(Received 20 December 2005; revised manuscript received 24 January 2006; published 17 March 2006)

The controlled self-assembly of thiol stabilized gold nanocrystals in a mediating solvent and confined within mesoporous alumina was probed *in situ* with small angle x-ray scattering. The evolution of the self-assembly process was controlled reversibly via regulated changes in the amount of solvent condensed from an under-saturated vapor. Analysis indicated that the nanoparticles self-assembled into cylindrical monolayers within the porous template. Nanoparticle nearest-neighbor separation within the monolayer increased and the ordering decreased with the controlled addition of solvent. The process was reversible with the removal of solvent. Isotropic clusters of nanoparticles were also observed to form temporarily during desorption of the liquid solvent and disappeared upon complete removal of liquid. Measurements of the absorption and desorption of the solvent showed strong hysteresis upon thermal cycling. In addition, the capillary filling transition for the solvent in the nanoparticle-doped pores was shifted to larger chemical potential, relative to the liquid/vapor coexistence, by a factor of 4 as compared to the expected value for the same system without nanoparticles.

I. INTRODUCTION

Structures of self-assembled nanoparticles have been studied extensively in recent years for their unique catalytic, electronic, and optical properties. The geometry of self-assembled structures can vary from two-dimensional (2D) sheets of nanoparticles, to spherical monolayers or 1D nanowire arrangements.¹⁻⁵ Reduced dimensionality systems, in particular nanowires, have been of recent interest for their potential electronic and optical properties.^{4,6} There has been additional interest in quasi-one-dimensional structures, such as the arrangement of nanoparticles into cylindrical monolayers, for their similarity with biological systems such as some virus protein coatings and cell microtubules.^{7,8} Understanding the process of nanoparticle self-assembly in the different geometries can be vital to production of functional nanoscale structures. Recently there have been several experimental and theoretical studies that examine the nanoparticle self-assembly on flat surfaces via the evaporation of macroscopic droplets.^{1,2,9-13} One-dimensional systems typically require templates, thus bulk methods, such as droplet evaporation, are not possible. Recent studies of quasi-1D nanoparticle structures within cylindrical templates^{4,5,14-18} primarily probed the end product and did not explicitly measure the evolution of the self-assembly process. In order to investigate the self-assembly process itself within confined geometries, it is necessary to perform *in situ* experiments with precise control of the solvent amount, analogous to controlled evaporation of macroscopic droplets of nanoparticles on flat surfaces.

Here we describe *in situ* small angle x-ray scattering (SAXS) experiments that probed the solvent mediated self-

assembly of Au core, colloidal nanoparticles within nanoporous alumina. Experiments were carried out within an environmental chamber which allowed precise control over the amount of solvent condensed from vapor into the porous system. Analysis determined that the nanoparticles self-assembled into a cylindrical monolayer that evolved with the addition and removal of liquid. The evolution of this cylindrical monolayer structure was completely reversible upon removal of liquid, albeit with strong hysteresis typical in capillary systems. In addition to the cylindrical monolayer, isotropic clusters temporarily formed during desorption of the liquid. These clusters disappeared upon complete removal of the liquid from the pores.

II. EXPERIMENTAL

Anodized alumina membranes were electrochemically prepared using a two-step anodization technique described elsewhere.¹⁹⁻²¹ The aluminum backing layer was then dissolved in HgCl₂. Pores were opened by floating on phosphoric acid followed by thorough rinsing in deionized water. The resultant alumina membrane consisted of a dense matrix of pores running completely through the membrane and perpendicular to its surface. The long axes of the pores were parallel and arranged in a 2D powderlike arrangement with local hexagonal packing. Nearest-neighbor distances (center to center) of 63 ± 2 nm were determined via x-ray scattering. This is consistent with electron microscopy of similarly prepared samples (see Fig. 1). Alumina nanopores were 29 ± 4 nm in diameter (from TEM). The macroscopic dimensions of the nanoporous membrane were about $1 \text{ cm} \times 1 \text{ cm} \times 90$ microns.

FIG. 1. (Left) SEM image shows well ordered hexagonal packing of alumina nanopores prepared under similar conditions to samples used for x-ray experiments. (Right) Bright-field TEM image of the nanoparticles (arrow) on the wall (faint diagonal lines) of alumina pores. The nanoparticles are Au core with octane-thiol coating. Cross sections were prepared by the ultra-microtome method from the sample used for x-ray experiments.

