $P$  that the observed level of correlation is due to chance, we see that the level of significance of the correlation is never very high ( $P$  is of the order of a few percent and never lower than 0.05%), especially in the hard X-ray and  $\gamma$ -ray selected samples and for BL Lacs. This result is partly due to the large number of upper limits in the simultaneous  $\gamma$ -ray flux, which was estimated typically over a period of one week. To improve the statistics, in the middle panel of Fig. 14 we show the same plot using the *Fermi*-LAT  $\gamma$ -ray flux integrated over a two month period centered on

**Table 22.** Spearman correlation parameters for 143 GHz flux density vs. X-ray flux.

<sup>(a)</sup> Number of *Planck* detections. <sup>(b)</sup>Number of *Planck* upper limits.

\* The number of detections is too low to allow a reliable estimation of  $\rho$ .

**Fig. 12.**  $\alpha_{HF}$  vs.  $\alpha_{LF}$  diagram for  $\nu_{Break} = 70$  GHz for different blazar classes: Flat Spectrum Radio Quasars (FSRQ), BL Lac objects (BL Lac), and AGN of uncertain classification.

the time of the *Planck* observations. From Table 23 we see that, although the significance of the correlation in the various samples and blazar classes substantially increases, it is never very high and the scatter remains.

This result may be due to the limited flux dynamic range in the  $\gamma$ -ray band in the *Fermi*-LAT sample and to the small number of objects (for the case of BL Lacs). However, the low level of correlation could occur if the microwave flux density represents the superposition of multiple synchrotron components while the simultaneous  $\gamma$ -ray flux represents the emission from a single dominant component which may be active only for a short time. For this reason in the bottom panel of Fig. 14, we plot the *Planck* ERCSC flux densities (which in most cases represents the flux density averaged over more than one *Planck* observation) versus the *Fermi*-LAT flux averaged over the entire 27 month period. In this case the correlation is highly significant, however, the many upper limits in both energy bands clearly imply that the dispersion is very large.

### 7.3. X-ray vs. $\gamma$ -ray

Figure 15 plots the 2 month  $\gamma$ -ray flux versus the simultaneous X-ray flux for all sources observed by *Swift* that do not show signatures of thermal contamination in the X-ray spectrum. Open

**Fig. 13.** The *Planck* 143 GHz flux density plotted vs. the simultaneous *Swift* XRT X-ray flux for all sources where the X-ray flux is expected to be due to the inverse-Compton component are plotted. Blazars with significant X-ray contamination due to accretion have been excluded from the plot.

red circles represent HSP sources, where the X-ray flux is due to the tail of the synchrotron emission, while black filled circles are LSP and ISP sources for which the X-ray flux is related to the inverse-Compton radiation. This distinction is needed in order to properly compare sources where the emission is due to the same mechanism. We therefore compute the  $\gamma$ -ray vs. X-ray correlation coefficient only for LSP and ISP sources. The Spearman rank test shows moderate evidence for a correlation which is less significant in the longer integrations:  $P = 2.55\%$  for simultaneous data,  $P = 6.9\%$  for 2 months integration, or  $P = 17.4\%$  for 27 months integration.

Figure 16 plots the power law spectral index in the *Swift* XRT energy band (0.3–10 keV) versus the spectral slope in the *Fermi*-LAT  $\gamma$ -ray band (100 MeV–100 GeV) derived using the 2-month  $\gamma$ -ray data. A significant correlation is present, confirming the results of Abdo et al. (2010a). The top right corner of Fig. 16 shows the same plot built with simultaneous  $\gamma$ -ray data; although the number of objects is lower the correlation is still present.

## 8. Discussion and conclusions

We have collected simultaneous *Planck*, *Swift*, *Fermi*-LAT, and ground-based multi-frequency data for 105 blazars included in three statistically well defined samples characterized by flux limits in the soft X-ray (0.1–2.4 keV, *ROSAT*), hard X-ray (15–150 keV, *Swift*-BAT), and  $\gamma$ -ray ( $E > 100$  MeV, *Fermi*-LAT) energy bands. This study complements a similar study of a sample of 104 radio-bright AGN ( $f_{37GHz} > 1$ Jy) (Planck Collaboration

2011e). Altogether the four samples include a total of 175 distinct objects. The acquisition of this unprecedented multi-frequency/multi-satellite data set was possible thanks to coop-

**Fig. 15.** The *Swift* XRT flux is plotted against the 2 month *Fermi*-LAT flux for the sources included in the three high energy flux limited samples. Open red circles represent HSP sources, i.e., high synchrotron peaked BL Lacs where the X-ray flux is dominated by synchrotron radiation. Filled black circles represent LSP sources, i.e., blazars with low synchrotron peak, for which the X-ray flux is dominated by inverse-Compton radiation.

eration between the *Planck*, *Swift* and *Fermi*-LAT teams, who agreed to share data and to organize an extensive program of multi-frequency observations involving over 160 *Swift* ToO pointings scheduled when the blazars were within the field of view of the *Planck* instruments.

