Abstract

This paper reviews some recent developments in digital currency, focusing on platform-sponsored currencies such as Facebook Credits. In a model of platform management, we find that it will not likely be profitable for such currencies to expand to become fully convertible competitors to state-sponsored currencies.

Bank classification: Bank notes; Economic models; Payment clearing and settlement systems

Résumé

Les auteurs examinent les récentes évolutions qu'ont connues certaines monnaies numériques, en s'intéressant en particulier aux monnaies exclusives à une plateforme, comme les crédits Facebook. À l'aide d'un modèle formalisant la gestion d'une plateforme, ils concluent qu'il ne sera sans doute pas rentable pour leurs promoteurs que de telles monnaies se développent au point de concurrencer les monnaies émises par les États en devenant pleinement convertibles.

1 Introduction

As digitization has progressed, there has been an increase in *private digital currencies*. These are virtual goods offered by companies that have the characteristics of money, offering a unit of account, a medium of exchange and a store of value. Examples include Facebook Credits, Microsoft Points or Amazon Coins. They are digital in the sense that they have no physical counterpart; specifically, they are not a claim on real assets. Moreover, they are “issued” by companies whose activities focus on social networking, video games or sales of applications for tablets. In this analysis we ask why companies would find issuing those private digital currencies beneficial, and what strategic considerations are related to such currencies.

It is important to distinguish between private digital currencies and *digitization of state-issued currencies*. The latter are digitized transactions that involve the execution of a contractual promise to transfer actual currency between two accounts (i.e., from one owner to another owner). This has been extensively studied in the literature on payments systems and, specifically, the contractual terms and standards that govern the settlement of inter-account transfers of currency.¹ In effect, this is a digital layer to a set of activities that were previously performed non-digitally. In this case, however, digitization plays a straightforward role of reducing transaction costs associated with payments including the carrying of physical money, the storage and protection of that money and the provision of short-term liquidity, as most naturally seen with credit and charge cards. Since this has been extensively studied, we will not concern ourselves with such digitization here.

However, both analyses of digitized money transfer systems and private digital currencies are closely related to economic research on platforms. A platform is a business, mechanism or

¹ See Rochet and Tirole (2002) and Gans and King (2003).

institution that brings together two or more distinct parties (or more generally, groups) for their eventual mutual gain. Economic research on platforms has been spurred by payments systems literature, such as the analysis of credit card associations, particularly their pricing and competitive elements.² The platforms literature is related to the issue of private digital currencies in a few ways. First, one can argue that currencies themselves are intrinsically platforms, and that coexisting multiple currencies should be analyzed as platform competition. Second, there have been a number of companies whose primary purpose is the transfer and storage of money; e.g., PayPal, M-Pesa, Bitcoin or Liberty Exchange. Some of them use private digital currencies (Bitcoin, Liberty Exchange), while others do not (PayPal, M-Pesa). But what is interesting is that, for the most part, private digital currencies have been set up in association with non-currency-specific platforms. In this analysis, we will focus exclusively on these.

Consider the example of Linden dollars. These were set up as a currency inside the game Second Life. Participants could earn Linden dollars by trading with other players for virtual goods. Players could bring more Linden dollars to the game by ‘buying in’ with actual dollars. Moreover, Linden dollars earned in the game could be converted back into actual dollars. Thus, there was the potential for some individuals to earn more actual dollars than they put in. This gave rise to calls for some taxation of those earnings as income but, in reality, the underlying principle was no different from that of casino chips.

Other platform-specific currencies did not have the full convertibility of Linden dollars. Game console makers (Nintendo and Microsoft) required players to pay for points that could be used to purchase games. However, once points were paid for, they could not be converted back. In Microsoft’s case, consumers also required points to purchase songs on their Zune portable music player. Nintendo have since phased out their points system and Microsoft has been criticized for

² See Rochet and Tirole (2003), Armstrong (2006), Weyl (2010).

using points that may obscure the true purchase value for some consumers. By contrast, Sony asked for prepayment of funds to download games to its console, but did not have an alternate unit of account, while Apple allowed consumers to purchase songs and games directly on their iOS platform. It is likely that these systems were set up in response to fees and logistical difficulties related to credit card payments (e.g., for small transactions, those fees could be a burden to merchants). Over time, this became less of an issue as the volume of transactions rose, allowing merchants to bundle smaller consumer transactions into larger ones and save on those payment costs.

While these platform-specific currencies could be seen as moves to improve transactional efficiency subject to existing constraints, others that have evolved appear to be more tightly linked with the overall functioning of the platform. For instance, in the online multiplayer game, World of Warcraft (WoW), players can perform activities and earn WoW Gold that allows them to buy improved weaponry, amongst other things. While this might seem like a currency akin to Monopoly money, WoW Gold can be expanded in supply by the activities of players. For this reason, players are prohibited from trading WoW Gold outside of the game. This, however, has not prevented a black market from arising, literally outsourcing ‘Gold farming’ to be produced by players in countries with low market wages. In other cases, such as FarmVille, this trading has been alleviated by allowing players to purchase more ‘FV Dollars’ in the game (and profiting from it). But, unlike Linden dollars, this currency cannot be converted back into real dollars.

In this paper, we focus on these digital currencies that are platform-specific and can be exchanged ‘inwards’ for real dollars.³ In section 2, we will discuss in more detail the case of Facebook Credits that have this feature. We focus on them because commentators in 2011 saw

³ There are currencies that feature the alternative approach: they can be earned via activity only and then converted into real goods and services; for instance, airline and other loyalty points schemes.

them as a threat to traditional currencies. “Could a gigantic nonsovereign like Facebook someday launch a real currency to compete with the dollar, euro, yen and the like?” wrote Matthew Yglesias (2012). And as the payments economist David Evans (2012) stated:

Social game companies could pay developers around the world in Facebook Credits and small businesspeople could accept Facebook Credits because they could use them to buy other things that they need or reward customers with them. In some countries (especially those with national debts that are greater than their GDPs) Facebook Credits could become a safer currency than the national currency.

In other words, there was concern that Facebook Credits could become a currency, like the 2013 attention-getter, Bitcoin, which involved full convertibility.