Nanoporous alumina membranes were further cleaned in solvents to remove organic impurities, with 15 min ultrasonic baths in each of the following (in order): HPLC grade chloroform, 99.7% pure acetone, HPLC grade methanol, and HPLC grade toluene. The membrane was then allowed to soak in HPLC grade toluene for 24 h to remove any further impurities. After soaking, the membrane was transferred without drying to 2 ml of a 2.26 mg/ml solution of octane-thiol (OT) stabilized Au-core nanocrystals^{22,23} in HPLC grade toluene for two weeks at 25 °C. Fits of SAXS data from bulk scattering of a dilute suspension of the same solution of nanoparticles used in doping the nanopores yielded $R_s=1.2$ nm and $\Delta_R=0.16$ nm giving a polydispersity of $\Delta_R/R_s=13\%$. Since the electron density of the Au core is much higher than the organic ligands, R_s was primarily a measure of the core radius.

The nanoparticle solution was drawn into the alumina pores via capillary forces.^{4,5} The initial concentration (and volume) of the nanoparticle solution was chosen such that the total number of particles in the initial solution was about 2–3 times the number of nanoparticles needed to form a complete monolayer of nanoparticles along the walls of the pores (assuming hexagonal close packing), but less than that required for complete volume filling of the pores. In addition to soaking, the solution with the immersed membrane was placed in an ultrasonic bath for 15 min per day to facilitate movement of the particles into the membrane. The long time period and frequent ultrasonic baths were imposed to ensure maximal integration of nanoparticles into the porous membranes.

After 24 h in solution the alumina membrane color changed from clear to dark red color, similar to the solution color. This was an indication that nanoparticles had been absorbed into the membrane. The presence of nanoparticles in the pores was confirmed with cross-sectional TEM of the sample (see Fig. 1). No further color changes of the membrane were observed. Additionally, no significant color change of the solution was observed, indicating that some particles were left in the solution. The sample was then removed from the solution and allowed to dry in air for five minutes before being loaded into an environmental chamber^{24,25} (see Fig. 2) for the SAXS experiment.

FIG. 2. Schematic of the environmental chamber used for *in situ* x-ray experiments. The outer (inner) cell was kept at 28 °C (32 °C) during the experiment. The sample temperature T_s was controlled independently from the inner cell and liquid solvent reservoir temperature T_r . The sample was mounted in a transmission geometry where the long axis of the pores can be rotated (θ_s) in the horizontal plane. The $\Delta T=T_s-T_r$ was controlled to vary liquid condensation on the sample via the vapor.

Prior to sample mounting, all components of the inner cell of the environmental chamber were cleaned with solvents: 15 min ultrasonic baths of each of HPLC grade chloroform, 99.7% pure acetone, and HPLC grade methanol. During the x-ray experiment the inner cell was hermetically sealed and the temperatures of the inner and outer cells were kept at $T_{in}=32.0\pm 0.5$ °C and $T_{out}=28.0\pm 0.5$ °C, respectively. The actual temperature stability during each measurement was better than ± 50 mK, though the temperature of the cells did vary ± 0.5 K between different measurements due to the differing heat loads on the sample as described below (see the description of ΔT). The sample mounting block was thermally isolated to a high degree from the walls of the inner cell with independent thermal control via a heater on the mounting block. All temperatures were continuously monitored with YSI No. 44108 thermistors. A liquid solvent reservoir was created by injecting 5 ml of HPLC grade liquid toluene into the inner cell. Solvent condensation in the sample was precisely controlled via the (positive) offset between the sample temperature T_s and the liquid solvent reservoir temperature T_r : $\Delta T=T_s-T_r$.^{24,25} The chemical potential offset (from the liquid/vapor coexistence) is given by $\Delta\mu\approx H_{vap}\Delta T/T_r$. Here, $H_{vap}=38.06$ kJ/mol is the heat of vaporization of toluene²⁶ and T_r was kept constant throughout the experiment (as described above) via temperature control of the inner cell. Liquid was injected into the cell at $\Delta T\approx 3$ K. Since ΔT could be varied from about 50 mK up to 30 K, the corresponding $\Delta\mu$ could be varied about four orders of magnitude. As ΔT and thus $\Delta\mu$ decreased the amount of condensed solvent increased. Likewise, solvent was removed by increasing ΔT . In this experiment, the pores became saturated with liquid for all $\Delta T<4$ K, thus the experimental range of ΔT probed was only $0.5\text{ K}<\Delta T<30\text{ K}$.