We have used this unique multi-frequency dataset to build well-sampled, simultaneous SEDs of all the blazars included in our high-energy selected samples. This collection of SEDs is an improvement over previous compilations (e.g., Abdo et al. 2010a) because: a) the SEDs presented here are strictly simultaneous while in Abdo et al. (2010a) the multi-frequency data were collected over a period of up to 9 months centered on the first three months of *Fermi*-LAT operations; b) the sources were selected according to different statistical criteria allowing us to probe the blazar parameter space from widely different viewpoints; and c) we took care to identify and separate radiation components unrelated to the emission from the jet, such as the

**Fig. 16.** The power law spectral index in the *Swift* XRT energy band (0.3–10 keV) is plotted versus the slope in the *Fermi*-LAT  $\gamma$ -ray band (100 MeV–100 GeV) derived using *Fermi*-LAT data integrated over a period of 2 months. The same plot built with simultaneous  $\gamma$ -ray data is shown in the inset at the upper right. A clear anti-correlation is present; the Spearman test gives a probability of less than 0.01% that the correlation is due to chance, even in the simultaneous data.

light from the blazar's host galaxy and the radiation due to the accretion onto the central black hole, which often contaminate the non-thermal blazar spectrum in the optical, UV, and X-ray bands.

Our findings are broadly consistent with those of Abdo et al. (2010a). However, our larger samples selected in different parts of the electromagnetic spectrum, better wavelength coverage, level of simultaneity, and separation of the emission components, allowed us to make significant progress in several areas. The use of four widely different samples has allowed us to investigate the consequences of selection effects on the estimation of important parameters such as  $\langle v_{\text{peak}}^S \rangle$ , average Compton dominance, etc., especially for the case of BL Lacs.

Some of our sources have been observed simultaneously by *Swift*, *Planck*, and *Fermi*-LAT during more than one *Planck* survey. In these cases here we have presented only the data collected during the first observation. Multiple simultaneous observations of a subset of our blazars and detailed model fitting of the SEDs will be the subject of future papers. The main results of this work are discussed below.

#### 8.1. *Fermi*-LAT detection statistics and the effects of variability

The percentage of *Fermi*-LAT detected sources during the simultaneous integrations, typically lasting about one week, ranges from  $\lesssim 40\%$  in the *Fermi*-LAT sample to 20–25% in the radio and X-ray selected samples (see Table 11). When 2-month integrations centered on the *Planck*-*Swift* observations are considered, these percentages grow to 80% in the *Fermi*-LAT sample and to  $\sim 35\%$  in the other samples. But even with the 27-month

*Fermi*-LAT integrations available at the time of writing, many of the blazars belonging to the radio, soft and hard X-ray selected samples remain undetected.

It is interesting to note that the detection rate is quite different in FSRQs and BL Lacs: if we exclude the *Fermi*-LAT sample where all the objects have been detected (by definition), the percentage of detections is 95% for BL Lacs and only  $\sim 60\%$  for FSRQs, with values ranging from 72% in the radio sample to just 53% in the RASS sample (see Table 12).

A comparison of our simultaneous data with published and archival measurements shows that the use of non-simultaneous data in the SED of blazars typically introduces a scatter of about a factor 2 in the microwave band, and of a factor of up to ten or more in the X-ray and  $\gamma$ -ray bands.

#### 8.2. The spectral slope in the radio–sub-millimetre region

We confirm that the energy spectrum of blazars in the radio–microwave spectral region is quite flat, with an average slope  $\langle \alpha \rangle \sim 0$  ( $f(\nu) \propto \nu^\alpha$ ) up to about 70 GHz, above which it steepens to  $\langle \alpha \rangle \sim -0.6$ . This behaviour is very similar to that observed in the sample of radio bright blazars considered by Planck Collaboration (2011e) (see also Tucci et al. 2011) confirming the findings of Abdo et al. (2010a) that the radio to microwave part of the spectrum is approximately the same in all blazars (FSRQs and BL Lacs) independently of the selection band. However, the spectral slope of BL Lacs above  $\sim 70$  GHz is flatter than that of FSRQs with  $\langle \alpha_{\text{HF}} \rangle = -0.51 \pm 0.07$  for BL Lacs compared to  $\langle \alpha_{\text{HF}} \rangle = -0.73 \pm 0.04$  for FSRQs (see Table 21 and Fig. 11). A KS test, performed on the subsamples of FSRQs and BL Lacs with radio flux density larger than 1 Jy, gives a probability of less than 3% that the two samples come from the same parent population. This difference in the high frequency spectral index may be due to a primary dependence of  $\alpha_{\text{HF}}$  on  $v_{\text{peak}}^S$ , as illustrated in Fig. 17, because only BL Lacs show high  $v_{\text{peak}}^S$  values.

#### 8.3. Synchrotron self-absorption

We searched for signatures of synchrotron self-absorption, which in simple homogeneous SSC models is expected to cause strong spectral flattening below  $\sim 100$  GHz, but we found no evidence for common behaviour; indeed, the average spectrum in that region steepens instead of flattening. Possible cases where some evidence of synchrotron self-absorption may be present are PKS 0454–234, PKS 0521–36 (Fig. 28), S4 0917+44 (Fig. 30), PKS 1127–145 (Fig. 32) and 3C 454.3 (Fig. 41).

#### 8.4. Non-thermal versus disk radiation

In several blazars the optical/UV light is significantly contaminated by thermal/disk radiation (known as the blue bump, see Figs. 6 and 7) while the soft X-ray flux is contaminated by radiation produced in the accretion process in approximately 25% of the blazars in our samples (see Fig. 9). In some of the closest sources the optical light is instead contaminated or dominated by the emission from the host galaxy. Ignoring this contamination may cause an overestimate of the position of both  $v_{\text{peak}}^S$  and  $v_{\text{peak}}^{\text{IC}}$  by 0.5 dex or more.