These predictions have raised issues as to whether such platform-specific currencies should be subject to additional regulation and oversight. However, in our opinion, first it would be useful to understand whether such expansion of the role of platform-specific credits would be in the interests of platform owners. Specifically, would it be worthwhile for a currency such as Facebook Credits to move from limited convertibility to full convertibility? If the answer is no, as we will argue below, then it would appear that the concerns being raised are potentially overblown.

This paper is organized as follows. In the next section, we detail our motivating case of Facebook Credits. While now discontinued, these capture clearly all of the elements of the debates regarding platform-specific currencies. Section 3 then considers a model of platforms and how different attributes of a platform-specific currency can influence platform business models. Our goal here is not to model any one platform in particular, but to give a framework for some suggested forces that will impact on any platform-specific currency choices. Future work, tailored to specific platforms, would likely yield richer results. Section 4 considers some issues associated with regulation. Since these are fast moving and involve deeper issues of monetary economics rather than digitization per se, we merely note some of these. A final section offers some thoughts as to future research directions.

2 Motivating Case: Facebook Credits

In the middle of 2009 the most popular social networking site, Facebook, introduced its virtual currency—Facebook Credits (FB Credits). In 2011, Facebook announced that game developers on its platform would be required to process payments solely through Facebook Credits.⁴ However, the next year, Facebook decided to phase out Credits, since they were a confusing proposition to consumers who also had to purchase points or other currency-like instruments within Facebook games. Nonetheless, the case is instructive because it represents a clear instance of platform-sponsored currencies that, upon their introduction, led many to believe that these could become a significant payment instrument.

To recount this, even before the 2011 announcement, as noted above, many commentators expressed concern that FB Credits could become global currency, and perhaps take over state-issued currency. As early as 2009, predictions were made that “Facebook could rival PayPal by creating a virtual currency and making it usable for financial transactions, essentially making Facebook Credits the currency of the web.”⁵ And with 1 billion users,⁶ this currency would be more popular than most state currencies. After the 2011 announcement, those voices became more frequent.⁷ It may have been one of the factors leading the European Central Bank to investigate virtual currencies in 2012.⁸

Facebook equipped its Credits with limited functionality. One can buy Credits (i.e.,

exchange state-issued currency for FB Credits) at the rate 50 FB Credits for US\$5, with quantity discounts.⁹ FB Credits can be spent in any Facebook application that accepts them.¹⁰ It is also important to note that buying FB Credits is not the only way of obtaining them. A user can *earn* the Credits if they test a new game, or take a survey.

However, the users cannot transfer FB Credits between each other. They also cannot exchange FB Credits back for state-issued currency. This severely limits functionality of FB Credits as a means of payment. Clearly, with such limited functionality, FB Credits cannot really become a global currency rivalling state-issued currencies. Internet pundits, however, claimed that it was only a matter of time, and soon Facebook would turn Credits into a functional currency—by allowing inter-user transfers, and exchanging the FB Credits back into the state-issued currency.¹¹

In this paper, we claim that it would not be beneficial for Facebook to equip FB Credits with those additional attributes. Facebook's main source of revenue is advertising, which is linked directly to the activity of the users on the platform. Therefore, Facebook's objective is to increase the activity of its users. Limiting functionality and allowing for both "buying" and "earning" are features that maximize activity on the platform. Users spend FB Credits to enhance their platform experience, which increases their utility from using the platform and leads to more activity. With "buying" and "earning," both time-poor and time-rich users obtain the Credits. If Facebook were to allow for reverse exchange (i.e., exchanging FB Credits to state currency), the time-rich users would sell the Credits they earned without increasing their activity on the platform. Allowing a transfer of FB Credits between users opens a way for the exchange of FB Credits into state-issued currency to bypass the platform: users can transfer FB Credits and pay each other outside the

⁹ For example, for \$10 there is a 5% bonus, and one receives 105 Credits.

¹⁰ The applications were required to use FB Credits between July 2011 and June 2012. Before and after that period, use of FB Credits was voluntary.

¹¹ See, e.g., http://www.slate.com/articles/business/cashless_society/2012/02/facebook_credits_how_the_social_network_s_currency_could_compete_with_dollars_and_euros_.html.

platform for the acquired Credits, as has happened with WoW Gold. Thus, current functionality of FB Credits is optimal for Facebook’s objective.

3 The Model

Consider an environment with one platform and two users, A and B .¹²

3.1 Users

Each user i can spend some time x_i using the platform, which yields utility $v(x_i, x_j)$. To account for consumption complementarity between the two users, the utility of i depends on that user’s own consumption (x_i) as well as the consumption of the other user (x_j). The utility of an agent increases as the agent spends more time on the platform (but the rate of increase is declining). Due to complementarity, the agent’s utility and marginal utility increases also when the other agent spends more time on the platform; i.e., $\frac{\partial v(x_i, x_j)}{\partial x_i} > 0$, $\frac{\partial^2 v(x_i, x_j)}{\partial x_i^2} < 0$, $\frac{\partial v(x_i, x_j)}{\partial x_j} > 0$ and $\frac{\partial^2 v(x_i, x_j)}{\partial x_i \partial x_j} > 0$.

Each user has total time Z available. The time can be spent either using the platform or working. When working, the user can earn wage w per unit of time. The total amount of money earned allows the user to consume a *numeraire* good (i.e., a composite of goods and services consumed outside of the platform), which adds to the user’s utility. Both users are the same, with the exception of the wage—user A earns a higher wage than user B ($w_A > w_B$). Hence, if user i spends n_i time to earn the *numeraire*, then he can consume $n_i w_i$ of the *numeraire*.

Each user aims to maximize their utility given the time constraint:

$$\max_{x_i, n_i} v(x_i, x_j) + n_i w_i$$

¹² The model can be easily extended to A and B denoting types of users with an arbitrary number of agents in each type. The qualitative results stay the same, but the notation is more complicated.

such that $x_i + n_i \leq Z$.

Clearly, the constraint binds in the optimum, so $n_i = Z - x_i$, and the utility maximization problem simplifies to $\max_{x_i} v(x_i, x_j) + (Z - x_i)w_i$.

In the interior solution,¹³ the optimal usage \hat{x}_i is given by

$$\frac{\partial v(\hat{x}_i, x_j)}{\partial x_i} = w_i. \quad (1)$$

Since $\frac{\partial^2 v(x_i, x_j)}{\partial x_i^2} < 0$, $w_A > w_B$ implies $\hat{x}_A < \hat{x}_B$. That is, the user earning the higher wage is choosing to spend less time on the platform.