FIG. 3. Geometry for SAXS measurements: X rays were incident at $\theta_s=10^\circ$ from normal to the nanopore long axis. Scattered intensity was measured with a fixed position CCD detector downstream. The \vec{m} and \vec{q} describe the coordinate space and wave vector transfer of the nanopore, respectively. Note that the geometry shown here has been rotated about the incident beam by 90° for clarity.

After injecting small angle scattering was measured at the extremes $\Delta T=0.5, 30$ K and found to be reproducible. The full scattering was then measured stepwise from $\Delta T=30$ K. X rays were allowed to pass through the chamber via 0.02 mm Kapton© (Dupont) windows on the outer chamber and 0.005 in. thick beryllium windows on the inner chamber.

III. SMALL ANGLE X-RAY SCATTERING

In situ x-ray measurements were carried out at the SAXS facility at ChemMatCARS beamline at the Advanced Photon Source (Argonne National Lab, Argonne, IL). The incident x-ray energy of 11.55 keV was well below the $L3$ absorption edge of Au (11.92 keV) to avoid fluorescence. The sample chamber was mounted on a goniometer in a transmission geometry with two degrees of rotational freedom—sample rotation and tilt—plus the standard three translations. The sample rotation was done internally and allowed rotation angles θ_s of the sample with respect to the incident beam in excess of $\pm 90^\circ$ (see Fig. 2). A fixed position geometry CCD detector measured the SAXS intensity at a camera length L of 1880 mm downstream from the sample. Powder diffraction rings were seen at small angles due to the 2D hexagonal packing of the nanopores. Sample alignment was performed with the membrane nearly perpendicular to the incident beam and thus the pores were parallel to the incident beam. The sample rotation and tilt were adjusted to maximize the symmetry of the diffraction rings in both the vertical and horizontal directions. After alignment, the membrane was exactly perpendicular to the incident beam and the long axes of the pores were parallel to the incident beam. This defined $\theta_s=90^\circ$ between the incident beam and the short axis of the pores. The membrane was then rotated to $\theta_s=10\pm 1^\circ$ from the incident beam, i.e., the pore long axis was then at 80° to the incident x rays (see Fig. 3). This geometry allowed a bulk measurement of the nanoparticle/nanopore system while maximizing the wave vector transfer along the nanopore long axis q_z that was probed.

It is important to note that the geometry shown in Fig. 3 is rotated by 90° about the incident beam for ease of viewing. In the figure, the long axis of the pores is depicted as approximately perpendicular to the incident beam and vertical

FIG. 4. (Main) Volume adsorption (Δ, \square) / desorption (\circ) curves as a function of ΔT . Dashed lines are added as a guide for the eye. Note the strong hysteresis upon cycling. Vertical dotted lines indicate location of capillary transition for empty (no nanoparticles) pores predicted by the Kelvin equation $\Delta\mu \sim \gamma/\rho R_c$. Data are normalized to the liquid saturation volume of the pores. (Inset) Plot showing the powder diffraction peaks from the 2D nanopore packing. Volume information was extracted from the first peak (the $\langle 10 \rangle$).

with rotations θ_s in the vertical plane. In the actual experiment, the only difference was that the long axis of the pore was horizontal (though still perpendicular to the incident beam) and rotations θ_s were done in the horizontal plane.

IV. VOLUME OF ADSORBED SOLVENT

A measure of absorbed volume of solvent in the pores was calculated from the small angle powder-diffraction peaks mentioned above. As liquid was condensed into the pores, the electron density contrast in the pores decreased relative to that of the dry pores, thus reducing the scattering intensity of the diffraction peaks $I_{\text{peak}}(\Delta T)$ relative to the dry peaks $I_{\text{peak}}(\text{dry})$. Neglecting absorption corrections, the added solvent volume V_{liq} was then approximately determined from the lowest order peak (small angle approximation) via²⁷

$$V_{\text{liq}}(\Delta T) \propto \sqrt{I_{\text{peak}}(\text{dry})} - \sqrt{I_{\text{peak}}(\Delta T)}. \quad (1)$$

Plots of the added volume derived from the $\langle 10 \rangle$ diffraction peak are shown in Fig. 4. The data represent three different thermal cycles: two cooling cycles (large ΔT to small ΔT) and one heating cycle. The data have been normalized to the saturated (pores completely filled with liquid) volume for each curve. There are two main features in this figure: the first is the presence of a sharp transition (from low relative volume to saturation and reverse) for both adsorption and desorption curves and second, there is a marked hysteresis which is reproducible (at least for the cooling cycle). For both sets of curves, the nanopore-nanoparticle system is saturated with toluene for $\Delta T \leq 4$ K and has negligible amounts of toluene for $\Delta T \geq 30$ K. These two regions will be referred to throughout the rest of the paper as the “saturated” and “dry” regions, respectively.

