Single-Cell Genomics Reveals Organismal Interactions in Uncultivated Marine Protists

Hwan Su Yoon,[1,2]* Dana C. Price,[3]* Ramunas Stepanauskas,[1] Veeran D. Rajah,[3] Michael E. Sieracki,[1] William H. Wilson,[1] Eun Chan Yang,[1] Siobain Duffy,[3] Debashish Bhattacharya[3]†

Whole-genome shotgun sequence data from three individual cells isolated from seawater, followed by analysis of ribosomal DNA, indicated that the cells represented three divergent clades of picobiliphytes. In contrast with the recent description of this phylum, we found no evidence of plastid DNA nor of nuclear-encoded plastid-targeted proteins, which suggests that these picobiliphytes are heterotrophs. Genome data from one cell were dominated by sequences from a widespread single-stranded DNA virus. This virus was absent from the other two cells, both of which contained non-eukaryote DNA derived from marine Bacteroidetes and large DNA viruses. By using shotgun sequencing of uncultured marine picobiliphytes, we revealed the distinct interactions of individual cells.

Culture-independent analyses of environmental ribosomal DNA (rDNA) clone libraries and metagenomes can uncover unexpected microbial species and gene diversity (e.g., *1–3*). These methods cannot, however, reveal in situ interactions among organisms. To achieve this level of resolution, genome data from single cells captured from the wild environment are needed. We used single-cell genomics (*4–7*) to study the marine plankton group Picobiliphyta, recently described as a previously unknown lineage of pigmented eukaryotes with a phylogenetic affinity to cryptophytes and katablepharids (*8*, *9*). The cells were originally identified microscopically with the use of 18*S* rDNA-based fluorescent in situ hybridization probes. Although their ultrastructure is unknown, previous studies using autofluorescence and 4′,6-diamidino-2-phenylindole staining data (*9*, *10*) appeared to show that picobiliphytes contain a plastid derived from a cryptophyte alga (owing to the presence of phycobilin proteins; hence the phylum name) and the associated remnant nucleus (nucleomorph). These taxa have not yet been successfully cultivated, leaving open the possibility that the plastid and nucleomorph may not be permanent acquisitions but rather come from a klepto-plastid or a cryptophyte alga

