

# Solar Measurements for 21 cm Wavelength Using 3 m Radio Telescope

Uday E. Jallod\* and Kamal M. Abood

**Abstract**—Solar hydrogen line emission has been observed at the frequency of 1.42 GHz (21 cm wavelength) with 3 m radio telescope installed inside the University of Baghdad campus. Several measurements related to the sun have been conducted and computed from the radio telescope spectrometer. These measurements cover the solar brightness temperature, antenna temperature, solar radio flux, and the antenna gain of the radio telescope. The results demonstrate that the maximum antenna temperature, solar brightness temperature, and solar flux density are found to be 970 K, 49600 K, and 70 SFU respectively. These results show perfect correlation with recent published studies.

## 1. INTRODUCTION

Most of the radio data obtained from distant objects like stars, galaxies, pulsars, and quasars are useful for studying the universe. One of the important radio data is the hydrogen line emission at 21 cm wavelength, and this line has different applications in radio astrophysics [1]. This line arises from transitions between the hyperfine structure levels in the ground state of the hydrogen atom. A lot of radio emissions especially from the sun have been studied over decades [2]. Also, many empirical models have been proposed for the solar atmosphere based on spectral lines emissions using Very Large Array (VLA) [3]. Solar radio observations at frequency of 1.42 GHz (equivalent 21 cm wavelength) provides valuable information on the structure and dynamics of the solar atmosphere. At this frequency, we could measure the solar brightness temperature, solar radio flux, and understanding the basic of the physical processes operating in quiet and active regions of solar atmosphere [4]. Most of the solar radio waves originate from the chromosphere and corona. The propagation of these radio waves depends basically on the index of refraction in these layers. Each value of the index of refraction is related to an electron density and a critical frequency. If this frequency of the solar atmosphere below this critical frequency, then the propagation becomes impossible and vice versa [5].

One of the important issues is the solar brightness temperature at centimeter wavelengths measured by different technical methods. Since 1960, the first published studies determined the brightness temperature of the quiet sun at 21 cm wavelength. The technique that has been used for that study is an aerial system which consists of two long arrays, each made up of 32 steerable and spaced by 12.2 m apart on a 380 m base line [6]. In 1968, another paper measured the brightness temperature of quiet sun at centimeter, millimeter, and infrared wavelengths [7]. Solar observations were made with a single dish of 27 m diameter using frequency — agile receiver at 20 frequencies over the range 1.4 to 18 GHz by Zirin et al. [8]. Many authors have made compilations of the solar brightness temperatures at microwave and millimeter ranges by different observation techniques [9]. The development of the interferometry technique leads to recording the first solar radio image at Kit Peak National observatory using 21 cm wavelength [10].

Nowadays, solar radio physics is one of the most rapidly developing fields of astrophysics after developing the observational facilities such as Chinese Spectral Radio Heliograph (CSRH), Siberian Solar Radio Telescope (SSRT), and Atacama Large Millimeter/Submillimeter Array (ALMA) [11]. Other observing systems are used to observe solar radio emissions, and one of the most important observing systems is a broadband radio spectrometer. It plays an important role in observing and revealing the physical processes of the solar atmosphere. There are several solar broadband radio spectrometers running in the world, such as Phoenix at ETH Zurich (100–4000) MHz, Ondrejov Radio Spectrograph in the Czech Republic (800–5000) MHz, and Brazil broadband spectrometer (200–2500) MHz. All the above spectrometers are single dish telescopes which receive the radio emission of the full solar disk without spatial resolution [12].

## 2. METHODOLOGY

### 2.1. Theoretical Concepts

The Plank's law for blackbody radiation is given by [13]:

$$B = \frac{2hv^3}{c^2} \frac{1}{e^{hv/kT} - 1} \quad (1)$$

where  $B$  is the brightness (intensity of specific frequency) measured in ( $\text{W}/\text{m}^2/\text{Hz}/\text{rad}^2$ ),  $h$  the Planck's constant (Joule. second),  $v$  the frequency in Hz,  $k$  the Boltzmann constant (Joule/K),  $c$  the speed of light, and  $T$  the source temperature in K.