Example. Suppose that $v(x_i, x_j) = x_i^\alpha x_j^{1-\alpha}$, for $\alpha > \frac{1}{2}$. Combining the first-order conditions, we get

$$\frac{w_A}{w_B} = \left(\frac{\hat{x}_B}{\hat{x}_A} \right)^{2(1-\alpha)}.$$

Clearly, $w_A > w_B$ implies that $\hat{x}_A < \hat{x}_B$. Moreover, there are multiple equilibria possible. Any combination of x_A and x_B such that $\frac{w_A}{w_B} = \left(\frac{x_B}{x_A} \right)^{2(1-\alpha)}$ and $x_B \leq Z$ constitutes an equilibrium. Multiplicity of equilibria is not surprising, given the consumption complementarity.

3.2 The platform

We assume that the platform's revenue directly depends on the usage, $r(x_A + x_B)$ where $r > 0$ is the revenue from an additional unit of activity, say from advertising. For now, we assume

¹³ Corner solutions may happen for very high and very low w 's. When w_i is low enough that $\frac{\partial v(\hat{x}_i, x_j)}{\partial x_i} \Big|_{x_i=Z} > w_i$, then the user spends all their time using the platform, $\hat{x}_i = Z$. Notice that, in such a case, increasing x_j does not change \hat{x}_i , but decreasing x_j may decrease \hat{x}_i below Z if the derivative decreases to $\frac{\partial v(\hat{x}_i, x_j)}{\partial x_i} \Big|_{x_i=Z} < w_i$. Similarly, when w_i is high enough that $\frac{\partial v(\hat{x}_i, x_j)}{\partial x_i} \Big|_{x_i=0} < w_i$, then the agent spends no time using the platform, $\hat{x}_i = 0$. Decreasing x_j will not change i 's consumption decision. But increasing x_j may induce i to set positive $\hat{x}_i > 0$, when the increase in x_j increases the derivative to $\frac{\partial v(\hat{x}_i, x_j)}{\partial x_i} \Big|_{x_i=0} > w_i$.

that this is the only source of the platform's revenue. Under this assumption, the platform aims at maximizing the total usage: $x_A + x_B$. Later in the analysis, we allow other sources of revenue, e.g., the sale of platform-specific currency. In that latter case, the platform's optimal decisions do not necessarily maximize total usage. Notice that, due to consumption complementarity, there may exist multiple equilibria with different total usage.

Example (continued). *Given multiplicity of equilibria, the platform's usage depends on the equilibrium played. In our example, the largest usage that may be obtained in an equilibrium is for*

$$\hat{x}_B = Z \text{ and } \hat{x}_A = Z \left(\frac{w_B}{w_A} \right)^{\frac{1}{2(1-\alpha)}}. \text{ The smallest one is arbitrarily close to 0, when } \hat{x}_B = \varepsilon \neq 0 \text{ and } \hat{x}_A = \varepsilon \left(\frac{w_B}{w_A} \right)^{\frac{1}{2(1-\alpha)}}.$$

3.3 Enhancing the platform: “buying” and “earning”

Suppose that now the platform allows the users to acquire options, e_i , that enhance the value of platform usage. For example, this may be additional options in a game. The enhancement increases the usage utility; i.e., for the same level of usage, $v(x_i, e_i', x_j) > v(x_i, e_i, x_j)$ for $e_i' > e_i$.

Moreover, we assume that $\frac{\partial v(x_i, e_i', x_j)}{\partial x_i} > \frac{\partial v(x_i, e_i, x_j)}{\partial x_i}$, $\frac{\partial v(x_i', e_i, x_j)}{\partial e_i} > \frac{\partial v(x_i, e_i, x_j)}{\partial e_i}$ for $x_i' > x_i$ and $\frac{\partial v(x_i, e_i, x_j)}{\partial e_i} \rightarrow \infty$

as $e_i \rightarrow 0$.¹⁴ The enhancement may be obtained by “buying” it, or by “earning” it (e.g., through

testing functionality or simply by playing the game more intensively). Specifically, we assume that

$e_i = \gamma y_i + \phi t_i$, where y_i are the units of the *numeraire* (“buying”) and t_i are in units of time (“earning”).

User i 's utility in the environment with the enhancement is

$$v(x_i, e_i(t_i, y_i), x_j) + (Z - x_i - t_i)w_i - y_i, \quad (2)$$

¹⁴ This is on top of the usual second-order conditions: $\frac{\partial^2 v(x_i, e_i, x_j)}{\partial x_i^2} < 0$ and $\frac{\partial^2 v(x_i, e_i, x_j)}{\partial e_i^2} < 0$.

which the user maximizes by choosing x_i , t_i , and y_i subject to the constraints that $y_i \leq (Z - x_i - t_i)w_i$ and $Z \geq x_i + t_i$. For a solution interior in all three variables, the first-order conditions are

$$\text{w.r.t. } x_i : \frac{\partial v(x_i, e_i, x_j)}{\partial x_i} = w_i \quad (3)$$

$$\text{w.r.t. } t_i : \frac{\partial v(x_i, e_i, x_j)}{\partial e_i} \phi = w_i \quad (4)$$

$$\text{w.r.t. } y_i : \frac{\partial v(x_i, e_i, x_j)}{\partial e_i} \gamma = 1. \quad (5)$$

Notice, however, that t_i and y_i are perfect substitutes in achieving e_i . Therefore, each user chooses only one way of obtaining e_i , whichever is cheapest. “Buying” a unit of e_i costs the user $\frac{1}{\gamma}$, while “earning” it costs $\frac{w_i}{\phi}$.

If $w_i < \frac{\phi}{\gamma}$, then user i only “earns” the enhancement, and $y_i = 0$. Then, the two relevant first-order conditions are

$$\frac{\partial v(x_i, e_i, x_j)}{\partial x_i} = w_i \quad \text{and} \quad \frac{\partial v(x_i, e_i, x_j)}{\partial e_i} \phi = w_i. \quad (6)$$

When $w_i > \frac{\phi}{\gamma}$, then user i only “buys,” i.e., $t_i = 0$. Then, the two relevant first-order conditions are

$$\frac{\partial v(x_i, e_i, x_j)}{\partial x_i} = w_i \quad \text{and} \quad \frac{\partial v(x_i, e_i, x_j)}{\partial e_i} \gamma = 1. \quad (7)$$

For exogenously given w 's, ϕ , and γ , we assume here that Z is large enough that solutions on the relevant parameters (x_i and t_i , or x_i and y_i) are interior. For an interior x_i , we can prove the

following result.