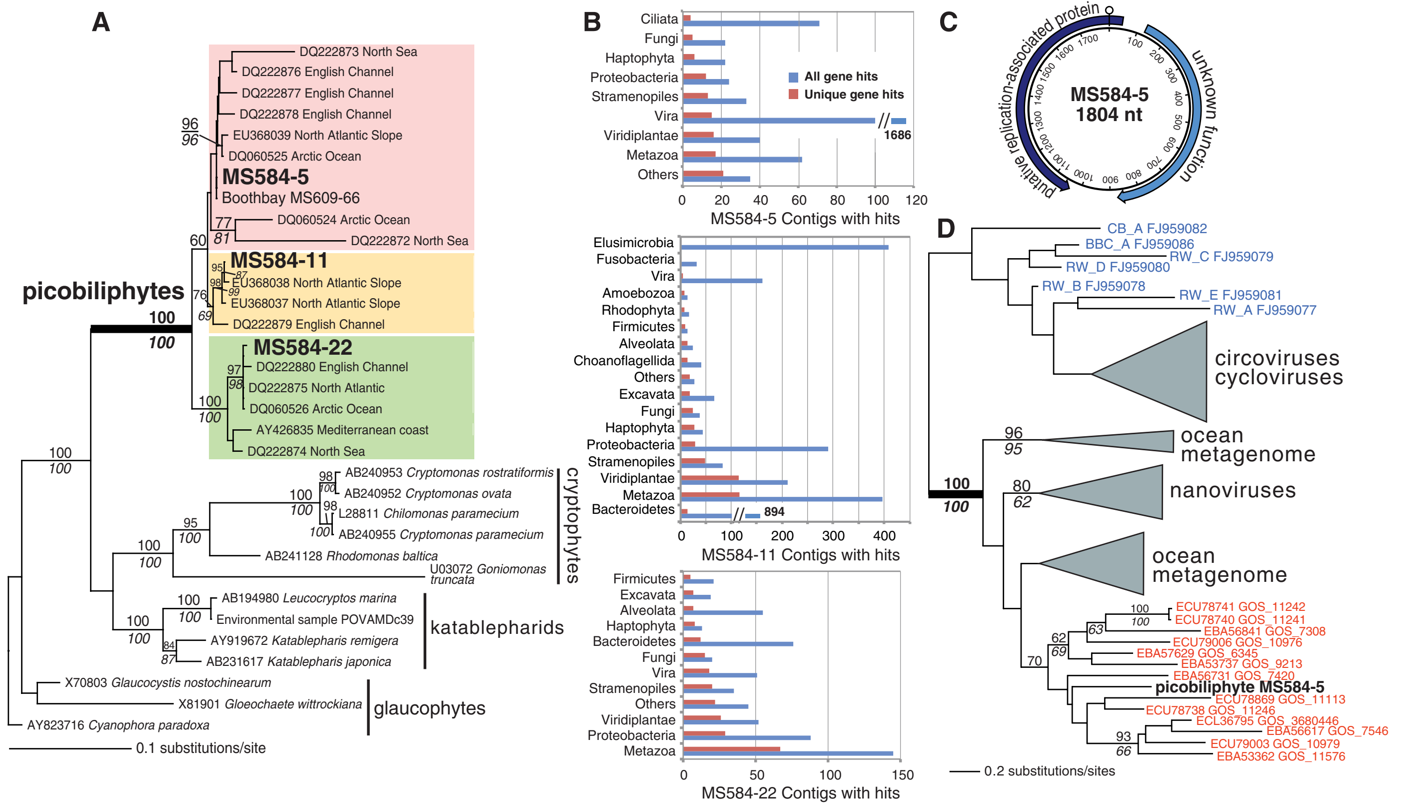

Fig. 1. (**A**) Randomized accelerated maximum likelihood (RAxML) phylogenetic tree of picobiliphyte SSU rDNA coding regions. RAxML bootstrap values are above the branches, and those derived from maximum parsimony (when nodes are shared) are below the branches. Only bootstrap values ≥60% are shown. Sequenced genomes are in bold. GenBank numbers are shown for each taxon. (**B**) Analysis of the taxonomic distribution of BLASTx hits using as query the 454-derived contigs from each SAG assembly (when ≥10; if ≤10, the different hits were grouped under "Others"). The total number of hits (blue bars) and the unique gene hits (red bars) are shown for MS584-5, MS584-11, and MS584-22. Some taxa are overrepresented, such as virus hits in MS584-5 and Bacteroidetes in MS584-22 that are probably explained by MDA bias. (**C**) Genome structure of the previously unknown ssDNA virus. (**D**) Simplified RAxML tree of Rep proteins from representative ssDNA viruses, showing the phylogenetic position of the MS584-5 sequence. Rep from marine ssDNA viruses is shown in blue, whereas sequences derived from ocean metagenome data are shown in red. The bootstrap values (when ≥60%) above the branches are from RAxML, whereas those below are from PhyML. The full tree is shown in fig. S2A.

captured as food. Picobiliphytes are distributed in variable physicochemical habitats (4 to 89 m in depth, 5° to 30°C in temperature) over broad geographical ranges from the Arctic Ocean to the Sargasso Sea and the Mediterranean coast (*8*, *9*, *11*).

We used fluorescence-activated cell sorting to separate individual heterotrophic (lacking chlorophyll fluorescence) protist cells <10 μm in diameter from a single 50-ml seawater sample collected at Boothbay Harbor in the Gulf of Maine. The temperature, amount of chlorophyll, and composition of the microbial community were typical for midsummer at this site (table S1). After whole-genome amplification using multiple displacement amplification (MDA), the taxonomic identity of each single-cell amplified genome (SAG) was determined by sequencing the 18*S* rDNA gene. Of 35 protist SAGs that were analyzed, 6 (17%) were picobiliphytes (*12*) representing three evolutionarily divergent clades, all of which have been previously regarded as photosynthetic (Fig. 1A). The finding of picobiliphytes in the heterotrophic fraction is consistent with the results of another study of 109 SAGs derived from fluorescent and nonfluorescent protists isolated from Boothbay Harbor (table S2). In that analysis of SAG rDNA sequences, picobiliphytes were present only among cells that lacked chlorophyll fluorescence.

Shotgun sequencing of picobiliphyte SAGs MS584-5, MS584-11, and MS584-22 was done using Roche 454 FLX Titanium series reagents and resulted in ~90 mega–base pairs (Mbp) of individual reads and ~5 Mbp of assembled contigs per SAG (table S3). A BLASTx analysis of contigs (Fig. 1B) and unassembled singletons (fig. S1A) revealed many top hits in different eukaryotes. For MS584-5, the majority [85%; 1686 out of 1995 (1686/1995)] of total contig hits were to viral genes. To reduce the impact of possible amplification bias introduced by MDA (*7*, *13*), we reduced the picobiliphyte lists to unique gene hits in each phylum. This was done by reducing multiple hits to the same protein within a single species in our database (table S4) to a single entry. This assumed that each of the duplicated hits represented the same DNA fragment that was overrepresented because of MDA bias. This procedure reduced the overrepresentation of sequences from particular phyla [for example, Elusimicrobia (408 hits to a PBSX phage terminase in *Elusimicrobium minutum* Pei191) and Bacteroidetes in MS584-11] and increased the relative number of hits to Metazoa, Viridiplantae, and Stramenopiles (Fig. 1B and fig. S1A).

Taxonomic analysis of MS584-5 contigs indicated that this SAG contains a previously uncharacterized virus absent in the other two cells (fig. S1A). The assembled genome of this virus (1804 nt; Fig. 1C) was used in a BLASTx search against the NCBI RefSeq viral repository. This showed that the genome encoded a putative replication-associated protein (Rep), with all 58 hits being to Rep proteins in single-stranded DNA (ssDNA) nanoviruses of plants and circoviruses of animals. The top hit was the Rep protein in the Faba bean necrotic yellows virus [expect (*e*) value that by chance another alignment exists with a higher probability = 6.00×10^{-24}; see fig. S1B]. A BLASTn analysis of the individual 454 reads derived from MS584-5 using the assembled viral genome sequence as a query identified 109,748 reads (46.2% of the total data from this SAG) with an *e* value $\leq 1 \times 10^{-20}$, consistent with the large number of virus-derived contigs in this cell. The sequence coverage across this genome was relatively uniform (mean = 22740; standard deviation = 3396). Given the high abundance of shotgun reads spanning the entire genome of a single "nanovirus" genotype in picobiliphyte MS584-5, our data probably indicate virus infection captured in situ by single-cell sequencing. The MS584-5 Rep protein shares no similarity with plasmids of the red alga *Porphyra pulchra* or ssDNA viruses of diatoms (*14*, *15*) or organelle DNA. The virus is larger than any characterized nanovirus genome segment and has a second open reading frame in the opposite sense to Rep (Fig. 1C). Analysis of the Global Ocean Survey metagenome data (*16*) showed that related Rep protein sequences are abundant in the ocean (Fig. 1D).