In the centimeter wavelengths regions ( $hv \ll kT$ ), this provides the Rayleigh-Jeans approximation for blackbody radiation at radio wavelength ( $\lambda$ ) [13]:

$$B = \frac{2KTv^2}{c^2} \frac{2kT}{\lambda^2} \quad (2)$$

The concept of the antenna temperature ( $T_A$ ) could be defined as the temperature of antenna radiation resistance, which equals resistance temperature.  $T_A$  is created due to the relation between the power radiated by the source, which is associated with the brightness temperature  $T_B$ , and the antenna normalized power pattern  $P(\theta, \Phi)$ . Consider a receiving antenna that is pointed at a source brightness distribution  $B(\theta, \Phi)$  when the source power radiated intercepted by the antenna terminals creates power called antenna power  $P_A$ .  $T_A$  is associated with  $P_A$  at antenna radiometer, and  $P_A$  could be given by [14]:

$$P_A = \frac{1}{2} A_e \int \int B(\theta, \Phi) P(\theta, \Phi) d\Omega \quad (3)$$

where  $(\theta, \Phi)$  are the azimuth and elevation of the source.  $A_e$  is the effective aperture of the radio telescope antenna, and  $d\Omega$  is the element solid angle. Utilizing Raleigh-Jeans limit. Therefore, the brightness distribution given by Eq. (3) can be changed by an equivalent  $T_B$ , and  $T_A$  can be given by the following equation [14]:

$$T_A = \frac{1}{2k} A_e \int \int T_B(\theta, \phi) P(\theta, \phi) d\Omega \quad (4)$$

This means that  $T_A$  is equivalent to the convolution between the source brightness temperature and beam power pattern of the radio telescope. Using the Nyquist theorem can introduce  $T_A$  by [15]:

$$T_A = \frac{P_A}{k\Delta v} \quad (5)$$

where  $\Delta v$  is the bandwidth frequency of the telescope radiometer in Hz.

In the case of the solid angle  $\Omega_s$  subtended by the source is much larger than the solid angle subtended by the antenna  $\Omega_A$ , and this leads to assuming that  $T_A$  is exactly equal to  $T_B$ . If the source does not completely fill the beamwidth, i.e.,  $\Omega_A \gg \Omega_s$ , the measured  $T_A$  will be less than  $T_B$ , then  $T_B$  is given by [15]:

$$T_B = \frac{\Omega_A}{\Omega_s} \Delta T_A \quad (6)$$

$\Delta T_A$  can be written as [16]:

$$\Delta T_A = T_{A_{on-source}} - T_{A_{off-source}} \tag{7}$$

Eq. (7) represents the subtraction between  $T_{A_{on-source}}$  due to the observed source and  $T_{A_{off-source}}$  due to the sky background.

For a discrete radio source of temperature  $T$  and a source solid angle  $\Omega_s$ , the source flux density ( $s$ ) in Rayleigh-Jeans limit is obtained by integration over the source  $\Omega_s$  [17]:

$$s = \int \frac{2kT_B v^2}{c^2} d\Omega \tag{8}$$

If  $T_B$  of the source is uniform across  $\Omega_s$ , this is reduced to [18]:

$$s = \frac{2kT_B}{\lambda^2} \Omega_s \tag{9}$$

The observed radio flux density of the source can be written in terms of  $T_A$  as [18]:

$$s = \frac{2kT_A}{\lambda^2} \Omega_A \tag{10}$$

Eq. (9) and Eq. (10) are equivalent.

Equation (10) can be written as:

$$s = \frac{2kT_A}{A_e} \tag{11}$$

The real observed solar flux density ( $s_o$ ) should subtract the contribution of the sky background ( $s_{sky}$ ) as given by [19]:

$$s_o = s_{\odot} - s_{sky} \tag{12}$$

where  $s_{\odot}$  is the flux density on the surface of the sun.