The simplest theory to describe the observed capillary transition is the Kelvin equation

$$\Delta\mu_{\text{adsorption}} \approx \frac{\gamma}{n_l R_c}, \quad (2)$$

$$\Delta\mu_{\text{desorption}} \approx \frac{2\gamma}{n_l R_c}, \quad (3)$$

where R_c is the cylindrical nanopore radius, $\gamma=28.4$ mN/m is the surface tension of bulk toluene, and $n_l=\rho/m_{\text{wt}}=9 \times 10^{-3}$ moles/cm³ (mass density divided by molecular weight) is the molar density of the toluene. The chemical potential at the capillary transition for the adsorption and desorption differ by a factor of 2 due to different physical mechanisms for adsorption and desorption. Pores are expected to fill by coaxial film growth (curvature of $1/R_c$) and empty from the ends of the pores via a spherical meniscus (curvature of $2/R_c$) that travels the length of the pore.²⁸ This argument provides a motivation for the presence of the hysteresis, even though the system studied is clearly more complicated due to the presence of the nanoparticles. According to the Kelvin equation, the observed capillary filling transition in Fig. 4 would indicate an effective radius for the pores of about 4 nm, almost a factor of 4 smaller than the actual pore radius of 15 nm. For similar nanoporous alumina samples with no nanoparticles, it was found that the Kelvin equation provides a good prediction of the capillary transition.²⁹ Significantly higher values of ΔT for the capillary transition indicated that there was a real reduction in the effective radius of the pores due to the presence of the nanoparticles. Assuming a monolayer thickness due to the nanoparticles of 2.4 nm for the Au core plus 1.2 nm \times 2 for the organic OT shell³⁰ \approx 5 nm, this would bring the effective radius down to about 10 nm. Additionally, roughness from the nanoparticle monolayer surface contributes to the transition shift by increasing the amount of adsorbed liquid at large ΔT .³¹

V. NANOPARTICLE-NANOPARTICLE SCATTERING

A. Elliptical transforms

In addition to the low angle powder diffraction from the 2D hexagonal pore packing, a ringlike structure was observed at larger angles ($q \approx 0.18 \text{ \AA}^{-1}$, see Fig. 5), which corresponds to nanoparticle interference scattering and contains information about the local packing structure. This scattering ring underwent dramatic changes with the gradual addition, and subsequent removal, of liquid solvent in the pores (see Fig. 6). No sharp diffraction spots were observed upon rotation of the sample through 90° about the short axis of the pore, indicating that the nanoparticle packing must be powderlike with only short-range order.

To interpret these particle-particle scattering results, it was necessary to transform the scattering intensity from lab (CCD detector) coordinates into the coordinates relative to the nanopore axis as shown in Fig. 5. The transform is given by the constraints of the scattering geometry (see Fig. 3). The wave vector transfer $\vec{Q}=[Q_x, Q_y, Q_z]$ is

FIG. 5. (Color) (Left) Schematic of elliptical transforms of scattering intensity data. Lines of constant q_r are ellipses in CCD coordinates where the scattering (CCD) plane intersects the cylindrical surfaces of constant q_r . (Right top) CCD image of scattering intensity (linear scale) at $\Delta T=30$ K. The direct beam is in the lower left corner. The triangular region here is due to an attenuator used to block the intense pore-pore scattering at low q . (Right bottom) The same data set transformed to the \vec{q} coordinates relative to the nanopore axis.

$$\vec{Q} = \vec{k}_{\text{inc}} - \vec{k}_{\text{scatt}} \quad (4)$$

$$= \frac{k}{\sqrt{x^2 + z^2 + L^2}} [x, L - \sqrt{x^2 + z^2 + L^2}, z] \quad (5)$$

$$\approx \frac{k}{L} [x, 0, z]; \quad L \gg r. \quad (6)$$

Transforming to coordinates of the nanopore (here we use \vec{q} , lowercase for clarity), for $\theta_s \ll \pi/2$:

$$q_z = \frac{\vec{q} \cdot \vec{m}_z}{|m_z|^2} \approx \frac{kz \cos \theta_s}{L}, \quad (7)$$

$$q_y = \frac{\vec{q} \cdot \vec{m}_y}{|m_y|^2} \approx \frac{kz \sin \theta_s}{L}, \quad (8)$$

$$q_x = \frac{\vec{q} \cdot \vec{m}_x}{|m_x|^2} \approx \frac{kx}{L}, \quad (9)$$

$$q_r \approx \frac{k\sqrt{x^2 + z^2 \sin^2 \theta_s}}{L}, \quad L \gg r, z \gg \Delta \cot \theta_s. \quad (10)$$