Contig and singleton BLASTx hits to non-eukaryote DNA from MS584-11 included marine Bacteroidetes, Proteobacteria, and Firmicutes (Fig. 1B and fig. S1A). MS584-22 harbored a diverse range of larger double-stranded DNA viruses, phages, and Proteobacteria (Fig. 1B and

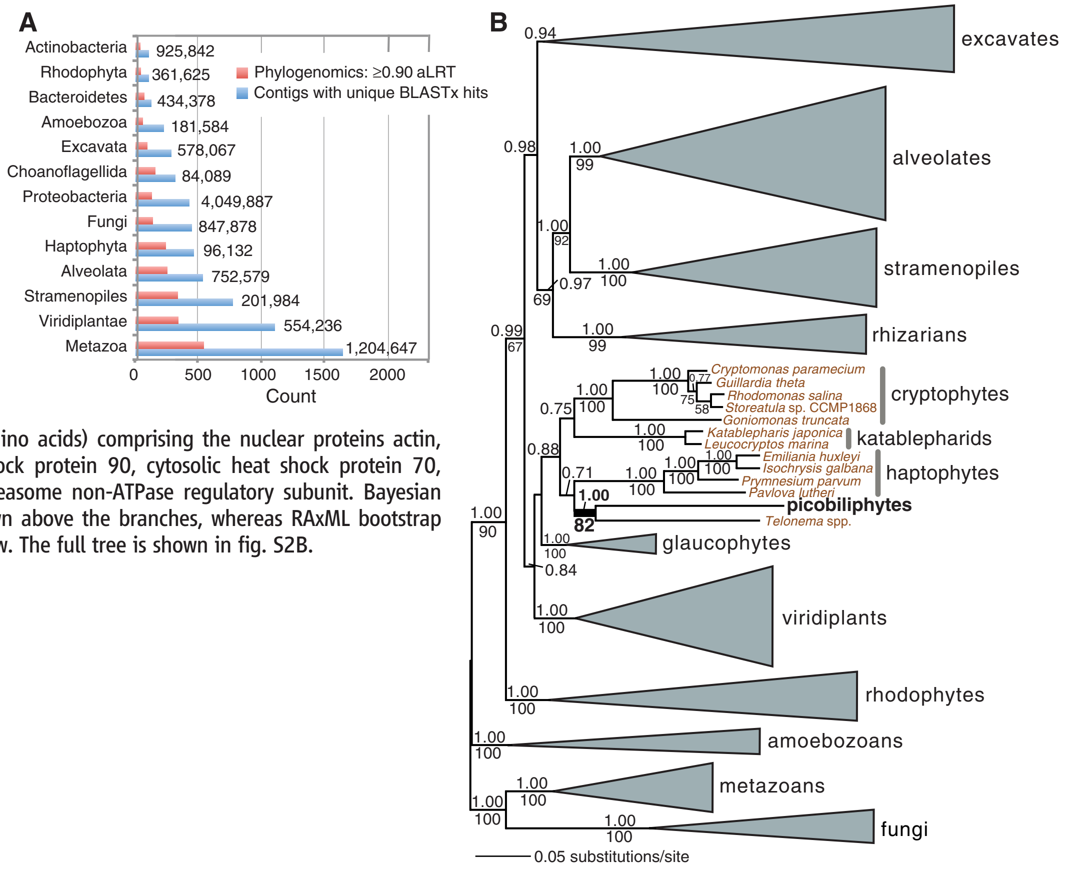

Fig. 2. (**A**) Analysis of the taxonomic distribution of unique BLASTx hits (blue bars) using as query the contigs from the 454 + Illumina assembly of MS584-11. Only phyla with >100 hits are shown. The red bars show the phylogenetic distribution of MS584-11 proteins in PhyML trees at aLRT ≥0.90. The value at the right of the bars is the total number of proteins representing each phylum in our database. (**B**) Simplified phylogeny inferred with Bayesian inference, showing the phylogenetic position of picobiliphytes. This tree was built using a concatenated alignment (2594 amino acids) comprising the nuclear proteins actin, alpha-tubulin, beta-tubulin, heat shock protein 90, cytosolic heat shock protein 70, ribosomal protein L3, and 26*S* proteasome non-ATPase regulatory subunit. Bayesian posterior probability values are shown above the branches, whereas RAxML bootstrap values (when ≥60%) are shown below. The full tree is shown in fig. S2B.

fig. S1A). Presumably, the picobiliphytes feed on Proteobacteria, Bacteroidetes (some apparently phage-infected), and large DNA viruses (*17*), although attachment of viral and bacterial DNA to the picobiliphyte cell surface cannot be ruled out with our approach.

To address the possibility that the picobiliphytes we studied might contain a plastid (*9*) and were sorted as heterotrophs because of a loss of autofluorescence as a result of damage caused by photobleaching, we searched the SAG data for hits to plastid- and mitochondrion-encoded proteins. BLASTx analysis identified 62, 3646, and 102 hits to mitochondrial proteins in the sequence reads from MS584-5, MS584-11, and MS584-22, respectively, but failed to recover plastid proteins (contig hits are shown in table S5). We then generated an additional ~3 Gbp of data from MS584-11 using an Illumina GAIIx sequencer. These data (29.3 million paired-end reads) were coassembled with the existing 454 data, resulting in ~28 Mbp of contigs. Assessment of the two sets of sequence data showed that 94% of the 454 data mapped (at ≤3 mismatches in a 53-bp sliding window of comparison) to the Illumina reads. BLASTx analysis of the combined assembly again failed to identify plastid DNA. As a final step, we generated ~9 Gbp of Illumina data from MS584-22 and used BLASTx to search the assembled ~27 Mbp of contigs for hits to plastid genes; none were found except for a hit to a site-specific DNA endonuclease and to a hypothetical protein that are plastid-encoded in two different green algae (table S6). To assess our ability to identify plastid genes in a SAG-MDA sample, we examined Illumina data derived from a photosynthetic amoeba, *Paulinella chromatophora* [for details, see (*S24*)]. This analysis showed that over one-half of the *P. chromatophora* plastid-encoded genes could be successfully retrieved with BLASTx.