We investigated the relationship between the radiation due to accretion and to the jet, which co-exist in most FSRQs, using the parameter  $\alpha_{\text{R-O(Thermal)}}$ , defined as the spectral slope between the 5 GHz radio (non-thermal) flux and the 5000 Å op-

**Fig. 17.** The spectral slope  $\alpha_{HF}$  is plotted against  $v_{\text{peak}}^S$  for all the sources in our samples with a measured value of  $\alpha_{HF}$  and  $S_{5 \text{ GHz}} > 1 \text{ Jy}$ . High  $v_{\text{peak}}^S$  blazars tend to be harder microwave sources.

tical flux that can be attributed to the blue-bump/disk emission. In the blazar paradigm this quantity depends both on the amount of relativistic amplification (which only affects the non-thermal radiation from the jet) and the intrinsic ratio between non-thermal/jet radiation and disk emission. We estimated the value of  $\alpha_{R-O(\text{Thermal})}$  in all sources for which we have optical data of good quality. Since BL Lacs do not show broad lines only lower limits to  $\alpha_{R-O(\text{Thermal})}$  can be derived.

Figure 8 shows the distribution of  $\alpha_{R-O(\text{Thermal})}$  for all our samples, which range from  $\sim 0.4$  to just above  $1.0$  with peak values between  $0.6$  and  $0.8$ . The distributions are all similar, with the largest difference being between the *Fermi*-LAT and the RASS samples (a KS test gives a probability of  $3.6\%$  that the two distributions are from the same parent population), possibly reflecting differences in the amplification factor or a different ratio of accretion to jet emission in  $\gamma$ -ray and soft X-ray selected blazars. We note that the distribution of the  $\alpha_{R-O(\text{Thermal})}$  limits for BL Lacs is consistent with intrinsic values of  $\alpha_{R-O(\text{Thermal})}$  for BL Lacs that are within the range of values observed in FSRQs.

### 8.5. The distribution of rest-frame peak energies

The distribution of rest-frame synchrotron peak energies ( $v_{\text{peak}}^S$ ) of FSRQs is very similar in all our samples with an average of  $\langle v_{\text{peak}}^S \rangle \approx 10^{13.1 \pm 0.1} \text{ Hz}$  and a dispersion of only  $0.5 \text{ dex}$ . But for BL Lacs the value of  $\langle v_{\text{peak}}^S \rangle$  is at least one order of magnitude larger than that of FSRQs, the exact value depending considerably on the selection method (see Table 20 and Fig. 18). The distributions of  $v_{\text{peak}}^{\text{IC}}$  for FSRQs and BL Lacs also differ, but not as much as those of  $v_{\text{peak}}^S$  (see Fig. 19). The majority of the sources in all the samples (both FSRQs and BL Lacs) peak between  $10^{21}$  and  $10^{23} \text{ Hz}$ , with a few extreme HSP BL Lacs reaching  $\sim 10^{26} \text{ Hz}$ .

**Fig. 18.** The rest-frame synchrotron  $v_{\text{peak}}$  distributions of FSRQs and BL Lacs in different samples. Black solid histograms: radio sample; red dashed histograms: *Fermi*-LAT sample; green dot-dashed histograms: *Swift* BAT sample; blue dotted histograms: RASS sample.

**Fig. 19.** The rest-frame inverse-Compton  $v_{\text{peak}}$  distributions of FSRQs and BL Lacs in different samples. Black solid histograms: radio sample; red dashed histograms: *Fermi*-LAT sample; green dot-dashed histograms: *Swift* BAT sample; blue dotted histograms: RASS sample.

### 8.6. Correlations between fluxes and other blazar parameters

Despite the strict simultaneity of our data, plots of fluxes in different spectral regions (microwave vs. X-ray, microwave vs.  $\gamma$ -ray, X-ray vs.  $\gamma$ -ray) still show a large scatter (see Figs. 13, 14, and 15). This is somewhat surprising, as positive correlations between the radio and  $\gamma$ -ray have been reported (e.g. Kovalev et al. 2009; León-Tavares et al. 2010; Giroletti et al. 2010; Ghirlanda et al. 2010; Mahony et al. 2010; Peel et al. 2010; Linford et al. 2011; Ackermann et al. 2011). The difference might be due to the

different synchrotron peak energies of the objects in the samples. Even in simple SSC scenarios this introduce a scatter in the correlation between the fluxes (e.g., for the same radio flux, an object with larger  $\nu_{\text{peak}}^S$  is expected to produce more  $\gamma$ -rays than one with a smaller  $\nu_{\text{peak}}^S$ ). The large scatter present in Fig. 14 could also imply that  $\gamma$ -ray emission is due to components not always directly related to radiation in other energy bands, e.g., multiple SSC components (see also Abdo et al. 2010a). A good correlation is present between the X-ray and  $\gamma$ -ray spectral slopes, however (see Fig. 16).