Here, $\vec{x}=[x, y, z]$ ($|\vec{x}|=r$) and $\vec{m}=[m_x, m_y, m_z]$ are the Cartesian coordinates of the CCD detector (lab) and nanopore, respectively, and $\Delta=\sqrt{x^2+z^2+L^2}$. The wave vector transfer in the pore coordinates is denoted \vec{q} , with magnitude $k=2\pi/\lambda$. In the above approximation, the intersection of the cylindrical surfaces of constant q_r , and the CCD plane, are ellipses.

FIG. 6. (Color) Scattering intensity distributions at four representative ΔT . Data (intensity log scale) were background subtracted, then tiled into all quadrants to simulate a full ring. (Top left) Data from $\Delta T=30$ K (dry): the scattering intensity is an asymmetric ring structure from particle-particle scattering. (Top right) Data from $\Delta T=8$ K (adsorption curve): note the ring is broader with a smaller radius. (Bottom right) Data from $\Delta T=6$ K (saturated with liquid): here the ring is even broader with an even smaller radius. (Bottom left) Data from $\Delta T=12.4$ K (desorption curve): note the presence of an isotropic scattering ring just inside the asymmetric ring.

Figure 5 shows typical scattering intensity data (upper right) from $\Delta T=30$ K (dry pores). The scattering intensity is transformed into the q_z, q_r coordinates of the nanopore (lower right). The transform excludes data up to $\theta_s=10^\circ$ from the q_z axis (aligned along the nanopore long axis) as a result of the incident angle of the x rays to the pore axis. Images were taken with the detector off center to maximize the recorded q range. The triangular region at low q is a result of an attenuator necessary to reduce the intense scattering of the powder diffraction peaks associated with the hexagonal pore-pore packing. The intense scattering concentrated along the q_r axis was mainly a result of scattering described by the pore form factor which is narrow in q_z due to the length of the pores.

The intensity distribution along the nanoparticle scattering ring changed significantly with ΔT . For the dry pores, $\Delta T=30$ K (Fig. 6, upper left) a sharp, strongly asymmetric ring was present, brighter near the q_z axis than the q_r axis. Here the data have been tiled to all four quadrants to simulate the full ring for ease of viewing. The strong feature along the q_r axis was due to the sum of the scattering of the individual pores. The ring asymmetry indicates a structure that is preferentially aligned along the nanopore axis. A model to explain this scattering will be presented in the next section. As liquid was added to the pores (adsorption curve) there was a general trend that the ring became broader and its radius decreased (see Fig. 6, $\Delta T=30$ K \rightarrow 8 K \rightarrow 6 K). This was an indication that the nanoparticle nearest neighbor spacing had increased and the ordering was reduced in comparison with that of the dry case. Upon gradual removal of the liquid (desorption curve) there was a qualitatively different feature that appeared (see Fig. 6, lower left, $\Delta T=12.4$ K). For this value of ΔT , the inner portion of the asymmetric ring was nearly isotropic. This isotropic scattering was an indication of an additional structure of nanoparticle aggregates or clus-

ters. With removal of nearly all of the liquid achieved at the highest ΔT , the scattering again showed a sharp, well defined, asymmetric ring (almost identical to Fig. 6, upper left, $\Delta T=30$ K), indicating that the self-assembly was reversible. The formation of the clusters indicated that there was a form of hysteresis in the self-assembly process as well as in liquid adsorption and desorption.