## 2.2. Observations and Data Reduction

The 3 m University of Baghdad radio telescope is used to observe the sun in this study. This telescope has focal length of 1 m, 5 degrees beamwidth, and 3.7 degrees of Half Power Beam Width (HPBW) which represents  $\Omega_A$  measured by sun drift scan technique [20]. Aperture efficiency of this telescope ( $\eta$ ) is (0.54) measured by observing Cassiopeia-A source [21]. First of all, any radio telescope should be calibrated before any process of observation. Our telescope has been calibrated using the sun and the moon as a reference source. This calibration is applied to two methods including antenna position and radio detector calibrations [22]. This telescope can make daily measurements of the radio signals at the frequency of 1.42 GHz. The spectrometer software of this telescope divides the received data into 600 channels of the frequency. These channels are used to obtain the amplitude of the measured power in unit (dBm). The values of this power are divided according to the frequency channels and arrangements as rows data. This power has been obtained after setting the optimum values of spectrometer parameters of the radio telescope. These parameters are span, sweep time, center frequency, Resolution Bandwidth (RBW), and Video Bandwidth (VBW).

The best solar observations are recorded using spectrometer parameters as listed in Table 1.

**Table 1.** Selecting spectrometer parameters values.

Source	Date	Local Time	Input Value of Spectrometer Parameters				
			Center Freq. (Hz)	Sweep Time (Sec.)	Span (Hz)	RBW (Hz)	VBW (Hz)
Sun	30-12-2018	12:02 Noon					
Noise Background	21-1-2019	6.06 Night	$1.42 \times 10^9$	30	$2 \times 10^7$	$10^5$	10

These values are chosen after many attempts. The telescope is pointed to the sun's position (azimuth = 179°, elevation = 33°). The observations are then recorded within 5 minutes to ensure that

the sun remains within the beamwidth. Sky background noise is estimated after the sunset (the sun is completely disappeared). This estimation is then subtracted from our observation in order to avoid unwanted noise error. It should be pointed out here that the sky background noise is also recorded within 5 minutes in order to maintain the signal and noise observations in the same size.

### 3. THE RESULTS AND DISCUSSIONS

Our telescope saves the observed radio data into a notepad sheet and then transferred to Excel. This sheet is imported to the MATLAB environment to implement many processes such as the conversion units of the observed power data, applying most equations that are listed in the theoretical section, and displaying the results. All the results of this article are plotted as a function of frequency in order to reveal the quality of the radio telescope at the center frequency of our detector (1.42 GHz).

Figures 1 and 2 demonstrate the received power as a function of frequency for the sun and sky background noise, respectively.

**Figure 1.** Received power (dBm) as a function of  $\nu$  (GHz) (date Dec. 30, 2018).

**Figure 2.** Received sky background power (dBm) and  $\nu$  (GHz) (date Jan. 21, 2019).

The center portion of Figure 1 is extracted, and a Gaussian function is then made to fit the observed data. The quality of fitting is verified by using Cross Correlation Coefficient ( $CCC$ ) criterion [23]:

$$CCC = \frac{\sigma_{xy}}{\sigma_x \sigma_y} \quad (13)$$

$$\sigma_{xy} = \frac{1}{N} \sum_{i=1}^N (x_i - m_x)(y_i - m_y) \tag{14}$$

where  $x$  and  $y$  represent the received power data and fitted data, respectively.  $\sigma_{xy}$  is the standard deviation for both real and fitted data.  $\sigma_x$  and  $\sigma_y$  are the standard deviations of the observed power data and fitted data, respectively.  $m_x$  is the mean value of the observed power data, and  $m_y$  is the mean value of the fitted data.  $N$  is the number of frequency channels (here  $N = 600$  channels).

The optimum value of  $CCC$  that verifies the fitting Gaussian function, shown in Figure 3, is found to be 0.799. This value shows high correlation between the observed and fitted data.

**Figure 3.** Real data (solid line) and its Gaussian fitting (o-).

The received powers for the sun and sky background are converted to the temperatures (K) via Eq. (5) using  $k = 1.38 \times 10^{-23}$  (Joule/K) and  $\Delta v = 2 \times 10^8$  Hz. The measured  $T_A$  due to the sky background is then subtracted from the measured  $T_A$  due to the sun via Eq. (7).

The results are shown in Figure 4.

**Figure 4.** (a)  $T_A$  (K) due to the sun as a function of  $\nu$  (GHz). (b)  $T_A$  (K) due to the background as a function of  $\nu$  (GHz). (c) The subtraction (b) from (a), and (d) logarithmic scale of (c).