Lemma 1. *Holding e_i and x_j fixed, a user i with lower w_i optimally chooses higher usage, x_i .*

PROOF: Since Z is large enough for x_i to be interior for both users, $\frac{\partial v(x_i, e_i, x_j)}{\partial x_i} = w_i$. With $w_A > w_B$, for the same e_i and x_j , the derivative is higher for the higher-wage user. And since $\frac{\partial^2 v(x_i, \cdot)}{\partial x_i^2} < 0$, the derivative is higher for smaller usage x_i . Hence $x_A < x_B$ if e_i and x_j are unchanged.

Given that users have different wages, in equilibrium it will not be the case that e_i and x_j are the same for both users. With the higher usage x_i , the marginal benefit of enhancement is higher.

Thus, users with lower w_i choose larger e_i , which further increases their optimal usage.

Lemma 2. *The low-wage user acquires more enhancements and has higher usage in equilibrium.*

PROOF: We conduct this proof in two steps. In the first one, we show that the low-wage user acquires more enhancements for a fixed x_i and x_j . In the second step, we combine the result of the first step and of Lemma 1 to complete the proof for the equilibrium outcome.

When both w_A and w_B are greater—or both lower—than $\frac{\phi}{\gamma}$, we find that the low-wage user acquires more enhancement directly from the second-order conditions (for a fixed x_i and x_j). The interesting case is when $w_A > \frac{\phi}{\gamma} > w_B$. In this case, the first-order conditions are $\frac{\partial v}{\partial e_B} \phi = w_B$ and $\frac{\partial v}{\partial e_A} \gamma = 1$. Those conditions imply that $\frac{\partial v}{\partial e_B} = \frac{w_B}{\phi}$ and $\frac{\partial v}{\partial e_A} = \frac{1}{\gamma}$. And since $\frac{\phi}{\gamma} > w_B \Leftrightarrow \frac{1}{\gamma} > \frac{w_B}{\phi}$, then $\frac{\partial v}{\partial e_A} > \frac{\partial v}{\partial e_B}$. Therefore, if faced with the same x_i and x_j , $e_A < e_B$.

In the second step of the proof, notice, from Lemma 1, that we know that $x_A < x_B$ for the same e_i and x_j . Moreover, because own consumption has a larger effect on utility than x_j , it is still true that $x_A(x_B) < x_B(x_A)$ for the same e_i . Moreover, from the previous step of this proof, given x_i and x_j , $e_A < e_B$ reinforces the fact that in equilibrium $x_A^* < x_B^*$ (i.e., $x_B(e) - x_A(e) < x_B^*(e_B^*) - x_A^*(e_A^*)$).

Notice that usage increases more when both ways of procuring e_i are available. Because users

choose the cheapest way, they choose more e_i than they would if only one way of procurement was allowed. Higher e_i leads to higher x_i . Moreover, due to consumption complementarities, it further increases the consumption of the other user, x_j . Therefore, by allowing users to both “earn” and “buy” an enhancement of the platform usage (e.g., Facebook points), the platform increases usage, as compared to allowing for only one type of enhancement procurement.

Proposition 1. *When the platform allows for both “earning” and “buying” of the enhancement, the direct usage, $x_A + x_B$, (weakly) increases by more than when the platform allows for only one type of enhancement procurement (only “buying” or only “earning”).*

The increase is “weak,” because if both users are choosing the same means of obtaining the enhancement, and the only option is the optimal option, then adding a new option does not strictly improve usage. The following proof focuses on the interesting case where improvement is strict.

PROOF: Let $w_A > \frac{\phi}{\gamma} > w_B$. Suppose that only option “buy” is available. Both $i = A, B$ choose their enhancement investment and usage based on (7). Let B ’s optimal choices in this case be \hat{x}_B and \hat{e}_B .

When it becomes possible to “earn,” user B prefers to go for the new option, and chooses enhancement $\hat{\hat{e}}_B$ according to condition (6). Since $\frac{w_B}{\phi} < \frac{1}{\gamma}$, then $\frac{\partial v(\hat{x}_B, \hat{\hat{e}}_B, x_A)}{\partial e_B} > \frac{\partial v(\hat{x}_B, \hat{e}_B, x_A)}{\partial e_B}$, which implies $\hat{\hat{e}}_B(\hat{x}_B) > \hat{e}_B(\hat{x}_B)$. But then also $\hat{\hat{x}}_B > \hat{x}_B$. So, in equilibrium $\hat{\hat{e}}_B$ and $\hat{\hat{x}}_B > \hat{x}_B$. Given the complementarity in users’ activity, increasing x_B also increases x_A . Thus, allowing for “earning” of platform enhancement along with “buying” increases total platform usage, by increasing both x_B and x_A .

In a similar way, we can also show that starting from “earning” only, and then allowing “buying” as well, increases total platform usage by increasing both x_A and x_B .

It is useful to consider the relevance of this proposition for digital currency. For instance, Facebook Credits represent a unit of account. It could have been that, like Microsoft and Nintendo, these credits were solely bought. In this way, they would merely be a way of converting real currency into on-platform payments. However, to the extent that some users of the platform are

income or wealth constrained, this would reduce their use of enhancements. Complementarity amongst users would then imply a reduction in overall activity on the platform. Instead, by offering a means of earning enhancements, the platform provides an alternative pathway for income-constrained users. Of course, this may be strengthened if such earning was itself platform activity—as sometimes occurs—but we have suppressed that effect here. Later, in section 3.5, we also discuss how Proposition 1 may sometimes fail if the platform has different objectives than maximizing total usage.

The proposition also demonstrates that allowing ‘inwards convertibility’ from real currency onto the platform encourages more usage from income-rich users. Once again, complementarity amongst users leads to more overall usage from convertibility. Thus, while World of Warcraft may officially prohibit ‘Gold farming,’ there is a sense in which it increases platform usage. Of course, it could be imagined that digital currencies associated with platforms could go further and allow ‘outwards convertibility.’ It is this feature that would put those currencies on a path to competing with state-issued currencies. We examine this option next.