B. Nanoparticle tiling model

We propose in this section a simple model to describe the scattering from monolayers of Au nanoparticles along the walls of the cylindrical nanopores. Motivation for a self-assembled cylindrical monolayer comes from analogy with self-assembled nanoparticle monolayers on flat substrates¹ and the attractive van der Waals (vdW) forces between the particles and between the particles and the walls of the nanopore. In the Derjaguin approximation, where the separation D is much less than the nanoparticle Au-core radius R_s , the vdW forces between neighboring nanoparticles F_{np-np} and between a nanoparticle and the alumina pore wall $F_{np-wall}$ are^{12,32}

$$F_{np-np} = \frac{A_{nn}R_s}{12D^2}, \quad (11)$$

$$F_{np-wall} = \frac{A_{nw}R_s}{6D^2}. \quad (12)$$

Here, A_{nn} and A_{nw} are the Hamaker constants for the nanoparticle-nanoparticle interaction and nanoparticle-nanopore wall, respectively. The Hamaker constants are reduced in the presence of a mediating solvent, but the forces remain attractive. Steric repulsions, due to the OT coating, prevent irreversible nanoparticle aggregation. The attractive

vdW forces are expected to partially confine the particles to remain in a monolayer near the walls of the pores. Though the interparticle ordering within the monolayer lacks long-range crystalline order theoretically predicted for polydispersity $<5-10\%$, the packing is expected to exhibit glasslike short-range order up to polydispersities of $\sim 25\%$ where size segregation issues become important.^{33,34} Pore wall roughness is expected to further reduce interparticle ordering via geometric constraints, though since the roughness is much less than the average particle size (see Fig. 1) the effect is minimal. The lack of strong diffraction peaks confirmed that the nanoparticle order was short range only.

There were two distinct length scales involved, the nanoparticle diameter and the nanopore diameter, that differ by an order of magnitude ($\sim 3\text{ nm} - \sim 30\text{ nm}$). Thus, there were two independent scattering regimes: one for low angles $qR_c \lesssim 1$ and another for higher angles $qR_s \gtrsim 1$ where R_s is the average nanoparticle core radius and R_c is the average nanopore radius. For the low angle scattering, which has already been discussed above in the context of added liquid volume, the scattering due to interference from neighboring nanoparticles was ignored for this reason. For the scattering at higher angles, the structure factor associated with the nanopore packing should have decayed to approximately unity (since any pore-pore ordering must be short range in 2D). This high- q regime may then be written as the sum of scattering from the pores (as in the low- q region, but where now the structure factor is unity) plus a term that describes the local particle-particle scattering. The scattered intensity in the two regimes is given by

$$I(q) \approx |S_p(q)[F_s(q) + F_p(q)]|^2, \quad qR_c \lesssim 1, \quad (13)$$

$$I(q) \approx |F_p(q) + S_{np}(q)F_{np}(q)|^2, \quad qR_s \gtrsim 1. \quad (14)$$

Here, S_p and S_{np} are the structure factors associated with the local packing of the nanopores and the nanoparticles, respectively. F_p , F_s , and F_{np} are the form factors associated with the scattering from the nanopores, an average nanoparticle monolayer, and individual nanoparticles, respectively. Since the nanopores are about four orders of magnitude longer than their diameter, the scattering associated with them will occur at small q_z . With the pores almost perpendicular to the direct beam, the intersection of this scattering with the image plane will be such that scattering associated with the pores will be only along the q_r axis. The scattering associated with the form factor of the pores is complicated by polydispersity, roughness and the presence of liquid, thus it is treated only as background scattering for this analysis. Strong scattering away from the q_r axis must then be attributed to nanoparticle-nanoparticle scattering. Thus away from the q_r axis, we may treat the second term in Eq. (14) as dominant and the first term (and cross term) as a background.

The nanoparticle form factor is described by

$$|F_{np}|^2 \propto G(q, R_s, \Delta_R), \quad (15)$$

where $G(q, R_s, \Delta_R)$ is given by the Schulz distribution³⁵ for polydisperse spheres with radius R_s and Δ_R defined as the root mean square deviation. For $qR_s \lesssim 1$, the nanoparticle form factor is given by the Guinier Law³⁶

FIG. 7. (Left) Schematic of the tiling of the cylindrical nanoparticle monolayer. The monolayer is broken up into small regions, or tiles, which are approximately flat. The scattering is then powder averaged over all tiles at a given orientation ϕ from all pores. The total scattering is a sum over all such orientations $\phi \in [0, 2\pi]$. The azimuthal angle is ψ (not to be confused with the sample rotation angle θ_s).

$$G(q) \approx \exp(-q^2 R_s^2/5). \quad (16)$$

A “tiling” model for calculating $S_{np}(q)$, valid for $qR_s \gtrsim 1$ is explored below. To model the nanoparticle structure factor for high q (where nanoparticle-nanoparticle interference scattering dominates), the monolayer of particles was broken up into small regions, or tiles, that were approximately flat, as shown in Fig. 7. The approximation was made that the scattering between individual tiles was independent and that the radius of curvature of the pore is large compared with the interparticle distance. The first approximation is valid when the dimensions of the tiles are on the order of the average correlation length (order parameter) ξ within the tile or smaller.