We confirm the correlations between the *Fermi*-LAT spectral index and the SED peak energies  $\nu_{\text{peak}}^S$  and  $\nu_{\text{peak}}^{\text{IC}}$  found by Abdo et al. (2010a). As an illustration of the agreement, Fig. 20 plots the *Fermi*-LAT spectral slope estimated using the full 27-month data set as a function of  $\nu_{\text{peak}}^{\text{IC}}$ . The gray points represent the  $\gamma$ -ray spectral slopes estimated using the quasi simultaneous 2-month dataset. These points, plotted without the much larger error bars to avoid confusion, clearly cluster around the 27-month data, confirming the correlation. The solid line represents the best fit obtained by Abdo et al. (2010a).

where  $\gamma_{\text{peak}}^{\text{SSC}}$  is the Lorentz factor of the electrons radiating at the peak energy. This is related to the observed peak frequency of the observed photon spectrum by:

$$\gamma_{\text{peak}}^{\text{SSC}} \propto \left( \frac{\nu_{\text{peak}}^S}{B\delta} \right)^{1/2} \quad (4)$$

where  $\nu_{\text{peak}}^S$  is the synchrotron peak frequency in the rest-frame of the emitting region,  $B$  is the magnetic field, and  $\delta$  is the usual Doppler factor (e.g. Urry & Padovani 1995).

In objects where  $\nu_{\text{peak}}^S$  is larger than  $\approx 10^{15}$  Hz the Thomson approximation is no longer valid and the inverse-Compton scattering occurs under the Klein–Nishina (KN) regime. By means of Monte Carlo simulations, Abdo et al. (2010a) estimated the area covered by SSC models in the plane  $\log(\nu_{\text{peak}}^S)$ – $\log(\gamma_{\text{peak}}^{\text{SSC}})$ . This area is delimited by the solid contour lines shown in Fig. 21 where we plot the  $\log(\gamma_{\text{peak}}^{\text{SSC}})$  of our sources, calculated from the observed values of  $\nu_{\text{peak}}^S$  and  $\nu_{\text{peak}}^{\text{IC}}$  using eq. 3, versus the rest-frame  $\log(\nu_{\text{peak}}^S)$ .

**Fig. 20.** The  $\gamma$ -ray spectral index, estimated from the entire 27-month *Fermi*-LAT data set of all sources in our samples is plotted against  $\log(\nu_{\text{peak}}^{\text{IC}})$ . Gray points, plotted without statistical errors to avoid confusion, represent the *Fermi*-LAT spectral slopes estimated using the 2-month integrations. The solid line is the best fit given by Abdo et al. (2010a)

**Fig. 21.**  $\log(\gamma_{\text{peak}}^{\text{SSC}})$ , obtained from Eq. 3 for all the objects in our samples for which we could obtain  $\nu_{\text{peak}}^S$  and  $\nu_{\text{peak}}^{\text{IC}}$  is plotted against  $\log(\nu_{\text{peak}}^S)$  in the rest frame of the blazars. The two black lines delimit the area predicted by simple homogeneous SSC models obtained through extensive Monte Carlo simulations (see Abdo et al. 2010a, for details).

#### 8.7. Comparison with the expectation of simple SSC models

As discussed in Abdo et al. (2010a), simple SSC models predict that in the Thomson regime the peak frequency of the synchrotron ( $\nu_{\text{peak}}^S$ ) and inverse-Compton ( $\nu_{\text{peak}}^{\text{IC}}$ ) components are related by:

$$\frac{\nu_{\text{peak}}^{\text{IC}}}{\nu_{\text{peak}}^S} \simeq \frac{4}{3} (\gamma_{\text{peak}}^{\text{SSC}})^2 \quad (3)$$

As in the case of the bright  $\gamma$ -ray blazars considered by Abdo et al. (2010a), only a few objects are inside or close to the SSC area, implying that simple SSC models cannot explain the SED of many blazars in our samples. This conclusion is supported by other evidence including the lack of a strong correlation between radio and  $\gamma$ -ray and the fact that the local optical/UV spectral slope in some objects, although not contaminated by thermal radiation, is inconsistent with the expectations of SSC. See, e.g., PKS 0426–380 (J0428–3756, Fig. 28), PKS 0851+202 (J0854+2006, Fig. 30), S5 1803+784 (J1800+7828, Fig. 38).

**Fig. 22.** The logarithm of the Compton dominance is plotted as a function of  $\log(v_{\text{peak}}^{\text{S}})$  for all sources for which  $v_{\text{peak}}^{\text{S}}$  and  $v_{\text{peak}}^{\text{IC}}$  could be reliably determined.

Note, however, that the  $\gamma_{\text{peak}}^{\text{SSC}}$  of blazars that were not detected by *Fermi*-LAT and for which we could obtain a limit to  $v_{\text{peak}}^{\text{IC}}$  (30 to 40% of the FSRQs in the radio and X-ray selected samples; see Fig. 10 for one example) are plotted as upper limits in Fig. 21; many of these limits are close to or inside the SSC area and therefore the SEDs of these objects are likely consistent with simple SSC emission.

#### 8.8. The Compton dominance of blazars

The Compton dominance (CD, defined as the ratio between the inverse-Compton and synchrotron peak luminosities) is a crucial parameter for the study of blazar physics, as it is strictly related to the location of the maximum power output in the energy spectrum of a blazar.

Figure 22 plots the CD values, estimated from our SEDs, as a function of  $v_{\text{peak}}^{\text{S}}$ , showing that  $\log(\text{CD})$  ranges from about  $-0.5$  to about  $2$ . The larger values are always associated with LSP objects while HSP sources always show  $\log(\text{CD})$  lower than  $\approx 0.5$ . In this figure the two blazar subclasses appear to be quite different, with BL Lacs having significantly lower CD values, even when their  $v_{\text{peak}}^{\text{S}}$  values are equal to those of FSRQs. To better understand this difference, in Fig. 23 we plot the CD distributions of FSRQs and BL Lacs for different samples and  $v_{\text{peak}}^{\text{S}}$  intervals.