The 454 + Illumina draft genome assembly for MS584-11 afforded assessment of the level of gene homology between the poorly understood picobiliphytes and other eukaryotes. The MS584-11 data were initially analyzed with BLASTx to determine the number of hits of MS584-11 contigs to the total set of predicted proteins in the sequenced genomes of brewer's yeast *Saccharomyces cerevisae* S288c and the model diatom *Phaeodactylum tricornutum* CCAP 1055/1. Using the cutoff *e* value $\leq 1 \times 10^{-5}$, 1866/5863 (31.8%) and 2792/9488 (29.4%) of proteins in the yeast and the diatom, respectively, had hits to picobiliphyte contigs. This suggests that ~2000 picobiliphyte proteins shared detectable similarity with sequences in other eukaryotes. We searched annotations for all diatom protein hits to the picobiliphyte data, now at the more stringent *e* value $\leq 1 \times 10^{-10}$ (1687 proteins) for putative nuclear-encoded plastid-targeted proteins in MS584-11. This analysis turned up a weak hit to a putative chloroplast-targeted nuclear-encoded recombinase and a plastidic inositol phosphatase in *P. tricornutum* (GenBank identification nos. 219111175 and 219110535, respectively). The picobiliphyte recombinase homolog was, however, of bacterial origin, and the inositol phosphatase was of eukaryotic provenance but related to nonplastidic forms of the enzyme. A BLASTx analysis of the MS584-11 contigs against our local database (Fig. 2A) found more unique hits to eukaryote genes in this SAG (with most hits to Metazoa, Viridiplantae, and Stramenopiles) than to prokaryote genes. The large number of hits to Metazoa probably reflects the size of our database (>1.2 million proteins, Fig. 2A), combined with an absence of data from genomes that are closely related to picobiliphytes (Figs. 1A and 2B). Summing the lengths of all MS584-11 contigs with significant BLASTx hits to eukaryote proteins gave an estimate of 7.9 Mbp of detectable, gene-encoding regions of the picobiliphyte genome in our assembly. Given that other pico-sized eukaryotes such as *Ostreococcus* sp. and *Micromonas* spp. have genome sizes of ~12 to 22 Mbp (*18*), and that picobiliphyte-specific proteins will not be detected by our approach, the MS548-11 assembly probably covers a minimum of 50% of the picobiliphyte genome.

The predicted proteins from the MS584-11 assembly that had significant BLASTx hits (8334 proteins) were used as input for a phylogenomic analysis against our local genome database (see the supporting online material) (*19*). The picobiliphyte data included many highly conserved eukaryotic proteins such as beta-tubulin (contig21336_2; average coverage = 457x) and the second-largest subunit of DNA-directed RNA polymerase I (contig20686_4; average coverage = 11x). We concatenated seven conserved proteins present in the picobiliphyte genome data [actin, alpha-tubulin, beta-tubulin, heat shock protein 90, cytosolic heat shock protein 70, ribosomal protein L3, and 26*S* proteasome non–adenosine triphosphatase (non-ATPase) regulatory subunit] to infer their position in the tree of life. This Bayesian phylogeny (Fig. 2B) shows picobiliphytes to comprise an ancient divergence among eukaryotes with a putative phylogenetic relationship to the plastid-lacking telonemids. The picobiliphyte-telonemid clade is sister to the photosynthetic haptophytes and cryptophytes and the plastid-lacking katablepharids. The union of plastid-containing and plastid-lacking taxa suggests the possibility that picobiliphytes may once have been photosynthetic, as has been suggested for ciliates (*20*) and telonemids (*21*).

Phylogenomics using the MS584-11 data returned 5231 maximum likelihood (PhyML) trees that were sorted (*22*) to determine the taxonomic affinities of the different picobiliphyte proteins at the approximate likelihood-ratio test (aLRT) (*23*) cutoff ≥0.90 (Fig. 2A). This analysis showed that 2228 picobiliphyte proteins (3242 at aLRT ≥0.70) are monophyletic with the eukaryotes tested in our analysis (table S7), which is consistent with the BLASTx analysis described above using the yeast and diatom genome data. Phylogenomics provided a robust estimate of the number of eukaryotic proteins in the MS548-11 data set because it relied on maximum likelihood phylogenetic analysis to assess gene affiliation. The finding that 338, 335, and 240 picobiliphyte proteins group at aLRT ≥0.90 with the Viridiplantae, Stramenopiles, and Haptophyta (table S7), respectively, is consistent with a possible photosynthetic ancestry for picobiliphytes (Fig. 2B). An example of a PhyML tree returned by our pipeline (showing members of the major facilitator superfamily of transporters) that supports a close association of MS584-11 with photosynthetic lineages is shown in fig. S3.

In a final attempt to find potential plastid-targeted proteins in MS584-11, we collected all of the maximum likelihood trees resulting from the phylogenomic analysis that grouped the picobiliphytes with Stramenopiles at aLRT ≥0.70 (1683 individual proteins) and generated gene ontology annotations for these sequences (table S8). Again, we found no evidence for nuclear-encoded plastid-targeted proteins (such as photosystem or light-harvesting proteins) in this data set that included nuclear genome data from photosynthetic diatoms and the pelagophyte *Aureococcus anophagefferens*, which are known to contain these genes. We interpret these different lines of evidence as arguing against a photosynthetic lifestyle for the picobiliphyte SAGs we have studied.