The logarithmic scale is used to reduce the dynamic range between the values of  $T_A$  and gives more details about the behavior of the curve. A sharp transition reaches zero due to the subtraction which means that  $T_A$  for the sun and sky background are equal at this point, as shown in Figure 4(d).

$T_B$  is computed according to Eq. (6), using  $\Omega_s = 0.5^\circ$ ,  $\Omega_A = 3.7^\circ$ . The results are shown in Figure 5.

**Figure 5.** (a)  $T_B$  (K) as a function of  $\nu$  (GHz), (b) logarithmic scale of (a).

The observed solar flux density is computed in two units via Eq. (12). The first is the Solar Flux Unit (SFU), and the second is the Jansky (Jy). Using  $\text{SFU} = 10^4 \text{ Jy}$  or  $\text{SFU} = 10^{-22} \text{ W}\cdot\text{m}^{-2}\text{Hz}^{-1}$  and  $\text{Jy} = 10^{-26} \text{ W}\cdot\text{m}^{-2}\text{Hz}^{-1}$ .

The results are illustrated in Figure 6.

**Figure 6.** (a)  $s_o$  (SFU) as a function of  $\nu$  (GHz), (b)  $s_o$  (Jy) as a function of  $\nu$  (GHz).

These computed results are compared with Natural Resources Canada [24], Jodrell Bank Internet Observatory of Manchester University, and the values of  $T_A$ ,  $T_B$  are compared with MIT Haystack observatory reports [25].

Finally, the gain ( $G$ ) of the reflected parabolic antenna can be defined as the ability of the antenna to transform the available power at its input terminal to the radiated power. This quantity is used to measure the total power radiated by the antenna in practice. Our antenna gain is computed as follows [30]:

$$G = 10 \log_{10} \left[ \frac{4\pi A}{\lambda^2} \eta \right] \quad (15)$$

where  $A$  is the geometrical area of the radio telescope antenna ( $\text{m}^2$ ) for our telescope ( $A = 7.06 \text{ m}^2$ ), and  $\eta$  is the aperture efficiency.  $\eta$  can be obtained from the surface integral of the radiated power ( $p_r$ ) over the radiation sphere divided by the input power ( $p_o$ ).  $\eta$  is a measure of the relative power radiated by the antenna to the input power as given by [27]:

$$\eta = \frac{p_r}{p_o} \int_0^{2\pi} \int_0^\pi \frac{G(\theta, \phi)}{4\pi} d\Omega \quad (16)$$

and can be given as [27]:

$$\eta = \frac{A_e}{A} \quad (17)$$

The antenna gain against the frequency is computed according to Eq. (15) as shown in Figure 7.

**Figure 7.**  $G$  (dB) as a function of  $\nu$  (GHz).

$G$  is approximately constant with a little increment over the concentrated region of the frequency by the radio detector of our telescope.

#### 4. CONCLUSIONS

Several important points can be extracted from the results of this study.

1. The radio telescope spectrometer parameters are crucial parameters that control the observed signals. These parameters are considered primarily responsible for revealing the observed signal from the noise level. The best values of these parameters have been selected depending on empirical attempts, as displayed in Table 1.
2. Maximum value of  $T_A$  is 970 K. This value has been determined according to the strength measured power of the sun, as shown in Figure 4.
3. Total  $T_B$  profile has been measured and found to be equal to 49600 K. This value is computed from Figure 5 by taking the summation for all values of  $T_B$  inside  $\Omega_A$ .  $T_B$  value is considered very promising result because it is in a perfect correlation with recent published results.
4. Maximum of  $s_o$  is measured at a time of observation and found to be equal to 70 SFU or  $7 \times 10^5$  Jy according to the peaks shown in Figure 6.
5.  $G$  has a slight increment with the increment of the frequency and is approximately equal to 50.307 dB at 1.42 GHz as illustrated in Figure 7.

#### ACKNOWLEDGMENT

We would like to express our thank and gratitude to the head of the Department of Astronomy and Space, academic staff, colleagues and all friends at the College of Science, University of Baghdad for their valuable advices and encouragement.