3.4 Reverse exchange

In this section, we show that if the platform were to allow for the reverse exchange of “earned” credits into state-issued currency, it would decrease platform usage.

Proposition 2. *If the platform allows for the reverse exchange of e_i into y_i at any positive rate, it lowers platform usage.*

PROOF: Suppose that user i can spend t_i to get $e_i = \phi t_i$, but then can convert it back into cash at a rate of μ : $y_i = \frac{e_i}{\mu} = \frac{\phi t_i}{\mu}$. Then, the effective wage of user i is $\frac{y_i}{t_i} = \frac{\phi}{\mu}$. If the platform puts no restrictions on this exchange, it allows all agents with outside wage $w_i < \frac{\phi}{\mu}$ to achieve the effective wage of $\hat{w} = \frac{\phi}{\mu}$. But, from the previous results, we know that increasing the wage lowers the equilibrium usage x_i , and also lowers how much of e_i is

actually used by the agent on the enhancement, as the agent may redeem¹⁵ part or all of e_i for y_i).

The proof here does not take into account the fact that reverse exchange would be costly for the platform. In other words, it is unambiguously detrimental to the platform. Thus, as long as the goal of the platform is to maximize direct activity ($x_A + x_B$), platforms have no incentive to allow for ‘outwards convertibility’ or reverse exchange. In other words, despite the concern of commentators, platforms that utilize digital currencies for ‘within platform’ transactions have no incentive to move toward full convertibility.

It is worth considering the assumption that drives this strong result. Here we have assumed that platform activity—including the incentive to purchase an enhancement—is solely driven by utility earned within the platform. Specifically, the enhancement increases the marginal utility from activity and is reduced if currency is redeemed outside of the platform. However, it could be the case that by earning the enhancement, activity is increased even if the currency earned is redeemed rather than spent within the game. In this case, the incentive to earn that currency increases activity and could be enhanced by allowing convertibility. This may be part of the rationale for allowing full convertibility of Linden dollars in the game Second Life.

3.5 *Optimal choice of γ and ϕ*

Until now, we have taken γ and ϕ as given. Typically, however, the platform sets γ and ϕ . Each user’s choice of whether to earn or purchase an enhancement depends on the prices, $1/\gamma$ and $1/\phi$, and their relationship to the user’s wage. The prices chosen by a platform depend on its precise objective. Thus far, we have focused on the impact of various platform choices on

¹⁵ Since part or all of the enhancement is redeemed, it does not enter as e_i into $v(x_i, e_i, x_j)$.

$x_A + x_B$, direct platform usage. This would be relevant if the platform's only source of revenue was, say, advertising. In this case, the platform would aim to set both γ and ϕ as high as possible so that, regardless of how a user chooses to obtain the enhancement, each does so. In effect, the enhancement would be built into the platform and there would be little interesting question regarding currencies.

In some important situations, the platform may also earn the same advertising revenue from users' activity while earning an enhancement. In this case, the platform would aim to maximize $r(x_A + x_B + t_A + t_B)$. The platform may then benefit from users engaging in a variety of activities (depending on the nature of $v(\cdot)$), but, regardless, it would want ϕ to be as high as possible so that all users would earn the enhancement. For γ , the platform faces a trade-off. Decreasing γ can induce high-wage types to switch their activity toward earning the enhancement, which directly increases t_A . However, this involves some substitution from x_A which, depending upon $v(\cdot)$, may lead to a reduction in activity by B . Thus, it is not possible to characterize this price in the general case.

Of course, the purchases of enhancements can also represent an alternative revenue stream for the platform. In this case, it would be reasonable to consider the platform as maximizing $r(x_A + x_B) + (y_A + y_B)$ or $r(x_A + x_B + t_A + t_B) + (y_A + y_B)$. Depending on the level of r , the platform may prefer to withdraw the possibility of earning an enhancement and force all agents to buy it. That is, in such a case, Proposition 1 may fail. Regardless of whether Proposition 1 holds or fails, prices will be set so that each user's time constraint is binding and focused on the platform, either through activity or income. That is, for users buying an enhancement, $t_i = 0$ and $y_i = (Z - x_i)w_i$, while for a user earning the enhancement, $y_i = 0$ and $t_i = Z - x_i$.

This allows us to identify the first-order conditions for users. For users earning the enhancement, it is

$$\left. \frac{\partial v(x_i, e_i, x_j)}{\partial x_i} \right|_{e_i = \phi(Z - x_i)} = \phi \left. \frac{\partial v(x_i, e_i, x_j)}{\partial e_i} \right|_{e_i = \phi(Z - x_i)} . \quad (8)$$

Notice that this condition is independent of w_i . Thus, the optimal usage schedule for those earning the enhancement is independent of wage. That is, if both high-wage and low-wage agents decide to earn the enhancement, they would earn the same e_i and consume the same x_i . For a user buying the enhancement, we have

$$\left. \frac{\partial v(x_i, e_i, x_j)}{\partial x_i} \right|_{e_i = \gamma(Z - x_i)w_i} = w_i \gamma \left. \frac{\partial v(x_i, e_i, x_j)}{\partial e_i} \right|_{e_i = \gamma(Z - x_i)w_i} . \quad (9)$$

Thus, users who buy the enhancement will differ in their usage levels, depending on the wage. This suggests that allowing users to buy enhancements can be useful when it is optimal to exploit their differential usage rather than ignore it. Of course, a precise characterization is not possible in the general case. For our running example, however, we can provide a more precise conclusion.