FSRQs included in the *Fermi*-LAT sample, which are  $\gamma$ -ray bright by definition, show a CD distribution peaking at large values. Note that in this sample we also applied a radio flux-density limit of  $1 \text{ Jy}$ , so the sources below the radio cut must be on average more Compton dominated than those in our sample. This implies that the distribution of purely  $\gamma$ -ray selected blazars must be even more strongly peaked at high CD values than that of the *Fermi*-LAT sample. Considering instead FSRQs selected in the radio and in the X-ray bands, we get quite a different picture, with a broader distribution extending to values of less than  $1$ . Moreover, about 30–45% of FSRQs in the radio, soft X-ray,

**Fig. 23.** Distributions of the Compton dominance for FSRQs and BL Lacs of the LSP and HSP type. A significant fraction of FSRQs in the radio, RASS, and BAT samples have not been detected in the  $\gamma$ -ray band and therefore only limits to the Compton dominance (shown as a dashed histogram; only the radio sample to avoid confusion) can be calculated. The large difference between the CD distribution of FSRQs in the *Fermi*-LAT and in the other samples illustrates the strong bias that  $\gamma$ -ray selection induce.

and hard X-ray selected samples are not detected by *Fermi*-LAT and therefore they must populate the part of the CD distribution with low CD values. This is shown by the dotted red histogram, which also includes upper limits to the CD (estimated as the ratio of the upper limit to  $v_{\text{peak}}^{\text{IC}} F(v_{\text{peak}}^{\text{IC}})$  and  $v_{\text{peak}}^{\text{S}} F(v_{\text{peak}}^{\text{S}})$  where limits to  $v_{\text{peak}}^{\text{IC}}$  and  $v_{\text{peak}}^{\text{IC}} F(v_{\text{peak}}^{\text{IC}})$  are obtained by fitting the X-ray data together with the 27-month *Fermi*-LAT upper limits as shown in Fig. 10.

#### 8.9. The blazar sequence

The top panel of Fig. 24 plots the logarithm of the bolometric power, represented by the sum of the synchrotron and inverse-Compton peak luminosities [ $L_{\text{Bol}} \sim v_{\text{peak}}^{\text{S}} L(v_{\text{peak}}^{\text{S}}) + v_{\text{peak}}^{\text{IC}} L(v_{\text{peak}}^{\text{IC}})$ ] as a function of  $\log(v_{\text{peak}}^{\text{S}})$  for all sources in the four samples considered in this paper and in (Planck Collaboration 2011e) for which an estimate of  $v_{\text{peak}}^{\text{S}}$  and of the bolometric luminosity was possible. We use this plot to test the relationship known as the *Blazar Sequence*, that is the strong anti-correlation between bolometric luminosity and  $v_{\text{peak}}^{\text{S}}$  claimed by Fossati et al. (1998) and Ghisellini et al. (1998) which has been the subject of lively debate (e.g., Giommi et al. 1999; Padovani et al. 2003; Caccianiga & Marchâ 2004; Nieppola et al. 2006; Padovani 2007; Ghisellini & Tavecchio 2008).

We stress that in order to properly test for the existence of such a relationship it is mandatory to use samples that are *unbiased*, that is selected in such a way so as not to favour any part of the  $L_{\text{Bol}}-v_{\text{peak}}^{\text{S}}$  diagram. Although our samples are statistically well defined they are not unbiased from this viewpoint for the following reasons:

**Fig. 24.** Top panel: The bolometric luminosity (represented by the sum of synchrotron and inverse-Compton peak luminosities) is plotted against  $v_{\text{peak}}^S$ . The non-thermal optical light of blazars with no strong emission lines above the dashed line would be bright enough to swamp the emission from the host galaxy making the source appear featureless thus hampering any redshift measurement. The upper limits represent BL Lacs with no known redshift are estimated assuming that the non-thermal light is larger than ten times that of a giant elliptical host galaxy (see text for details). The bottom panel shows the same plot for the subsample of sources satisfying the selection criteria of Fossati et al. (1998).

a) As shown in Figs. 18 and 19, the distribution of  $v_{\text{peak}}^S$  strongly depends on the selection method; hence, depending on the mix of the samples, we obtain a different sampling of the parameter  $v_{\text{peak}}^S$ .

b) The area above the dashed line, which represents the luminosity above which the non-thermal emission of a blazar completely dominates the observed optical flux,<sup>12</sup> cannot be populated by blazars with no emission lines, like BL Lacs, as in this case they would appear completely featureless and therefore their redshift could not be measured. In this respect we note that over 40% of the BL Lacs in the BZCAT catalog, and an even larger fraction of the *Fermi*-LAT detected BL Lacs, still lack any

<sup>12</sup> We assume a non-thermal luminosity one order of magnitude larger than that of the host giant elliptical galaxy of luminosity equal to that found by Scarpa et al. (2000) and by Urry et al. (2000) and verified by us to fit our SEDs.

redshift measurement (Massaro et al. 2010; Shaw et al. 2009, 2010). All the BL Lacs in our samples for which redshifts are unknown are plotted in Fig. 24 as lower limits estimated assuming that their non-thermal light is larger than 10 times the optical light of the host galaxy. The fact that some BL Lacs with known luminosity (red points in Fig. 24) are above the red line is because their redshift was measured from emission lines with rest-frame equivalent width below the 5 Å limit; they might be intermediate objects between BL Lacs and FSRQs (see, e.g., Ghisellini et al. 2011).