In this study, SAG analysis allowed us to generate significant genome data from three individual, related cells found in a single 50-ml coastal seawater sample. This revealed complex biotic interactions among previously uncharacterized marine microorganisms, with each cell undergoing distinct types of interaction. Our single-cell sequencing approach opens novel opportunities to study protist, prokaryote, and viral interactions in situ, without cultivation artifacts, and has biomedical applications; for example, in determining DNA differences between healthy and diseased cells. The ability to generate substantial amounts of genome data from single cells also opens the possibility of reconstructing the eukaryotic tree of life, using a multitude of uncultured taxa isolated directly from their natural environment.

A Family of IFN-γ–Inducible 65-kD GTPases Protects Against Bacterial Infection

Bae-Hoon Kim,[1] Avinash R. Shenoy,[1] Pradeep Kumar,[1] Rituparna Das,[1,2] Sangeeta Tiwari,[1] John D. MacMicking[1]*

Immune interferon gamma (IFN-γ) is essential for mammalian host defense against intracellular pathogens. IFN-γ induces nearly 2000 host genes, yet few have any assigned function. Here, we examined a complete mouse 65-kilodalton (kD) guanylate-binding protein (Gbp) gene family as part of a 43-member IFN-γ–inducible guanosine triphosphatase (GTPase) superfamily in mouse and human genomes. Family-wide loss-of-function analysis found that at least four Gbps—Gbp1, Gbp6, Gbp7, and Gbp10—conferred cell-autonomous immunity to listerial or mycobacterial infection within macrophages and gene-deficient animals. These Gbps solicited host defense proteins, including the phagocyte oxidase, antimicrobial peptides, and autophagy effectors, to kill intracellular bacteria. Thus, specific 65-kD Gbps coordinate a potent oxidative and vesicular trafficking program to protect the host from infection.

Immune interferon gamma (IFN-γ) is critical for resistance to infection, exerting its effects through broad transcriptional programs involving ~2000 genes, many of which remain uncharacterized (*1*, *2*). Prominent within this transcriptional signature are several families of guanosine triphosphatases (GTPases). These include the 47-kD immunity-related GTPases (p47 IRGs), 65- to 73-kD guanylate-binding proteins (p65 Gbps), and 285-kD very large inducible GTPases (Vligs/Gvins) (*2*).

Recent mapping efforts have uncovered 43 members of this IFN-γ–inducible GTPase superfamily within mouse and human genomes (*3*–*7*) (fig. S1, A and B). p47 IRGs represent the largest subgroup (~18 to 21 genes) important for host defense (*8*–*12*). These GTPases bind phosphoinositides, cardiolipin, soluble NSF attachment protein receptor adaptor proteins, and other p47 IRGs to direct their membrane regulatory activities against compartmentalized bacteria and protozoa (*10*–*12*). In contrast, little is known about the p65 Gbp and Gvin subfamilies, despite accounting for ~20% of the relative abundance of all proteins induced by IFN-γ (*2*). Weak antiviral or antibacterial properties have been ascribed individually to Gbp1, Gbp2, and Gbp5 (*13*–*15*); however, integrated family contributions remain untested (*2*, *5*).

We thus conducted loss-of-function screens across the complete 11-member mouse *Gbp* family in macrophages where it is strongly induced by IFN-γ compared with other IFNs (IFN-αβ, IFN-λ, and IFN-Z) and Toll-like receptor (TLR) ligands (fig. S1, C and D) (*6*). These immune cells were infected with two intracellular bacteria particularly sensitive to IFN-γ–mediated killing: *Listeria monocytogenes* (*Lm*), a gram-positive bacterium responsible for food-borne infection in humans, or *Mycobacterium bovis* BCG (*Mb* BCG), which causes lethal mycobacteriosis in IFNγR-deficient patients (*1*). Using short 21-bp (base pair) Gbp small interfering RNA (siRNA) duplexes that gave robust gene-specific silencing (fig. S2, A and B), we found that Gbp1, Gbp6, Gbp7, and Gbp10 were critical for control of virulent *Lm* (EGD strain) or *Mb* BCG (Phipps strain). In resting RAW264.7 macrophages, *Lm* multiplied by a factor of ~85 ($\log10^{1.9}$ growth) over 6 hours after uptake. IFN-γ activation, however, curtailed replication (to a factor of ~18, or $\log10^{1.2}$ growth), a restriction that was reversed with siRNAs for Gbp1, Gbp6, Gbp7, Gbp10 and to a lesser extent Gbp5 (to a factor of 39 to 58 or $\sim\log10^{1.5-1.75}$ growth; $P < 0.0062$) (Fig. 1A and fig. S3A). Protective Gbps functioned cooperatively, with siRNA combinations exacerbating the loss of IFN-γ–induced killing (Fig. 1A and fig. S3A). siRNA phenotypes were not attributable to single- and double-stranded RNA sensing. Primary bone-marrow–derived macrophages (BMMs) and RAW264.7 cells defective in either TLR ($MyD88^{-/-}Trif^{-/-}$) or Rig-1/Mda5/Ips-1–dependent RNA recognition (expressing the viral Rig-1/Mda5/Ips-1 inhibitor, NS34A) yielded comparable results (Fig. 1A and fig. S3A).

Mb BCG challenge showed similar Gbp-dependent resistance. In short 48-hour killing assays that were necessitated by waning siRNA effectiveness at 96 hours, IFN-γ reduced *Mb* BCG by $\sim\log10^{0.8}$ [72 to 77% reduction in colony-forming units (CFU)] in untreated and scrambled RNA (scRNA)–treated macrophages. Inhibition was partly reversed by Gbp1, Gbp5, Gbp7, or Gbp6/Gbp10 siRNAs (56 to 64% CFU reduction) but not siRNAs for the remaining *Gbp* genes (77 to 82%; $P < 0.0112$) (Fig. 1A and fig. S3B).