Example (continued). Suppose that, in our example, the platform introduces the enhancement and now $v(x_i, e_i, x_j) = x_i^\alpha x_j^{1-\alpha} e_i^\beta$. Moreover, $e_i = \gamma y_i + \phi t_i$. Then, user i 's utility is $x_i^\alpha x_j^{1-\alpha} (\gamma y_i + \phi t_i)^\beta + (Z - x_i - t_i)w_i - y_i$. For $w_i < \frac{\phi}{\gamma}$, i.e., $y_i = 0$:

$$\begin{cases} \alpha x_i^{\alpha-1} x_j^{1-\alpha} (\phi t_i)^\beta = w_i \\ \phi \beta x_i^\alpha x_j^{1-\alpha} (\phi t_i)^{\beta-1} = w_i \end{cases} \Rightarrow t_i = \frac{\beta}{\alpha} x_i .$$

Using $t_i = \frac{\beta}{\alpha} x_i$, the first-order condition yields $x_i^{\alpha+\beta-1} = \frac{w_i}{\phi^\beta \alpha^{1-\beta} \beta^\beta x_j^{1-\alpha}}$ if the solution is interior, i.e., when $t_i < Z - x_i$. When ϕ is large enough (i.e., $\phi > \frac{\alpha}{\beta} \left(\frac{w_i (\alpha+\beta)^{\alpha+\beta-1}}{x_j^{1-\alpha} (\alpha Z)^{\alpha+\beta-1}} \right)^{\frac{1}{\beta}}$), so that $t_i = Z - x_i$, the user's problem becomes $\max_{x_i} x_i^\alpha x_j^{1-\alpha} (\phi(Z - x_i))^\beta$. The optimal usage is then $x_i = \frac{\alpha Z}{\alpha+\beta}$ and $t_i = \frac{\beta Z}{\alpha+\beta}$. Notice that it does not depend on ϕ once the time constraint is binding.

For $w_i > \frac{\phi}{\gamma}$, i.e., $t_i = 0$

$$\begin{cases} \alpha x_i^{\alpha-1} x_j^{1-\alpha} (\gamma y_i)^\beta = w_i \\ \gamma \beta x_i^\alpha x_j^{1-\alpha} (\gamma y_i)^{\beta-1} = 1 \end{cases} \Rightarrow y_i = \frac{\beta}{\alpha} x_i w_i .$$

And further it yields $x_i^{\alpha+\beta-1} = \frac{w_i^{1-\beta}}{\gamma^\beta \alpha^{1-\beta} \beta^\beta x_j^{1-\alpha}}$ for the interior solution. The corner solution, which arises when γ is sufficiently large, is: $x_i = \frac{\alpha Z}{\alpha+\beta}$ and $y_i = \frac{\beta Z}{\alpha+\beta} w_i$.

Depending on the wages and “prices” (γ and ϕ), there are three situations possible: both agents earn the enhancement, both buy it, or one buys and the other earns. We analyze each case in turn (for the interior solution).

1. When both agents are earning the enhancement, then any consumption patterns in equilibrium must satisfy $\left(\frac{x_B}{x_A}\right)^{2(1-\alpha)-\beta} = \frac{w_A}{w_B}$. Together with the formula for x_i derived above, it yields

$$x_i^\beta = \left(\frac{w_j}{w_i}\right)^{\frac{1-\alpha}{2(1-\alpha)-\beta}} \frac{w_i}{\alpha^{1-\beta} \beta^\beta \phi^\beta} .$$

This is a complicated formula, but it uniquely gives x_i with respect to the exogenous parameters.

2. When both agents are buying the enhancement, then in any equilibrium it must be that $\left(\frac{x_B}{x_A}\right)^{2(1-\alpha)-\beta} = \left(\frac{w_A}{w_B}\right)^{1-\beta}$. Then,

$$x_i^\beta = \left(\frac{w_j}{w_i}\right)^{\frac{(1-\beta)(1-\alpha)}{2(1-\alpha)-\beta}} \frac{w_i^{1-\beta}}{\alpha^{1-\beta} \beta^\beta \phi^\beta} .$$

3. When agent A is buying the enhancement, while agent B is earning, then in any equilibrium it must be that $\left(\frac{x_A}{x_B}\right)^{2(1-\alpha)-\beta} = \frac{w_B}{w_A^{1-\beta}} \left(\frac{\gamma}{\phi}\right)^\beta$. And then,

$$x_A^\beta = \left(\frac{w_B}{w_A^{1-\beta}}\right)^{\frac{1-\alpha}{2(1-\alpha)-\beta}} \left(\frac{\gamma}{\phi}\right)^{\frac{\beta(1-\alpha)}{2(1-\alpha)-\beta}} \frac{w_A^{1-\beta}}{\gamma^\beta \alpha^{1-\beta} \beta^\beta}$$

$$x_B^\beta = \left(\frac{w_A^{1-\beta}}{w_B}\right)^{\frac{1-\alpha}{2(1-\alpha)-\beta}} \left(\frac{\phi}{\gamma}\right)^{\frac{\beta(1-\alpha)}{2(1-\alpha)-\beta}} \frac{w_B}{\phi^\beta \alpha^{1-\beta} \beta^\beta}$$

Notice that, in all three cases, introducing the enhancement eliminates multiplicity of equilibria, since now x_i are uniquely characterized by the exogenous parameters.

Now consider the platform setting prices ϕ and γ to maximize its objective. We consider four possible objective functions for the platform:

(1) $\max r(x_A + x_B)$: The platform is indifferent on whether to buy or earn. Whether γ is so high

that both buy, ϕ so high that both earn, or one buys and one earns, the platform can always achieve the global maximum of $x_A = x_B = \frac{\alpha Z}{\alpha + \beta}$.

(2) $\max r(x_A + x_B) + (y_A + y_B)$: The platform raises γ so that not only both users buy the enhancement, but both reach the corner consumption schedule. The platform reaches the global maximum of $x_A = x_B = \frac{\alpha Z}{\alpha + \beta}$ and $y_i = \frac{\beta Z}{\alpha + \beta} w_i, i = A, B$.

(3) $\max r(x_A + x_B + t_A + t_B)$: The platform raises ϕ so that not only do both users earn the enhancement, but both reach the corner consumption schedule. The platform reaches the global maximum of $x_A = x_B = \frac{\alpha Z}{\alpha + \beta}$ and $t_A = t_B = \frac{\beta Z}{\alpha + \beta}$ earning $2Z$. If the platform were to set ϕ lower so that $w_B < \frac{\phi}{\gamma} < w_A$, then $t_A = 0$ and $x_A = \frac{\alpha Z}{\alpha + \beta}$. Thus, the platform would earn $Z(1 + \frac{\alpha}{\alpha + \beta}) < 2Z$.