The scattering was then powder-averaged over all tiles of a given orientation ϕ . Thus the scattering intensity from a particular set of tiles at a given ϕ was approximately the same as the powder-averaged scattering from a flat monolayer of nanoparticles with an order parameter ξ , and nanoparticle nearest neighbor separation d_{NN} . A (mathematically) simple Lorentzian model was used to approximate the structure factor S^ϕ for each of these orientations:

$$\begin{aligned} |S_{np}^\phi(q, \phi, \psi)|^2 & \\ \approx & \frac{I_0 \xi}{1 + \xi^2 \{q \sqrt{[\cos(\psi) - \cos(\phi)\sin(\psi)] - 2\pi/d_{NN}}\}^2}. \end{aligned} \quad (17)$$

Here I_0 is an adjustable scale parameter with I_0/d_{NN} being proportional to the number of scatters and ψ is the azimuthal angle relative to the long axis of the nanopore (not to be confused with the sample rotation θ_s). Note that if $\xi > d_{NN}$ then ξ may be thought of as the correlation length within the tiles, along the walls of the pore. For $\xi \leq d_{NN}$ then the particles are better described as a 2D dilute, gaslike phase. This analysis only considered the first-order peak due to the q range of this experiment, but higher orders would be treated similarly. The total structure factor S_{np} can be calculated by integrating over all ϕ :

FIG. 8. (Color) (Right top) Schematic of representative radial slices (dashed lines) taken for fitting with the tile model with $\psi_1 = 11 \times n^\circ$, n an integer from 1 to 7. (Left) Data (\square) at $\Delta T = 30$ K from each slice (color coded with dashed lines) along with fits (solid lines) from the tile model plus independent monotonically decaying, positive backgrounds. Error bars are smaller than data symbols. (Bottom right) Data (all at $\psi_1 = 11^\circ$) from four different ΔT : $\square = 30$ K, $\triangle = 8$ K (adsorption), $\diamond = 4.4$ K (saturated), and $\circ = 12.4$ K (desorption); solid lines are fits. $\Delta T = 12.4$ K is qualitatively different and requires an isotropic component in addition to the tile model to fit properly.

$$|S_{np}(q, \psi)|^2 = \int_0^{2\pi} |S_{np}^\phi(q, \phi, \psi)|^2 d\phi. \quad (18)$$

The above structure factor, along with the nanoparticle form factor given by the Schulz distribution, was used to fit the high q data of the Au-core nanoparticles in the nanoporous alumina. The CCD data were first flat-field corrected, then background (taken with the sample rotated out of the beam) was subtracted to account for scattering from our environmental chamber windows plus scattering from the toluene vapor. The data were then transformed into the q_r, q_z coordinates of the nanopore as described above. All of the data sets (at different ΔT) fit well with the above described tile model with a monotonic decaying background (which included scattering from both the porous membrane and the liquid) with the exception of the data at $\Delta T = 12.4$ K (desorption curve) where an additional isotropic scattering term was necessary for good agreement. This cross section of the isotropic scattering ring was fit using a Lorentzian with similar parameters as for the monolayer (ξ, I_0 , and d_{NN}). For this model, the number of scatters should be proportional to I_0/d_{NN}^2 .

For each data set of a given ΔT , a series of representative radial slices was chosen at $\psi_n = 11 \times n^\circ$ from the q_z axis (n an integer from one to seven), and intensity as a function of q was graphed for each slice (see Fig. 8). Each radial slice was fitted independently with the tiling model plus a monotonically decaying background. As stated above, the main contribution to the background was from the nanopore membrane which increased as ψ_n approached 90° . This was seen in the fits and thus a slice at 88° was not used due to the fact

FIG. 9. Plots of the “best fit” tile model (\circ) and isotropic (\blacksquare) parameters and uncertainties as a function of ΔT (data to the left of zero are from adsorption curves, to the right are from desorption curves). The physical parameters are (top to bottom): number of scatters $\propto I_0/d_{NN}$, nearest neighbor spacing d_{NN} , and order parameter ξ . Lines are added as a guide to the eye.

that the background was greater than the particle-particle scattering. After fitting all of the slices independently, average parameters and uncertainties for each ΔT were calculated from the mean and standard deviation of each of the three fit parameters I_0 , ξ , and d_{NN} . Since the uncertainties were small in comparison to the average value of the parameter, the average parameters were treated as “best fit” or global parameters for each ΔT .