c) The different radio flux density cuts applied to our samples imply that different subsamples probe different parts of the radio luminosity function. The radio and  $\gamma$ -ray selected samples, which are defined using a high radio flux limit ( $S \geq 1$  Jy), probe the high-luminosity end of the radio luminosity function, which, for  $v_{\text{peak}}^S = 10^{13}$  Hz and the observed redshift and CD distributions, translates into  $L_{\text{bol}} \gtrsim 10^{46}$  erg s<sup>-1</sup>. The soft and hard X-ray selected samples have a radio flux density cut of  $S = 0.1$ –0.2 Jy, or about one order of magnitude fainter than that of the radio and *Fermi*-LAT samples, and therefore can include significantly less powerful sources, down to bolometric luminosities of the order of  $10^{44}$  erg s<sup>-1</sup>.

If we remove the  $v_{\text{peak}}^S$  dependency on the selection method by considering FSRQs only (which show the same  $v_{\text{peak}}^S$  distribution in all samples), we see that the luminosity values span about five orders of magnitude from  $\sim 10^{44}$  to  $\sim 10^{49}$  erg s<sup>-1</sup> and show no trend with  $v_{\text{peak}}^S$ , which ranges between  $\sim 10^{12.5}$  and  $\sim 10^{14}$  Hz. No obvious correlation is present in each sample separately or in the union of the four samples.

Finally we consider the case of the subsample of sources that satisfy the *same conditions* as in Fossati et al. (1998), that is  $S_{5\text{ GHz}} > 2$  Jy for FSRQs,  $S_{5\text{ GHz}} > 1$  Jy for radio selected BL Lacs, no restrictions for X-ray selected BL Lacs, and excluding all BL Lacs with no redshift information. This case is illustrated in Fig. 24 (bottom panel) which shows a trend very similar to that presented in Fossati et al. (1998).

Taking into account all of the above, we conclude that our data do not show a correlation of the type predicted by Fossati et al. (1998), owing to the presence of low luminosity LSP objects and the difficulty of measuring redshifts for likely high-luminosity HSP sources. That such a correlation becomes evident when the objects are selected by the criteria of Fossati et al. (1998) supports the hypothesis that the correlation might be the result of a selection effect.

#### 8.10. Selection effects and sample composition

Our choice of considering flux-limited samples selected in widely different parts of the electromagnetic spectrum (radio, soft X-ray, hard X-ray, and  $\gamma$ -ray) allowed us to emphasize the strong selection biases that can affect important physical parameters such as the peak energy of both the synchrotron and inverse-Compton components (see Figs. 18 and 19) and the Compton dominance (see Fig. 23). Since FSRQs and BL Lacs show significantly different  $v_{\text{peak}}^S$  distributions, these selection biases also strongly affect the composition of the samples in terms of relative abundance of blazar subclasses (FSRQs vs. BL Lacs, LSPs vs. HSPs), as is apparent from Table 4.

Radio-selected samples include sources that are bright in the radio band. If there is no correlation between radio flux/luminosity and other parameters such as  $v_{\text{peak}}^S$ , Compton dominance, etc., this is the best selection for measuring the dis-

tributions of these important physical parameters. If instead there is a strong correlation between radio luminosity and  $v_{\text{peak}}^S$ , then the distribution of  $v_{\text{peak}}^S$  should strongly depend on the radio flux limit.

X-ray selection favors high  $v_{\text{peak}}^S$  (and consequently high  $v_{\text{peak}}^{\text{IC}}$ ) sources which are much brighter at X-ray frequencies than low  $v_{\text{peak}}^S$  for the same radio flux. X-ray flux limited samples are therefore much richer in high  $v_{\text{peak}}^S$  BL Lacs (HBLs or HSP sources) than radio-selected samples. This selection effect has been well known ever since the first soft X-ray surveys became available.

$\gamma$ -ray flux limits favor bright  $\gamma$ -ray objects and therefore highly Compton-dominated sources. *Fermi*-LAT TS-limited samples favor sources with flat  $\gamma$ -ray spectral slopes or high  $v_{\text{peak}}^{\text{IC}}$  sources. This explains the overabundance of HSP blazars (only BL Lacs) and of high CD blazars (only FSRQs) in *Fermi*-LAT catalogs.

**Acknowledgements.** We thank the entire *Swift* team for the help and support and especially the Science Planners and Duty Scientists for their invaluable help and professional support with the planning and execution of a large number of ToOs.

The *Planck* Collaboration acknowledges the support of: ESA; CNES and CNRS/INSU-IN2P3-INP (France); ASI, CNR, and INAF (Italy); NASA and DoE (USA); STFC and UKSA (UK); CSIC, MICINN and JA (Spain); Tekes, AoF and CSC (Finland); DLR and MPG (Germany); CSA (Canada); DTU Space (Denmark); SER/SSO (Switzerland); RCN (Norway); SFI (Ireland); FCT/MCTES (Portugal); and DEISA (EU). **Fig. 25.** The SED of III ZW 2 (J0010+1058, top left), S5 0014+8135 (J0017+8135, top right), 1ES 0033+595 (J0035+5950, middle left), Mkn 348 (J0048+3157, middle right), 1Jy 0118-272 (J0120-2701, bottom left), and S4 0133+47 (J0136+4751, bottom right). Simultaneous data are shown in red; quasi-simultaneous data, i.e. *Fermi* data integrated over 2 months, *Planck* ERCSC and non-simultaneous ground based observations are shown in green; *Fermi* data integrated over 27 months are shown in blue; literature or archival data are shown in light gray.