To amplify the smaller phenotypes for slow-growing *Mb* BCG, we devised a system of long-term Gbp inhibition. Dominant-negative (DN) mutants were identified and stably expressed under tetracycline-repressible control [tTA-TRE2-Gbp (DN)] to avoid polyketide antibiotics during infection. Two conserved P-loop residues (GxxH/RxKS) required for nucleotide-dependent self-assembly or a C-terminal CaaX box (CVIL) used for C_{20} isoprenyl membrane tethering were mutated (*16*, *17*). All Gbp1 ($Gbp1^{H48P}$, $Gbp1^{S52N}$, and $Gbp1^{SVIL}$) and Gbp7 ($Gbp7^{R48P}$ and $Gbp7^{S52N}$) mutants failed to target vesicle membranes; however, those of Gbp10 ($Gbp10^{R46P}$ and $Gbp10^{S50N}$) showed a less robust phenotype and were not pursued further as potential DN candidates (fig. S4A). Stable expression of Gbp1 and Gbp7 P-loop (S52N) mutants disrupted endogenous Gbp vesicle localization in IFN-γ–activated macrophages (fig. S4B), underscoring their DN action by binding wild-type partners for incorporation into "dead-end" multimeric complexes (fig. S5, A to C). This resembles dynamin-1 P-loop (S52N)

Analysis of Plastid Genes in *Paulinella chromatophora*

To determine whether the inability to identify plastid DNA in the picobiliphytes, in spite of extensive genome sampling of MS584-11 and MS584-22, may reflect an unknown bias associated with our approach, we searched for plastid DNA in SAG-MDA derived Illumina genome data from a 50-cell sample of the photosynthetic amoeba *Paulinella chromatophora* FK01 for which the plastid genome sequence is known (*S24*). We chose this species because the genome data for *P. chromatophora* were generated using the same approach as for the picobiliphytes and therefore provided a direct test of the idea that plastid genes can be successfully recovered from SAG-MDA derived Illumina sequence reads. Ten bins of unassembled data, each totaling 80 Mbp (theoretical 1x coverage of the amoeba nuclear genome), were created by randomly retrieving 640,000 reads of length 125 bp from a 3.1 Gbp *P. chromatophora* Illumina-generated DNA library. The bins were then each used as a BLASTx query (*e-value* ≤ 1e-20) against a protein database containing all FK01 plastid proteins. Using this approach, we identified an average of 149 matches per bin to the 841 distinct proteins on the FK01 organelle genome. A total of 459/841 plastid proteins had matches over the ten bins of data (the *P. chromatophora* plastid sequence and Illumina genome data used to determine the frequency of plastid genes recovered from these reads are freely available at http://dbdata.rutgers.edu/data/pico). Although the *P. chromatophora* plastid genome is ~5-6-fold larger than in a typical alga (*S24*), and we sampled pooled DNA from a culture, our data suggest that if present, plastid DNA should have been identified among the ~3 Gbp and ~9 Gbp of total data from MS584-11 and MS584-22, respectively.

Materials and Methods

A 50 mL coastal water sample was collected from 1 m depth in Boothbay Harbor in the Gulf of Maine, U.S.A. (43°50'39.76"N, 69°38'27.76"W). Sampling was at high tide (8:15 am) on July 25th, 2007. Water temperature was 18°C. Samples were kept in the dark at *in situ* temperature until processing (< 6h). Subsamples (3 mL) were incubated for 10 min with Lysotracker Green DND-26 (75 nmol.L^{-1}; Invitrogen), a pH-sensitive green fluorescing probe that stains food vacuoles in protists (*S25*). Target cells were identified and sorted using a MoFlo™ (Beckman-Coulter) flow cytometer equipped with a 488 nm laser for excitation. Prior to sorting, the cytometer was cleaned thoroughly with bleach: all tubes, plates, and buffers were UV-treated prior to use to remove any DNA contamination: a 1% NaCl solution (0.2 µm filtered and UV treated) was used as sheath fluid (*S26*).

Heterotrophic protists were identified by the presence of Lysotracker fluorescence and absence of chlorophyll fluorescence. Side scatter was used to select protists <10 µm in diameter that were deposited into 96 well plates, with some wells dedicated to positive (10 cells/well) and negative controls (0 cells/well). All wells on the microplates contained 5 µL 1 x PBS (sample labels starting with MS584) or Lyse-N-Go (Pierce) (sample labels starting with MS609). Samples were centrifuged briefly and stored at -80ºC. Processing of a cell to generate a single cell amplified genome (SAG) using multiple displacement amplification (MDA) was done as previously described (*S25*). The PCR survey of the SAGs included 18S rDNA, actin, alpha-, and beta-tubulin all of which returned positive gene products. DNA from four picobiliphyte SAGs (MS584-5, MS584-11, MS584-22, and MS609-66) were re-amplified using the Repli-G midi kit (Qiagen) using the manufacturer's instructions. The products of the second MDA reaction were de-branched with S1 nuclease to reduce chimeric sequences during MDA (*S27*) and purified with a spin column (QIAquick PCR Purification Kit, Qiagen).

About 5 µg of genomic DNA derived from each SAG with the A260/280 ratio of 1.85 were used for shotgun sequencing with the GS-FLX Titanium platform (Roche) at the DNA Facility at the University of Iowa (http://dna-9.int-med.uiowa.edu/). One-quarter of a picotitre plate was used to generate sequence data from each picobiliphyte SAG resulting in over 230,000 reads per SAG. The individual sequence reads were assembled using *Celera* wgs-6.0 beta (see http://sourceforge.net/apps/mediawiki/wgs-assembler/index.php?title=Main_Page) using default settings (see table S3 for assembly output).