(4) $\max r(x_A + x_B + t_A + t_B) + (y_A + y_B)$: Optimal prices (and optimal users' consumption schedule) depend on w_i 's and r . The interesting case is when $w_B < r < w_A$. Then the platform is strictly better off by setting the prices such that user A buys and user B earns the enhancement with consumption achieving a global maximum, $x_A = x_B = \frac{\alpha Z}{\alpha + \beta}$, $t_B = \frac{\beta Z}{\alpha + \beta}$ and $y_A = \frac{\beta Z}{\alpha + \beta} w_A$.

3.6 Summary

For a platform whose main source of revenue is advertising (e.g., Facebook), its objective is to increase the activity of its users (e.g., the use of social games). When activity on the platform is more valuable for a user when other users increase their activity (e.g., from the social component), there is complementarity in activity on the platform. A platform can provide an enhancement of user experience to encourage more activity (e.g., buying special versions of crops for your farm in FarmVille, which have a higher yield than regular crops). Higher activity by one user increases the utility—and activity—of other users, due to the complementarity. For this reason, if two users acquire the enhancement, the increase in activity is larger than double the increase of activity resulting from a single user's enhancement. Therefore, it is optimal for the platform to encourage all users to acquire the enhancement. But some users may find the monetary cost too high, e.g., if they have a low wage. Then, the platform gains if it allows for both “buying” and “earning” the enhancement. High-wage users will prefer to spend money rather than time,

while low-wage users can spend time instead of money. Both types will acquire the enhancement and increase activity on the platform.

This reflects the policies of many social networks and also some gaming platforms. Of particular significance is Proposition 2, which prevents platform-specific currencies from being traded back for state-issued currency. This provides a strong result that such platforms are not interested in introducing currencies that would directly compete with existing state-issued currencies. That said, for a platform such as Facebook, there is a flow of money back through developer payments: that is, a developer writes a game that induces people to purchase enhancements. The developer then receives part of the revenue that Facebook receives when Credits are purchased. Nonetheless, this is really just an extension of the platform notion, where the game itself is the platform of interest. Indeed, in mid-2012, Facebook announced that it would phase out Credits by the end of 2013, and rely only on state-issued currencies. The users often needed to further convert Facebook Credits into currencies within apps and games, e.g., zCoins in Zynga's games. Users and developers were against this additional layer of complication and wanted a direct link to state-issued currencies. This is consistent with the model, in that, for Facebook's core activity, literally the activity or news feed, all features were available to all users. It could still earn essentially 'referral' fees for revenue generated by others on its platform, but for its core activity, a currency would perform no additional role.

By contrast, it is easy to imagine that app developers such as Zynga introduced their own currencies for exactly the same reason as in our main model: to increase activity on their "app platform." Just as Facebook Credits once bought or earned cannot be exchanged back into cash, so zCoins—once bought or earned—cannot be exchanged back into state-issued currency (or indeed Facebook Credits when they were available). This policy is driven by Zynga's objective to

maximize activity on its *own* platform. This may, however, conflict with Facebook’s objective to increase activity on the Facebook platform, possibly across different apps. A richer model would be required to explore issues arising from interlocking platforms.

A distinct argument lies behind Amazon Coins introduced in the beginning of 2013. Amazon announced that it would give away “millions of U.S. dollars worth” of Amazon Coins to customers, starting in May 2013. Like all other introductions of digital currencies, this attracted the usual concern about the threat to state-issued currencies. “But in the long term what [central banks] should perhaps be most worried about is losing their monopoly on issuing money,” wrote the *Wall Street Journal*. “A new breed of virtual currencies are starting to emerge—and some of the giants of the web industry such as Amazon.com Inc. are edging into the market.”¹⁶

However, Amazon Coins is simply a subsidy to buyers to participate in the platform, with the purpose of starting and accelerating any indirect network effects on Amazon’s app platform. When Kindle Fire users purchase Amazon Coins, they receive an effective discount on apps (from 5 to 10%, depending on how many Coins are purchased), something that was a feature of Facebook Credits as well. Due to uncertainty about the quality of apps, a subsidy to users is more effective than a subsidy to the developers, since users will “vote” with their Coins for the best apps. At the same time, introducing Amazon Coins is potentially more convenient than subsidizing via cash, since it ensures that the subsidy is spent on the Amazon app platform, and not on other services on Amazon or outside.

4 Regulatory Issues

Our analysis of platform-specific currencies shows that voices calling for specific

¹⁶ *Wall Street Journal*, Market Watch
http://articles.marketwatch.com/2013-02-13/commentary/37064080_1_currency-war-bitcoin-central-banks

regulation of them overstate their case, since the purpose of those currencies is a natural complement to the business models associated with platforms such as Facebook or Amazon. To maximally benefit the platform, the use of currencies needs to be restricted. Thus, it is not in the interest of the platforms to provide fully functional currencies that could compete with state currencies.

In our analysis, however, we have not considered Bitcoin, which is a fully convertible, pure digital currency not associated with a given platform. It is explicitly designed to compete with state currencies. In March 2013, the U.S. government for the first time imposed regulations on online currencies.¹⁷ Virtual currencies are to be regulated by the U.S. Treasury, since the Financial Crimes Enforcement Network (FinCEN) decided they fall under the anti-money-laundering laws.¹⁸ According to the new rules, transactions worth more than \$10,000 need to be reported by companies involved in issuing or exchanging online currencies. The rules do not single out Bitcoin, but apply to all “online currencies.” This clarification of FinCEN laws was issued after evidence emerged that Bitcoin is used for illegal activity (e.g., Silk Road). Illegal activity is a concern because the anonymity of Bitcoin allows for untraceable trades.

There may be other reasons to regulate online currencies that apply to both anonymous and account-based currencies. The European Central Bank released a report at the end of 2012 analyzing whether virtual currency schemes can affect price stability, financial stability or payment stability.¹⁹ The report distinguishes between closed virtual currency schemes (i.e., used only within games or apps, akin to virtual Monopoly money) and virtual currency schemes that interact with state currencies (i.e., can be used to purchase real goods and services, or even directly

¹⁷ <http://finance.fortune.cnn.com/tag/facebook-credits/>

¹⁸ <http://www.newscientist.com/article/mg21729103.300-us-to-regulate-bitcoin-currency-at-its-alltime-high.html>

¹⁹ <http://www.ecb.europa.eu/pub/pdf/other/virtualcurrencyschemes201210en.pdf> The report focused specifically on case studies of Bitcoin and Linden dollars, but the conclusions were more general.

converted to state currencies).²⁰ Closed virtual currency schemes are not a concern in the view of the report, since only virtual currency that interacts with the real economy can affect price stability, financial stability and payment stability. However, the report also concluded that, currently, virtual currency that interacts with state currencies poses no risks, since such money creation is at a low level. Moreover, the interaction of Linden dollars, Bitcoin and similar schemes with the real economy is low because those currencies are used infrequently, by a small group of users, and—most importantly—their use is dispersed geographically, across many state currencies, hence the impact on any one state currency is negligible.