The three “best fit” parameters from the tiling model as a function of ΔT are plotted with uncertainties in Fig. 9. Also plotted in each of the three plots are the parameters from the isotropic component at $\Delta T = 12.4$ K (\blacksquare). The ΔT axis is read from left to right; to the left of zero are adsorption (cooling) data, to the right of zero are desorption (heating) data.

The data indicated that the number of nanoparticles in the monolayer, probed by the scattering volume, remained constant as liquid was added and subsequently removed (see Fig. 9, top) with the exception of $\Delta T = 12.4$ K where an additional isotropic component was necessary. For this data point, the number of particles in the monolayer decreased. It is likely that some of the missing particles went into the formation of the isotropic clusters. The fact that this data point is higher than the average monolayer number might indicate that the clusters fill the pore volume more effectively than the particles in the monolayer and that some particles from the ends of the pores may have been temporarily dragged into the volume.

The formation of these clusters is a surprising phenomenon. Additional isotropic scattering was seen only during desorption and then disappeared upon removal of additional

liquid. The formation of clusters, or aggregates may have been linked to the progression of a spherical meniscus through the pores, starting from the ends.²⁸ As the meniscus traveled through the pore, it would tend to drag particles with it. Another possibility would be the formation of bubbles within the liquid. Upon complete removal of liquid from the system these clusters would dissolve and reassemble into a monolayer structure on the nanopore wall. This is indicated in the data by the disappearance of the isotropic scattering as ΔT is increased.

The plots in Fig. 9, middle and bottom, demonstrate that with the addition of liquid there was a shift to larger nearest neighbor separation distance with a maximum of 4.5 nm (compared to 3.6 nm for dry), accompanied by a decrease in the order (in the plane of the cylindrical monolayer). Upon removal of the liquid solvent, the particle separation decreased again to the dry value, and the ordering increased back to almost the initial dry value. For relative added liquid solvent volume amounts up to about 0.5 (normalized to saturation; see Figs. 4 and 9) the order parameter was about twice that of the nearest neighbor spacing and may be interpreted as an in-plane correlation length. For higher relative amounts of solvent $V_{\text{liq}} > 0.5$, the order parameter was less than the nearest neighbor spacing, indicating a 2D dilute gas-like phase.

The value of 3.6 nm for the nearest neighbor spacing for the dry system (large $\Delta T = 30$ K) was less than $2(R_s + t_{\text{OT}}) \approx 4.8$ nm, where $t_{\text{OT}} \approx 1.2$ nm is the thickness of the OT shell, indicating interdigitation of the shell ligands of neighboring particles. As liquid was absorbed into the organic shells (with decreasing ΔT) the vdW attraction between nanoparticles would decrease^{12,13} relative to the dry system, while the osmotic pressure³⁷ between the ligand chains increased, driving the particles apart. This separation increase may have been further facilitated by gaps or voids in monolayer coverage. As liquid filled these gaps, the nanoparticles (undergoing thermal motion) could move into this new volume. Removal of the liquid by increasing ΔT reduced the repulsive osmotic pressure between the particles and increased the attractive vdW forces, reducing the particle-particle separation.

VI. CONCLUSIONS

Low angle measurements established the relative amount of liquid in the nanopores as a function of ΔT . A capillary filling transition occurred between 8 and 12 K, which was about four times less saturation than what is expected via the Kelvin equation for toluene absorption in pores with no nanoparticles. In addition to the shift, marked hysteresis was also observed.

Fits to the data indicated that the nanoparticles assembled in a cylindrical monolayer aligned along the pore. From the geometry of this structure we conclude that the particles were near the walls, which was physically sensible due to the vdW attraction of the nanoparticles to the nanopore wall. As liquid was added by reducing the relative chemical potential $\Delta\mu$, most of the particles remained in the monolayer structure. Also, the nearest neighbor separation distance increased and the correlation length within the monolayer decreased. The process was reversible: upon removal of the liquid, the nanoparticle nearest neighbor distance decreased to the initial dry value and the ordering increased to almost the dry value.

In addition to the cylindrical monolayer, there was evidence of the formation of isotropic clusters during desorption of the liquid solvent. This phenomenon could have been related to the process by which the liquid emptied from the pore, namely that it was likely to occur from the ends of the pores. This might also explain why this structure was not seen during the adsorption cycle.