Thereafter about 10 μg of MDA-derived total DNA from MS584-11 and MS584-22 were each used to construct a library (sheared DNA fragments were of size 500 bp) for 100 bp x 100 bp paired-end sequencing using an Illumina GAIIx instrument in the Bhattacharya lab. Standard Illumina protocols (http://www.illumina.com/) were used to generate the library. We generated 29,286,431 reads totaling nearly 3 Gbp for MS584-11 and 68,757,098 reads totaling 9.5 Gbp for MS584-22. The MS584-11 Illumina data were co-assembled with the 454 reads from this SAG-using the proprietary software in *CLC Genomics Workbench* (http://www.clcbio.com/) resulting in 73,286 contigs with a total size 27.6 Mbp and a N50 of 638 bp. Assembly of only the Illumina data from MS584-22 using the *CLC Genomics Workbench* resulted in 74,660 contigs with a total size 29.4 Mbp and a N50 of 506 bp.

A local database was used to analyze the singletons and contigs resulting from the picobiliphyte 454-derived single cell genome assemblies. This database is described in Moustafa et al. (*S28*) and is composed of predicted and annotated proteins from RefSeq (Release 42), the genome of the red alga *Cyanidioschyzon merolae* (*S29*), diatom and green algal genomes available from the Joint Genome Institute, and partial EST data from protists such as dinoflagellates and cryptophytes available from other public repositories. The singleton analysis was done from each SAG 454 assembly to determine the phylogenetic origins of the unassembled reads. Using a BLASTx cut-off value of $E \leq 1e^{-10}$ and the database described above, we found hits to 14402, 17671, and 2244 singletons in MS584-5, MS584-11, and MS584 -22, respectively (list of singleton hits for each SAG available at http://dbdata.rutgers.edu/data/pico). BLASTx analysis with a threshold value of $E \leq 1e^{-5}$ identified 62, 3646, and 102 hits to mitochondrial DNA in the contigs of MS584-5, MS584-11, and MS584-22, respectively. Phylogenomic analysis was done as described in Moustafa et al. (*S28*). Resulting alignments were analyzed using PhyML (*S30*) with the approximate likelihood ratio test (aLRT) SH-like support values (*S31*) to infer ML trees under the WAG model. These trees were filtered with PhyloSort (*S32*) by searching for the monophyly of picobiliphytes with other eukaryotic and prokaryotic groups of interest with aLRT support score ≥0.90, or ≥0.70. For the trees presented in the main text paper we also used

RAxML (*S33*) with the WAG + Γ + I model of amino acid evolution to generate the trees. One hundred bootstrap replicates were used with RAxML, PhyML, or maximum parsimony (for rDNA) to assess the stability of nodes in these phylogenies (e.g., *S34*)

Figure Legends

Figure S1. Analysis of genome data from picobiliphyte SAGs. (A) The bar graphs on the left are the results of analysis of the taxonomic distribution of total and unique BLASTx hits for genes in eukaryotic phyla using as query the 454-derived singleton reads from each SAG assembly. The total number of singletons analyzed for MS584-5, MS584-11, and MS584-22 is shown. The pie charts on the right of the bar graphs show the total number of hits to viral or bacterial phyla. (B) Distribution of the total number of BLASTx hits to different ssDNA virus sequences using as query contigs derived from the assembly of 454 data from MS584-5.

Figure S2. Phylogeny of picobiliphyte sequences. (A) Maximum likelihood (RAxML) tree of Rep proteins from representative ssDNA viruses showing the phylogenetic position of the MS584-5 Rep. RAxML bootstrap values are above the branches and those derived from PhyML (when nodes are shared) are below the branches. Only bootstrap values ≥60% are shown. Circoviruses and their proposed sister group cycloviruses are in maroon text and nanoviruses in green. Rep from marine ssDNA viruses are shown in blue, whereas sequences derived from ocean metagenome data is in red. RW viruses are from reclaimed water, CB from Chesapeake Bay, and BCC from the coast of British Columbia. (B) Bayesian phylogeny inferred using a concatenated alignment (2594 aa) of the nuclear proteins actin, alpha-tubulin, beta-tubulin, heat shock protein 90, cytosolic heat shock protein 70, ribosomal protein L3, and 26S proteasome non-ATPase regulatory subunit. This is the most-likely tree derived from Phylobayes (V3.2e) analysis under the LG rate matrix (*S35*). Rates across sites were modeled under a Dirichlet process (*S36*). Four independent chains were run for 43,191 cycles each, until the mean discrepancy (meandiff) across all bipartitions was < 0.0015 (burnin = 20%). Bayesian posterior probability values are shown above the branches, whereas RAxML bootstrap values (when ≥60%) are shown below.

Figure S3. Maximum likelihood (PhyML) tree returned by the phylogenomics pipeline that shows members of the major facilitator superfamily (MFS) of membrane transporters. MFS proteins are single-polypeptide secondary carriers that facilitate the transport across cytoplasmic or internal membranes of a variety of small metabolites. The aLRT values (when ≥0.500) are shown at the branches. GenBank numbers are shown for each taxon. Viridiplantae are shown in green text, chromalveolates are shown in brown text, and Cyanobacteria in blue.

Table S1. Temperature, chlorophyll *a* (Chl), and microbe abundances (by flow cytometry) in the 25 July 2007 sample, compared to the 10-year average for week number 30 in Boothbay Harbor, ME. Abbreviations: HBac: heterotrophic bacteria, Syn: *Synechococcus*, PPROT: phototrophic protists (<20μm), Crypt: cryptophytes, HPROT: heterotrophic protists (<20μm).