**Fig. 26.** The SED of PKS 0202–17 (J0204–1701, top left), PKS 0208–512 (J0210–5101, top right), GB6J 0214+5145 (J0214+5144, middle left), PKS 0215+015 (J0217+0144, middle right), 1Jy 0212+735 (J0217+7349, bottom left), and 1Jy 0218+357 (J0221+3556, bottom right). Simultaneous data are shown in red; quasi-simultaneous data, i.e. *Fermi* data integrated over 2 months, *Planck* ERCSC and non-simultaneous ground based observations are shown in green; *Fermi* data integrated over 27 months are shown in blue; literature or archival data are shown in light gray.

**Fig. 27.** The SED of 4C 28.07 (J0237+2848, top left), PKS 0235+164 (J0238+1636, top right), NGC 1275 (J0319+4130, middle left), PKS 0332–403 (J0334–4008, middle right), NRAO 140 (J0336+3218, bottom left) and PKS 0420–01 (J0423–0120, bottom right). Simultaneous data are shown in red; quasi-simultaneous data, i.e. *Fermi* data integrated over 2 months, *Planck* ERCSC and non-simultaneous ground based observations are shown in green; *Fermi* data integrated over 27 months are shown in blue; literature or archival data are shown in light gray.

**Fig. 28.** The SED of PKS 0426–380 (J0428–3756, top left), 3C 120 (J0433+0521, top right), PKS 0454–234 (J0457–2324, middle left), PKS 0521–36 (J0522–3627, middle right), PKS 0528+134 (J0530+1331, bottom left), and PKS 0537–441 (J0538–4405, bottom right). Simultaneous data are shown in red; quasi-simultaneous data, i.e. *Fermi* data integrated over 2 months, *Planck* ERCSC and non-simultaneous ground based observations are shown in green; *Fermi* data integrated over 27 months are shown in blue; literature or archival data are shown in light gray.

**Fig. 29.** The SED of 1Jy 0537–286 (J0539–2839, top left), PKS 0548–322 (J0550–3216, top right), IRAS-L 06229–643 (J0623–6436, middle left), PKS 0735+17 (J0738+1742, middle right), B2.2 0743+25 (J0746+2549, bottom left), and S4 0814+425 (J0818+4222, bottom right). Simultaneous data are shown in red; quasi-simultaneous data, i.e. *Fermi* data integrated over 2 months, *Planck* ERCSC and non-simultaneous ground based observations are shown in green; *Fermi* data integrated over 27 months are shown in blue; literature or archival data are shown in light gray.

J0824+5552 – OJ 535

J0841+7053 – 4C 71.07

**Fig. 30.** The SED of OJ 535 (J0824+5552, top left), 4C 71.07 (J0841+7053, top right), PKS 0851+202 (J0854+2006, middle left), B2 0912+29 (J0915+2933, middle right), S4 0917+44 (J0920+4441, bottom left), and PKS 0921–213 (J0923–2135, bottom right). Simultaneous data are shown in red; quasi-simultaneous data, i.e. *Fermi* data integrated over 2 months, *Planck* ERCSC and non-simultaneous ground based observations are shown in green; *Fermi* data integrated over 27 months are shown in blue; literature or archival data are shown in light gray.

**Fig. 31.** The SED of 4C 55.17 (J0957+5522, top left), 1H 1013+498 (J1015+4926, top right), 1RXSJ 105837.5+562816 (J1058+5628, middle left), 4C 01.28 (J1058+0133, middle right), PKS 1057-79 (J1058-8003, bottom left), and Mkn 421 (J1104+3812, bottom right). Simultaneous data are shown in red; quasi-simultaneous data, i.e. *Fermi* data integrated over 2 months, *Planck* ERCSC and non-simultaneous ground based observations are shown in green; *Fermi* data integrated over 27 months are shown in blue; literature or archival data are shown in light gray.

**Fig. 32.** The SED of PKS 1124–186 (J1127–1857, top left), PKS 1127–145 (J1130–1449, top right), B2 1128+31 (J1131+3114, middle left), S5 1133+704 (J1136+7009, middle right), PKS 1144–379 (J1147–3812, bottom left), and 4C 49.22 (J1153+4931, bottom right). Simultaneous data are shown in red; quasi-simultaneous data, i.e. *Fermi* data integrated over 2 months, *Planck* ERCSC and non-simultaneous ground based observations are shown in green; *Fermi* data integrated over 27 months are shown in blue; literature or archival data are shown in light gray.

**Fig. 33.** The SED of 4C 29.45 (J1159+2914, top left), ON 325 (J1217+3007, top right), PKS 1217+02 (J1220+0203, middle left), ON 231 (J1221+2813, middle right), PKS 1219+04 (J1222+0413, bottom left), and 3C 273 (J1229+0203, bottom right). Simultaneous data are shown in red; quasi-simultaneous data, i.e. *Fermi* data integrated over 2 months, *Planck* ERCSC and non-simultaneous ground based observations are shown in green; *Fermi* data integrated over 27 months are shown in blue; literature or archival data are shown in light gray.