In the case of Q-coin, used only in China, the impact could be significant enough for the central bank to step in and regulate the use of virtual currencies. A social networking site, Tencent QQ, introduced Q-coin to allow for virtual payments. This was not a platform-sponsored currency as we have modelled above, but instead a substitute for state-sponsored currency. Indeed, Q-coins are purchased with Chinese state currency. Thus, while Q-coin was intended for the purchase of virtual goods and services provided by Tencent, users quickly started transferring Q-coin as peer-to-peer payments, and merchants started accepting Q-coin as well.²¹ As the amount of Q-coins traded in one year reached several billion yuan, the Chinese authorities stepped in with regulation. In June 2009, the Chinese government banned exchanging virtual currencies for real goods and services, in order to “limit the possible impact on the real financial system.”²²

5 Future Directions

This paper has considered the economics of pure digital currencies and demonstrated that,

²⁰ The European Central Bank report also acknowledges that virtual currency schemes “can have positive aspects in terms of financial innovation and the provision of additional payment alternatives for consumers” (p. 47). However, the position of a central bank is to protect state currencies from the risks the virtual currencies may pose.

²¹ <http://voices.yahoo.com/a-virtual-currency-qq-coin-has-taken-real-value-278944.html>

²² <http://english.mofcom.gov.cn/aarticle/newsrelease/commonnews/200906/20090606364208.html>

in most cases, private currencies issued in support of a platform are unlikely to have implications that extend beyond the platform. Of course, our approach has been theoretical, but it does provide a framework to examine digital currencies as a lens for understanding platform strategy.

What is of broader future concern is the emergence of digital currencies that compete with state-issued currency. For this, the gap in economic knowledge arises from an imperfect set of frameworks for analyzing money and its uses per se, let alone whether they are real or virtual. That said, considering our exploration of these issues, we speculate here that platform economics may actually have a role in assisting a broader understanding of monetary economics.

Any currency can be viewed as a platform, where people need to “join” by believing in its value, i.e., they join by accepting it. Transactions occur only between people who accept the currency, i.e., who have joined the platform. Currencies also exhibit network effects: the more people accept it, the more value there is to accepting it.

If we were to consider any other technology platform instead of currency, regulation aiming to limit the impact of virtual currency schemes on existing payment systems (e.g., due to challenges such schemes might pose for the conduct of monetary policy²³) would be akin to protecting the incumbent standard against innovative entrants. We know from the technology literature that such protection usually leads to loss of efficiency, because new entrants can come up with ways to better and more cheaply serve the market, and perhaps also to expand the market.

Is there a good reason for such protection? The 19th and early 20th century in the United States saw a period of so-called “free banking,” where private banks were allowed, under some initial conditions, to issue their own currency. That is, the state did not have a monopoly on issuing currency. However, throughout this period, regulatory interventions increased, and in the early 20th century it became common practice to delegalize issuing currency by anyone except the state

²³ E.g., see the European Central Bank Report, p. 37.

(Frankel, 1998).

The experience of the free banking period showed that currencies may differ from other technology platforms. Especially, there may be a greater value in the monopoly of the state on issuing currency, as it provides greater stability of the financial system. Issuing currency is a source of profit, since the issuer gains seigniorage. As a monopoly, the state would capture the whole seigniorage profit. However, economic historians²⁴ argue that other factors lead the government to introduce increasingly stricter regulation and eventually monopolize the issuing of currency. One such factor is frequent bank failures. In a competitive environment, firms often fail and new ones enter. Prior to the early 20th century in the United States, however, bank failures left customers with bank notes redeemable for only a fraction of their nominal value, and sometimes not redeemable at all (i.e., worthless).

This undermined financial stability, and the public's trust in paper currency overall. Lack of trust sometimes resulted in bank runs, which led to more bank failures. The trust issues were also reflected in exchange rates between currencies from different issuers. Some private bank notes circulated at a discount (i.e., a \$1 bank note was considered worth less than the nominal \$1) when there were doubts about the bank's solvency. Another reason for lower trust was counterfeiting, which is, of course, also a concern with state-issued currency. But with multiple issuers the number and variety of notes in circulation is larger, and it is harder for the public to keep track of genuine features.

Since the notes were only redeemable at the issuing bank and banks were typically local, the acceptance of some notes would be geographically restricted. Further from the issuing bank's location, the notes would be accepted at a discount if they were accepted at all. Both of these factors—lack of trust and varying exchange rates—created difficulties for trade. At times, it even

²⁴ See, e.g., Rockoff (1974) or Smith (1990).

created worries that the trade could collapse altogether.

But how do those well-known factors compare to the analyses in the technology literature? We know that the presence of network effects often creates multiple equilibria—either lots of people join the platform because they expect lots of other people to join, or no one joins because they do not expect others to join. Similar equilibria can be seen in currency usage. Trust in the currency helps to coordinate on the better equilibrium where people generally adopt paper currency. Another parallel in the technology literature is compatibility. Having multiple networks, with limited or no compatibility, lowers efficiency as compared to one single network, since under limited compatibility the network effects cannot be realized to their full value.

This brings out a well-known tension: On the one hand, the presence of multiple competing platforms creates inefficiency by limiting the extent of network effects (when compatibility is limited), and presents the risk of coordination failure, when users will not join at all. On the other hand, a single well-established dominant platform overcomes the issue of coordination and renders compatibility irrelevant, while stifling innovation and possibly extracting monopoly profit from the users. In issuing currency, since the 20th century, states have traditionally considered one single network as the better side of this trade-off. Whether it is still a valid conclusion with respect to online currencies is a question for future research.