Table S2. Results of rDNA analysis of SAG DNA generated using FACS-MDA. The SAG data shown in black text were derived from cells sorted using Lysotracker Green DND-26 to identify heterotrophs. The SAG data shown in green text were derived from cells sorted using chlorophyll autoflourescence to identify phototrophs. The SAG data shown in red text had intermediate autoflourescence levels. Note that picobiliphytes occur only in the heterotrophic fraction in these SAG data.

Table S3. Results of the *Celera* wgs-6.0 beta draft genome assembly using as input 454 pyrosequencing reads from SAGs MS584-5, MS584-11, and MS584-22.

Table S4. The number of protein sequences in our local database that was used for the BLASTx and phylogenomic analyses (based on phyla).

Table S5. Annotation of representative BLASTx hits to mtDNA and ptDNA (in gray background) using as query, translated 454-derived picobiliphyte genome contigs (utg [unitig] under *Celera*) from MS584-5, MS584-11, and MS584-22.

Table S6. BLASTx top hits to contigs derived from the MS584-22 Illumina assembly using the *CLC Genomics Workbench*. Proteins with plastid-encoded homologs in other taxa are shown with the green background and mitochondrial proteins with the red background.

Table S7. Results of the phylogenomic analysis of contigs generated from the assembly of 454+Illumina data from MS584-11. The putative proteins were predicted using BLASTx, which were then used as a query against our local database and the output analyzed with *PhyloSort* (*S9*) to identify the different monophyletic groups. A total of 5231 maximum likelihood (PhyML) trees were returned by the pipeline.

Table S8. Gene ontology (GO) annotations of the 1683 Stramenopiles proteins that grouped at aLRT≥0.70 (using PhyML) with proteins encoded on MS584-11 contigs (454+Illumina assembly). The maximum likelihood phylogenetic approach provides strong evidence that the Stramenopiles and picobiliphyte proteins are putative homologs.

Table S1. Temperature, chlorophyll *a* (Chl), and microbe abundances (by flow cytometry) in the 25 July 2007 sample, compared to the 10-year average for week number 30 in Boothbay Harbor, ME. Abbreviations: HBac: heterotrophic bacteria, Syn: *Synechococcus*, PPROT: phototrophic protists (<20µm), Crypt: cryptophytes, HPROT: heterotrophic protists (<20µm).

	Temp °C	Chl µgL^{-1}	Chl <20µm %	HBac mL^{-1}	Syn mL^{-1}	PPROT mL^{-1}	Crypt mL^{-1}	HPROT mL^{-1}
25-Jul-07	18.1	2.65	96.2	3.06×10^6	39825	30506	786	2219
Average	19.1	2.60	90.8	3.11×10^6	25256	37823	577	2689

Table S2. Results of rDNA analysis of SAG DNA generated using FACS-MDA. The SAG data shown in black text were derived from cells sorted using Lysotracker Green DND-26 to identify heterotrophs. The SAG data shown in green text were derived from cells sorted using chlorophyll autoflourescence to identify phototrophs. The SAG data shown in red text had intermediate autoflourescence levels. Note that picobiliphytes occur only in the heterotrophic fraction in these SAG data.

[1] The actual numbers of EST contigs are the numbers in this column divided by 6 due to six-frame translations.

[2] These data represent protein models from *Cyanidioschyzon merolae* and *Calliarthron tuberculosum*.

Table S5. Annotation of representative BLASTx hits to mtDNA and ptDNA (in gray background) using as query, translated picobiliphyte genome contigs (utg [unitig] under *Celera*) from MS584-5, MS584-11, and MS584-22.

Table S7. Results of the phylogenomic analysis of contigs generated from the assembly of 454+Illumina data from MS584-11. The putative proteins were predicted using BLASTx, which were then used as a query against our local database and the output analyzed with *PhyloSort* (*S9*) to identify the different monophyletic groups. A total of 5231 maximum likelihood (PhyML) trees were returned by the pipeline.

Taxonomic Affinity	**aLRT ≥ 0.90**	**aLRT ≥ 0.70**
Monophyly with Metazoa	538	670
Monophyly with Viridiplantae	338	480
Monophyly with Stramenopiles	335	479
Monophyly with Haptophyta	240	355
Monophyly with Alveolata	252	376
Monophyly with Choanoflagellida	158	228
Monophyly with Fungi	136	200
Monophyly with Excavata	93	179
Monophyly with Rhodophyta	43	91
Monophyly with Amoebozoa	57	105
Monophyly with Rhizaria	16	24
Monophyly with Cryptophyta	6	22
Monophyly with Glaucophyta	11	24
Monophyly with Opisthokonta	5	9
Monophyly with Proteobacteria	130	188
Monophyly with Bacteroidetes	69	81
Monophyly with Actinobacteria	39	53
Monophyly with Chlamydiae-Verrumicrobia	32	47
Monophyly with Firmicutes	35	47
Monophyly with Cyanobacteria	25	31
Monophyly with Planctomycetes	18	26
Monophyly with Chloroflexi	6	9
Nonophyly with Archaea	5	8
Monophyly with Fibrobacteres	2	3
Monophyly with Elusimicrobia	0	0

Table S8. Gene ontology (GO) annotations of the 1683 Stramenopiles proteins that grouped at aLRT≥0.70 (using PhyML) with proteins encoded on MS584-11 contigs (454+Illumina assembly). The maximum likelihood phylogenetic approach provides strong evidence that the Stramenopiles and picobiliphyte proteins are putative homologs.