**Fig. 34.** The SED of PKS 1244–255 (J1246–2547, top left), PG 1246+586 (J1248+5820, top right), 3C 279 (J1256–0547, middle left), 1Jy 1302–102 (J1305–1033, middle right), 1Jy 1308+326 (J1310+3220, bottom left), and GB6B 1347+0955 (J1350+0940, bottom right). Simultaneous data are shown in red; quasi-simultaneous data, i.e. *Fermi* data integrated over 2 months, *Planck* ERCSC and non-simultaneous ground based observations are shown in green; *Fermi* data integrated over 27 months are shown in blue; literature or archival data are shown in light gray.

**Fig. 35.** The SED of 1WGAJ 1407.5–2700 (J1407–2701, top left) and of 3C 298.0 (J1419+0628, top right), CSO 643 (J1423+5055, middle left), of PG 1424+240 (J1427+2348, middle right), 1RXSJ 145603.4+504825 (J1456+5048, bottom left), and PKS 1502+106 (J1504+1029, bottom right). Simultaneous data are shown in red; quasi-simultaneous data, i.e. *Fermi* data integrated over 2 months, *Planck* ERCSC and non-simultaneous ground based observations are shown in green; *Fermi* data integrated over 27 months are shown in blue; literature or archival data are shown in light gray.

**Fig. 36.** The SED of BZQJ 1507+0415 (J1507+0415, top left), 4C –05.64 (J1510–0543, top right), AP Lib (J1517–2422, middle left), PG 1553+111 (J1555+1111, middle right), WE 1601+16W3 (J1603+1553, bottom left), and OS –237.8 (J1625–2527, bottom right). Simultaneous data are shown in red; quasi-simultaneous data, i.e. *Fermi* data integrated over 2 months, *Planck* ERCSC and non-simultaneous ground based observations are shown in green; *Fermi* data integrated over 27 months are shown in blue; literature or archival data are shown in light gray.

**Fig. 37.** The SED of 4C 38.41 (J1635+3808, top left), NRAO 512 (J1640+3946, top right), 3C 345 (J1642+3948, middle left), Mkn 501 (J1653+3945, middle right), ARP 102B (J1719+4858, bottom left), and 1ES 1741+196 (J1743+1935, bottom right). Simultaneous data are shown in red; quasi-simultaneous data, i.e. *Fermi* data integrated over 2 months, *Planck* ERCSC and non-simultaneous ground based observations are shown in green; *Fermi* data integrated over 27 months are shown in blue; literature or archival data are shown in light gray.

**Fig. 38.** The SED of OT 081 (J1751+0939, top left), S5 1803+784 (J1800+782, top right), PKSB 1830–210 (J1833–2103, middle left), PKS 1833–77 (J1840–7709, middle right), 2E 1908.2–201 (J1911–2006, bottom left), and PMNJ 1923–2104 (J1923–2104, bottom right). Simultaneous data are shown in red; quasi-simultaneous data, i.e. *Fermi* data integrated over 2 months, *Planck* ERCSC and non-simultaneous ground based observations are shown in green; *Fermi* data integrated over 27 months are shown in blue; literature or archival data are shown in light gray.

**Fig. 39.** The SED of OV–236 (J1924–2914, top left), 1ES 1959+6508 (J1959+6508, top right), 1Jy 2005–489 (J2009–4849, middle left), PKS 2052–47 (J2056–4714, middle right), 1Jy 2126–158 (J2129–1538, bottom left), and S3 2141+17 (J2143+1743, bottom right). Simultaneous data are shown in red; quasi-simultaneous data, i.e. *Fermi* data integrated over 2 months, *Planck* ERCSC and non-simultaneous ground based observations are shown in green; *Fermi* data integrated over 27 months are shown in blue; literature or archival data are shown in light gray.

**Fig. 40.** The SED of 1Jy 2144+092 (J2147+0929, top left), 4C 06.69 (J2148+0657, top right), PKS 2149–307 (J2151–3027, middle left), BL Lac (J2202+4216, middle right), 4C 31.63 (J2203+3145, bottom left), and PKS 2204–54 (J2207–5346, bottom right). Simultaneous data are shown in red; quasi-simultaneous data, i.e. *Fermi* data integrated over 2 months, *Planck* ERCSC and non-simultaneous ground based observations are shown in green; *Fermi* data integrated over 27 months are shown in blue; literature or archival data are shown in light gray.

**Fig. 41.** The SED of NGC 7213 (J2209–4710, top left), PKS 2227–08 (J2229–0832, top right), PKS 2227–399 (J2230–3942, middle left), 4C 11.69 (J2232+1143, middle right), 3C 454.3 (J2253+1608, bottom left), and PKS 2300–18 (J2303–1841, bottom right). Simultaneous data are shown in red; quasi-simultaneous data, i.e. *Fermi* data integrated over 2 months, *Planck* ERCSC and non-simultaneous ground based observations are shown in green; *Fermi* data integrated over 27 months are shown in blue; literature or archival data are shown in light gray.

**Fig. 42.** The SED of PKS 2325+093 (J2327+0940, top left), PKS 2331–240 (J2333–2343, top right), and 1ES 2344+514 (J2347+5142, middle). Simultaneous data are shown in red; quasi-simultaneous data, i.e. *Fermi* data integrated over 2 months, *Planck* ERCSC and non-simultaneous ground based observations are shown in green; *Fermi* data integrated over 27 months are shown in blue; literature or archival data are shown in light gray.

**Table 6.** *Planck* data integrated over a single survey during the *Swift* observations.
